PLENARY SPEAKERS

Federico Capasso

Harvard University, USA

Metaoptics in the visible

Federico Capasso is the Robert Wallace Professor of Applied Physics at Harvard University, which he joined in 2003 after 27 years at Bell Labs where he was Member of Technical Staff, Department Head and Vice President for Physical Research. He is visiting professor at NTU with both the School of Physical and Mathematical Sciences and Electrical and Electronic Engineering. His research has focused on nanoscale science and technology encompassing a broad range of topics. He pioneered band-structure engineering of semiconductor nanostructures and devices, invented and first demonstrated the quantum cascade laser and investigated QED forces including the first measurement of a repulsive Casimir force. His most recent contributions are new plasmonic devices and flat optics based on metasurfaces. He is a member of the National Academy of Sciences, the National Academy of Engineering, the American Academy of Arts and Sciences. His awards include the King Faisal Prize, the IEEE Edison Medal, the SPIE Gold Medal, the American Physical Society Arthur Schawlow Prize in Laser Science, the Jan Czochralski Award for lifetime achievements in Materials Science, the IEEE Sarnoff Award in Electronics, the Materials Research Society Medal, the Wetherill Medal of the Franklin Institute, the Rank Prize in Optoelectronics, the Optical Society Wood Prize, the Berthold Leibinger Future Prize, the Julius Springer Prize in Applied Physics, the European Physical Society Quantum Electronics Prize.

Dirk Englund

MIT, USA

Towards Scalable Semiconductor Quantum Networks

Dirk Englund received his BS in Physics from Caltech in 2002. Following a Fulbright year at TU Eindhoven, he earned an MS in electrical engineering and a PhD in Applied Physics in 2008, both from Stanford University. He was a postdoctoral fellow at Harvard University until 2010, when he started his group as Assistant Professor of Electrical Engineering and of Applied Physics at Columbia University. In 2013, he joined the faculty of MIT's Department of Electrical Engineering and Computer Science. Dirk's research focuses on quantum technologies based on semiconductor and optical systems. Recent recognitions include the 2011 Presidential Early Career Award for Scientists and Engineers, the 2011 Sloan Research Fellowship in Physics, the 2012 DARPA Young Faculty Award, the 2012 IBM Faculty Award, an 2016 R&D100 Award, the OSA's 2017 Adolph Lomb Medal , and the 2017 ACS Photonics Young Investigator Award.

Ortwin Hess

Imperial College London, UK

Active Quantum Nanoplasmonics : From Single Molecule Strong Coupling to Stopped-Light QED and Lasing

Ortwin Hess currently holds the Leverhulme Chair in Metamaterials in the Blackett Laboratory (Department of Physics) at Imperial College London. He obtained the PhD degree from the Technical University of Berlin (Germany) in 1993 and the Habilitation at the University of Stuttgart in 1997. From 2003 to 2010 he was professor at the University of Surrey (Guildford, UK) and visiting professor at Stanford University (1997/98) and at the Ludwig-Maximilians University of Munich (1999/2000). Ortwin's research interests bridge theoretical condensed matter physics with photonics and are focused on light-matter interaction in nano-photonics, metamaterials and spatio-temporal nano-laser dynamics. He discovered the 'trapped-rainbow' principle, had the idea of stopped-light lasing and made defining contributions to the fields of spatio-temporal dynamics of semiconductor lasers, ultraslow light in metamaterials, complex quantum dot photonics and photonic crystals and strong coupling in nanoplasmonics. Ortwin pioneered active nanoplasmonics and optical metamaterials with quantum gain for which he is awarded the 2016 Royal Society Rumford Medal.

Satoshi Kawata

Osaka University, Japan

Tip-enhanced Raman scattering microscopy : plasmonic molecular imaging beyond the limits

Satoshi Kawata has been a Professor (currently Distinguished Professor) of Applied Physics and Frontier Biosciences at Osaka University since 1993, and also a Chief Scientist in RIKEN from 2002 to 2012. He has served as the President of Japan Society of Applied Physics, the President for Spectroscopical Society of Japan, Editor of Optics Communications, and a Director of Board of OSA. Professor Kawata is one of pioneers in near field optics (the inventor of aperture-less near-field scanning optical microscope and tip-enhanced Raman microscopy), two-photon engineering (the inventor of 3D fabrication with two-photon polymerization, isomerization, photo-refraction, and reduction). He has published a number of papers and books on three-dimensional and nano-resolution microscopy, vibrational spectroscopy, bio-imaging, signal recovery and photon pressure on nano-structures. The "8-micron bull" fabricated with his invented two-photon polymerization has been awarded in Guinness World Record Book 2004 Edition. He is a Fellow of OSA, SPIE, IOP, and JSAP.

Yong-Hee Lee

Korea Advanced Institute of Science and Technology (KAIST), Korea

Squeezing of Photonic Energy into A Point-like Space

Yong-Hee Lee received his master degree in Applied Physics and Ph.D degree in Optical Sciences at Korea Advanced Institute of Science and Technology (KAIST) and at the University of Arizona, respectively. During his stay at AT&T Bell Laboratories, he pioneered and demonstrated the first proton-implanted VCSELs in 1990 and holds the original patent on this industrial VCSEL. In 1991 he joined the Department of Physics of KAIST where he continued his research on VCSELs and started new research on photonic crystal nano-lasers. His laboratory demonstrated various forms of photonic crystal laser including the first electrically-driven photonic crystal laser. His recent interest lies in on the physics of light-matter interaction at the nano-scale and the ultimate light source for photonic integrated circuits and quantum information science. From 2003 to 2004 he was an IEEE LEOS Distinguish Lecturer. Prof. Lee served as an Associate Editor of Optics Express. He is a Fellow of IEEE and the Optical Society of America. Domestically he received numerous awards including the National Academy of Science Award, Korea Scientist Award and the most recent Korea Best Scientist and Engineer Award. In 2014 He received the Humboldt Research Award and the IEEE Photonics Society Engineering Achievement Award. He co-authored more than 180 international journal papers and patents related to nanophotonics. He advised and produced over 40 PhD's in physics during his stay at KAIST.

Franco Nori

RIKEN, Japan & University of Michigan, USA

Parity-Time-Symmetric Optics, extraordinary momentum and spin in evanescent waves, and the quantum spin Hall effect of light

Franco Nori is a RIKEN Chief Scientist, as well as Group Director of the "Quantum Condensed Matter Research Group" at CEMS (Center for Emergent Matter Science). Also, he is a Team Leader of the Interdisciplinary Theoretical Science Program at RIKEN (the Japanese National Laboratory). Also, since 1990 he has been a faculty member of the Physics Department at the University of Michigan, Ann Arbor, USA. Prior to this, he did postdoctoral research work at the Institute for Theoretical Physics, at the University of California, Santa Barbara. He received a PhD in Physics from the University of Illinois. He has co-authored over 80 papers in Physical Review Letters as well as over 30 in Science and Nature journals, and has been cited over 29K times, with an h-index of 84. He is an Elected Fellow of the American Physics Society (APS), Institute of Physics (IoP), Optical Society of America (OSA), and the American Association for the Advancement of Science (AAAS). He received the 2014 Prize for Research in Physics, from the Matsuo Foundation, Japan ; and the 2013 Prize for Science, by the Minister of Education, Culture, Sports, Science and Technology, Japan. Also, an "Excellence in Research Award" and an "Excellence in Education Award" from the University of Michigan.

Eli Yablonovitch

UC Berkeley, USA

Optical Antennas ; Spontaneous Emission Faster Than Stimulated Emission

Eli Yablonovitch introduced the idea that strained semiconductor lasers could have superior performance due to reduced valence band (hole) effective mass. With almost every human interaction with the internet, optical telecommunication occurs by strained semiconductor lasers. He is regarded as a Father of the Photonic BandGap concept, and he coined the term "Photonic Crystal". The geometrical structure of the first experimentally realized Photonic bandgap, is sometimes called "Yablonovite".

Prof. Yablonovitch is elected as a Member of the National Academy of Engineering, the National Academy of Sciences, the American Academy of Arts & Sciences, and is a Foreign Member of the Royal Society of London. He has been awarded the Buckley Prize of the American Physical Society, the Isaac Newton Medal of the UK Institute of Physics, the Rank Prize (UK), the Harvey Prize (Israel), the IEEE Photonics Award, the IET Mountbatten Medal (UK), the Julius Springer Prize (Germany), the R.W. Wood Prize, the W. Streifer Scientific Achievement Award, and the Adolf Lomb Medal. He also has an honorary Ph.D. from the Royal Institute of Technology, Stockholm, & the Hong Kong Univ. of Science & Technology, and is honorary Professor at Nanjing University.

Eli Yablonovitch is the Director of the NSF Center for Energy Efficient Electronics Science (E3S), a multi-University Center headquartered at Berkeley. He received his Ph.D. degree in Applied Physics from Harvard University in 1972. He worked for two years at Bell Telephone Laboratories, and then became a professor of Applied Physics at Harvard. In 1979 he joined Exxon to do research on photovoltaic solar energy. Then in 1984, he joined Bell Communications Research, where he was a Distinguished Member of Staff, and also Director of Solid-State Physics Research. In 1992 he joined the University of California, Los Angeles, where he was the Northrop-Grumman Chair Professor of Electrical Engineering. Then in 2007 he became Professor of Electrical Engineering and Computer Sciences at UC Berkeley, where he holds the James & Katherine Lau Chair in Engineering.

Xiang Zhang

UC Berkeley, USA

Parity-time Symmetry Breaking Lasing and Anti-Lasing

Xiang Zhang is the Ernest Kuh Chaired Professor at the University of California, Berkeley and Director of Materials Science Division at Lawrence Berkeley National Laboratory (LBNL). He is also the Director of the NSF Nano-scale Science and Engineering Center (SINAM). He is an elected member of the US National Academy of Engineering (NAE), Academia Sinica and foreign member of Chinese Academy of Sciences. His research in optical metamaterials was selected by Times Magazine as "Top 10 Scientific Discoveries in 2008". Xiang Zhang was a recipient of many awards including the NSF CAREER Award, Fred Kavli Distinguished Lecturehip, Fitzroy Medal, Charles R. Richards Memorial Award, the Max Born Award, the Julius Springer Prize for Applied Physics. He received his BS/MS in physics in Nanjing University, China, and Ph.D from UC Berkeley in 1996 and was on faculty at Pennsylvania State University and UCLA prior returning Berkeley faculty in 2004.

Nikolay Zheludev

University of Southampton, UK & NTU, Singapore

Metamaterials, anapoles and flying donuts

Nikolay Zheludev's research interest are in nanophotonics and metamaterials. He is the Director of the Centre for Photonic metamaterials and Deputy Director of the Optoelectronics Research Centre in Southampton University, UK. He is also co-Director of The Photonics Institute and directs the Centre for Disruptive Photonic Technologies at Nanyang Technological University. His personal awards include the Thomas Young medal (IOP) for "global leadership and pioneering, seminal work in optical metamaterials and nanophotonics", the Leverhulme Trust Senior Research Fellowship ; Senior Research Professorship of the EPSRC ; The Royal Society Wolfson Research Merit Award & Fellowship. He is a Fellow of the European Physical Society (EPS), the Optical Society (OSA) and the Institute of Physics (London). He is Editor-in-Chief of the Journal of Optics (IOP) and an Advisory Board Member for Nanophotonics, ACS Photonics and Nature Publishing Group Scientific Reports. In 2007 created European Physical Society international meeting at the crossroads of nanophotonics and metamaterials, NANOMETA. He was among a small group of research community leaders who provided initial impetus to the International Year of Light, declared by United Nations for 2015.

KEYNOTE SPEAKERS

Harry Atwater
CALTECH, USA

Dynamic Wavefront Control and Imaging with Active Nanophotonic Structures

Che Ting Chan
HKUST, Hong Kong

Pseudo-spins and their consequences in classical waves

Andrei Faraon
California Institute of Technology, USA

Flat and conformal optics with dielectric metasurfaces

Michael Farle
University of Duisburg-Essen, Germany & Immanuel Kant Baltic Federal University, Russia

Functionalized Hybrid Nanomagnets : New Materials for Innovations in Energy Storage and Medical Theranostics

Peer Fischer
Max Planck Institute, Germany

Chiral plasmonic nanostructures

Jean-Jacques Greffet
Institut d'Optique Graduate School, France

Quantum plasmonics

Yurii Gun'ko
Trinity College Dublin, Ireland

Chiral nanomaterials and their applications

Teruya Ishihara
Tohoku University, Japan

Second order optical nonlinearity in metamaterial

Chennupati Jagadish

The Australian National University, Australia

Semiconductor Nanowires and Metastructures for Optoelectronic Device Applications

Yoon Young Kim

Seoul National University, Korea

Extreme elastic anisotropy – realization by metamaterials

Byoungho Lee

Seoul National University, Korea

Metasurfaces for in-plane plasmonic arbitrary pattern generation

Stefan Maier

Imperial College London, UK

Hybrid nanostructures for sub-wavelength imaging, nonlinear optics, and chemistry

Namkyoo Park

Seoul National University, Korea

Acoustic omni meta-atom for decoupled access to all octants of a wave parameter space.

Markus Raschke

University of Colorado Boulder, USA

Seeing with the nano-eye : accessing structure, coupling, and dynamics in matter on its natural length and times scales

Mu Wang

Nanjing University, China

Making Structured Metal Transparent for Ultra-Broadband Electromagnetic and Acoustic Waves

META'17 VENUE

META'17 will be held at the **Songdo Convensia**, 123 Central-ro, Yeonsu-gu, 21998, **Incheon**, Korea.
Tel. : +82-32-210-1037
Fax : +82-32-210-1005
Website : www.songdoconvensia.com

GETTING TO VENUE

Address

Songdo Convensia, 123 Central-ro, Yeonsu-gu, 21998, **Incheon**, Korea.
Tel. : +82-32-210-1037
Fax : +82-32-210-1005
Website : www.songdoconvensia.com

Seoul (Downtown) -> Songdo Convensia

- By Subway

Subway Station	Information
University of Incheon (Incheon Line)	Take Seoul subway line number 1 and get off at Bupyeong Station Transfer Bupyeong Station to Incheon subway and get off at University of Incheon Station Take a walk around 10-15minutes to Songdo ConvensiA (next to Sheraton Hotel)
Dongmak Station (Incheon Line)	Take Seoul subway line number 1 and get off at Bupyeong Station Transfer Bupyeong Station to Incheon subway and get off Dongmak Station Through exit 3, take bus 8, 6, 780 to Songdo ConvensiA Bus Stop

- By Taxi

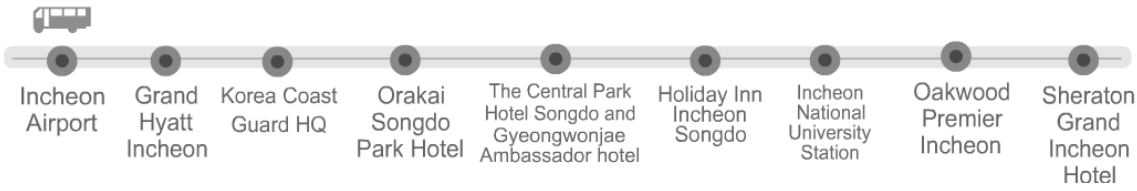
Fee	Taxi Fare ranges from 60,000 – 90,000 KRW ※ Receipt can be collected from driver if needed
Hours	Available 24hours
About	Ask Taxi Driver for 'Songdo ConvensiA' (at Songdo of Incheon City nearby Sheraton Hotel)

Incheon International Airport (ICN) -> Songdo Convensia

1) By KAL-limousine (~40 min, 7,000 KRW)

- Board the limousine bus (6707B) at the platform 4A

- Get off at **Sheraton Grand Incheon Hotel** (last stop)



Time schedule

Departure Point Incheon Airport (Bus Stop #4A) Arrival Point Sheraton Grand Incheon Hotel

Please be advised that actual times may vary depending on traffic conditions.

Travel Time : 30min

Departure time					
05:53	06:21	06:58	07:33	08:13	08:58
09:38	10:23	11:13	12:03	12:53	13:43

GUIDELINES FOR PRESENTERS

ORAL PRESENTATIONS

Each session room is equipped with a stationary computer connected to a LCD projector. Presenters must load their presentation files in advance onto the session computer. Technician personnel will be available to assist you.

Scheduled time slots for oral presentations are 15 mn for regular, 20 mn for invited presentations, 30 mn for keynote talks and 35 mn for plenary talks, including questions and discussions. Presenters are required to report to their session room and to their session Chair at least 15 minutes prior to the start of their session.

The session chair must be present in the session room at least 15 minutes before the start of the session and must strictly observe the starting time and time limit of each paper.

POSTER PRESENTATIONS

Presenters are requested to stand by their posters during their session. One poster board, A0 size (118.9 x 84.1 cm), in portrait orientation, will be available for each poster (there are no specific templates for posters). Pins or thumbtacks are provided to mount your posters on the board. All presenters are required to mount their papers 30mn before the session and remove them at the end of their sessions. Posters must prepared using the standard META poster template (available on the conference website).

PRE-CONFERENCE TUTORIALS

Frontier's Lectures on Metamaterials and Plasmonics

July 24 (Mon.), Seoul National University
Room 118, Building 301, Dept. of ECE

Lecturer	Session	Title
	08:50-09:00	**Opening**
Thomas Zentgraf	09:00-10:00	**Nonlinear Metasurfaces**
Jensen Li	10:00-11:00	**Spin-enabled optics with metamaterials and metasurfaces**
Yongmin Liu	11:00-12:00	**Reconfigurable Plasmonics and Metamaterials**
	12:00-13:30	**Lunch**
Mu Wang	13:30-13:55	**Meet Editors – Physical Review Letters**
Zachary Lapin	13:55-14:20	**Meet Editors – Nature Communications**
Ling Lu	14:20-15:20	**Topological Photonic Crystals**
	15:20-15:30	**Coffee Break**
Andrey Miroshnichenko	15:30-16:30	**Multipole decomposition and nonradiating sources in nanophotonics/metamaterials**
Renmin Ma	16:30-17:30	**Plasmonic nanolasers: fundamental, application and challenges**
Cristian Ciracì	17:30-18:30	**The optics of film-coupled nanoparticles: a bridge to the quantum realm**

Tutorial is free of charge, but registration is required. Please follow the link below to register:
https://docs.google.com/forms/d/1w4N8SrZSUlfRWgeuqDhmHoIDmMCgp9L7xEoPc5kowBI/edit

Chairs:

Namkyoo Park
Seoul National University

Hakjoo Lee
CAMM

Junsuk Rho
POSTECH

Session will be held in **Multimedia Room 118 of Building 301**
Lunch will be served at the faculty **cafeteria, first floor of Building 301**

Access to Meta Pre-conference
- Rm. 118, Building 301, Seoul National University

● From '*Incheon*' or '*Gimpo*' International Airport

- **By public transportation** [~2 hours: KRW ~10,200 (Incheon),~1.5 hour: KRW ~5,200 (Gimpo)]
o Board the limousine bus line number **6003** (The bus stop is **6A,12B in Incheon and 6 in Gimpo**).
o Get off at the front gate of Seoul National University.
o Board a bus line **5511 or 5513, or take a taxi.**
o Get off at either bus stop number 9 or 10 which are in front of buildings 301 and 302 (**last stop**).
- By taxi [~1 hour, KRW ~49,000 (Incheon), ~1 hour, KRW ~19,600 (Gimpo)]

● From Seoul Station

- **By public transportation** [~1 hour, KRW ~1300]
o Take the subway (**line No. 4**) **from Seoul station to Sadang station.**
o Transfer the subway line from No. 4 to No. 2.
o Take the subway (**line No. 2**) **from Sadang to Nakseongdae station.**
o Get out of **Exit 4**, turn left around the GS gas station, and board a bus line **02**.
o Get off in front of buildings 301 and 302 (**last stop**).
- By taxi [~45 minutes, KRW ~13,500]

● From Songdo Convensia, Incheon

- **By public transportation** [~1 hour, KRW ~2,000]
o Take the subway (**line Incheon No. 1**) **from Incheon Nat'l Univ station to Bupyeong station.**
o Transfer the subway line from 'Incheon No. 1' to 'No. 1' (not Incheon No. 1!).
o Take the subway (**line No. 1**) **from Bupyeong to Sindorim station.**
o Transfer the subway line from 'No. 1' to 'No. 2'.
o Take the subway (**line No. 2**) **from Sindorim to Nakseongdae station.**
o Get out of **Exit 4**, turn left around the GS gas station, and board a bus line **2**.
o Get off in front of buildings 301 and 302 (**last stop**).
- By taxi [~45 minutes, KRW ~32,500]

Nonlinear Metasurfaces

Thomas Zentgraf
Department of Physics
Ultrafast Nanophotonics
Paderborn University, Germany
Email: thomas.zentgraf@uni-paderborn.de

For efficient nonlinear processes the engineering of the nonlinear optical properties of media becomes important. In particular, the phase relation between the fundamental and the nonlinear waves plays here an important role. The most well-known technique for spatially engineering nonlinear properties is the quasi-phase matching scheme for second-order processes like second harmonic generation (SHG). The quasi-phase matching leads to efficient frequency conversion compared to a homogeneous nonlinear medium by providing the extra momentum to compensate the phase mismatch between the fundamental and harmonic waves. The so-called 'poling' is the most widely employed technique for achieving quasi-phase matching. By periodically reversing the crystalline orientation of ferroelectric materials, the sign of the $\chi^{(2)}$ nonlinear susceptibility can be spatially modulated along the propagation direction. However, such a poling only leads to a binary state for the nonlinear material polarization, which is equivalent to a discrete phase change of π of the nonlinear polarization.

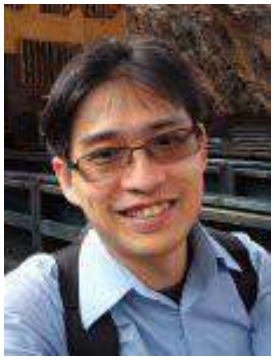
Here I will discuss a novel nonlinear metamaterial with homogeneous linear optical properties but continuously controllable phase of the local effective nonlinear polarizability. For the demonstration we use plasmonic metasurfaces with various designs for the meta-atom geometry together with circular polarized light states. The controllable nonlinearity phase results from the phase accumulation due to the polarization change along the polarization path on the Poincare Sphere (the so-called Pancharatnam-Berry phase) and depends therefore only on the spatial geometry of the metasurface. By using a fixed orientation of the meta-atom the nonlinear phase can be spatially arbitrarily tailored over the entire range from 0 to 2π. In contrast to the quasi-phase matching scheme the continuous phase engineering of the effective nonlinear polarizability enables complete control of the propagation of harmonic generation signals, and therefore, it seamlessly combines the generation and manipulation of the harmonic waves for highly compact nonlinear nanophotonic devices. We will demonstrate the concept of phase engineering for the manipulation of the SHG and THG from metasurfaces and the restriction on the symmetry properties of the geometry.

Furthermore, I will discuss a nonlinear Berry phase in the time domain which arises from the rotational Doppler shift that can be observed on spinning metasurfaces. The rotational Doppler shift in nonlinear optics was predicted nearly 50 years ago and recently demonstrated at nonlinear crystals. The Doppler frequency shift was determined for the SHG of a circularly polarized beam passing through a spinning nonlinear optical BBO crystal with three-fold rotational symmetry. In our experiments we found that the SHG signal with a circular polarization opposite to that of the fundamental beam experiences a Doppler shift of three times the rotation frequency of the optical crystal. This finding is of fundamental significance in nonlinear optics and also for tailored nonlinearities, as it provides a further degree of freedom with the design of nonlinear materials, in particular for moving media. We will briefly discuss how this rotational Doppler Effect can be also utilized for spinning metasurfaces in the nonlinear regime.

Biography: Professor Thomas Zentgraf received his bachelor's degree of Engineering from University of Applied Sciences Jena, Germany, in 2001 and a master's degree of Physics of the Technical University Clausthal, Germany, in 2002. After that, he joined the University of Stuttgart, Germany, where he under the supervision of Professor Harald Giessen received his PhD in the 2006. Prof Zentgraf was honored with a Feodor-Lynen-Fellowship by the Alexander von Humboldt Foundation in 2007 and joined as a research fellow the group of Professor Xiang Zhang at the Mechanical Engineering Department at University of California at Berkeley, USA. In 2011 he returned to Germany and became full professor for Applied Physics at the Department of Physics, University of Paderborn, where he is head of the Ultrafast Nanophotonics Group. His research interests focus on using ultrafast spectroscopy to study linear and nonlinear effects in plasmonic and dielectric metamaterials and plasmonic-hybrid materials.

Spin-enabled optics with metamaterials and metasurfaces

Jensen Li
School of Physics and Astronomy
University of Birmingham, United Kingdom
Email: j.li@bham.ac.uk



Light, similar to other vector waves such as elastic waves, has a spin-degree of freedom in its propagation. The interaction between spin and motion provides an interesting way to manipulate the orbital motion of light, in addition to the driving force from a refractive index gradient in conventional optics. In this tutorial, I will give an introduction of geometric phase and the associated optical-spin Hall effect in a systematic approach and will show its applications and new opportunities in metamaterials and metasurfaces. For example, the optical spin-Hall effect can be utilized to control dynamically the generation of surface plasmon on a plasmonic metasurface by putting a tailor-made array of anisotropic metamaterial atoms on a surface. When these anisotropic metamaterial atoms are assembled into a three dimensional material, I will also show how these can be used to generate a pseudo-magnetic field or gauge field for photon, which can guide light into cyclotron motion, as if it is a real magnetic field acting on electron motion. These discussions provide a feasible route to spin-enabled optics.

Biography: Dr. Jensen Li received his BEng degree with first class honours in electrical and electronic engineering from the University of Hong Kong in 1998 and his MPhil, PhD degree in physics from the Hong Kong University of Science and Technology in 2000 and 2004. In this period of time, he worked on the zero-th order photonic band gap and the theoretical proposal of acoustic negative index metamaterials.

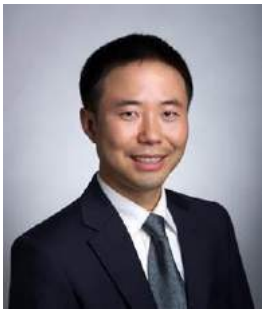
From 2005 to 2007, Jensen worked in Imperial College London, with support from a Croucher Foundation postdoctoral fellowship, where he developed a theoretical scheme of carpet cloaking.

From 2007 to 2009, he was a postdoctoral researcher at the University of California at Berkeley, participated in the realization of carpet cloaking at infrared frequencies. He also started to work on acoustic metamaterials with super-resolution there.

From 2009 to 2013, he was an assistant professor at the City University of Hong Kong. He continued his research in metamaterials and also worked on alternative schemes in achieving acoustic negative indices without local resonance from theory to realization.In 2013, he joined University of Birmingham as a senior lecturer.

Reconfigurable Plasmonics and Metamaterials

Yongmin Liu
Assistant Professor
Department of Mechanical and Industrial Engineering
Department of Electrical and Computer Engineering
Northeastern University, Boston, USA
Email: y.liu@neu.edu
Group Website: http://www.northeastern.edu/liulab



Plasmonics has become a very important branch in nano optics. It allows us to concentrate, guide, and manipulate light at the deep subwavelength scale, promising enhanced light-matter interaction, next-generation optical circuits, sub-diffraction-limited imaging, and ultrasensitive biomedical detection [1-3]. Furthermore, the assembly of judiciously designed metallic structures can be used to construct metamaterials and metasurfaces with exotic properties and functionalities, including anomalous refraction/reflection, strong chirality and invisibility cloak [4,5]. There is a pressing need of tunability and reconfigurability for plasmonics and metamaterials, in order to perform distinctive functionalities and miniaturize the device footprint. In this talk, I will present our recent work in reconfigurable plasmonics and metamateirals. First, I will discuss the first demonstration of reconfigurable plasmonic lenses operating in microfluidic environment, which can dynamically diverge, collimate and focus surface plasmons [6]. Second, I will present a novel graphene metasurface to fully control the phase and amplitude of infrared light with very high efficiency. It manifests broad applications in beam steering, biochemical sensing and adaptive optics in the crucial infrared wavelength range [7]. Finally, I will discuss origami-based, dual-band chiral metasurfaces at microwave frequencies. The flexibility in folding the metasurface provides another degree of freedom for geometry control in the third dimension, which induces strong chirality from the initial, 2D achiral structure [8]. These results open up a new avenue towards lightweight reconfigurable metadevices.

Biography: Dr. Yongmin Liu obtained his Ph.D. from the University of California, Berkeley in 2009. He joined the faculty of Northeastern University at Boston in fall 2012 with a joint appointment in the Department of Mechanical & Industrial Engineering and the Department of Electrical & Computer Engineering. Dr. Liu's research interests include nano optics, nanoscale materials and engineering, plasmonics, metamaterials, biophotonics, and nano optomechanics. He has authored and co-authored over 50 journal papers, including *Science*, *Nature*, *Nature Nanotechnology*, *Nature Communications*, *Physical Review Letters* and *Nano Letters*. Dr. Liu received Office of Naval Research Young Investigator Award (2016), 3M Non-Tenured Faculty Award (2016), Air Force Summer Faculty Fellowship (2015), and Chinese Government Award for Outstanding Students Abroad (2009). Currently he serves as an editorial board member for *Scientific Reports*, *EPJ Applied Metamaterials* and *Nano Convergence*.

Topological Photonic Crystals

Ling Lu
Institute of Physics, Chinese Academy of Sciences, Beijing, China

Due to the recent discovery of topological insulators, it has been recognized that topology is indispensable in distinguishing phases of matter. Similarly, new optical material systems are being discovered with non-trivial topologies of their global wave-functions in the momentum space, whose interfaces support novel states of light with ideal transport properties such as the robustness to large disorder or fabrication imperfections.

In this talk, I will show experimental realizations and theoretical predictions of 2D and 3D photonic crystals with topologically protected edge and surface states. Specifically, I will discuss single and multimode one-way waveguides, the observation of Weyl points, a single Dirac cone surface state immune to random disorder and topological one-way fibers. This research can be extended to phonons, plasmons and other bosons. These new degrees of freedom in bosonic band topologies promise wide exciting opportunities in both fundamental physics and technological outcomes.

Biography: Ling Lu is a professor in the Institute of Physics of Chinese Academy of Sciences in Beijing China. He obtained his bachelor in Physics in 2003 from Fudan University in Shanghai, China. He got his Ph.D. in Electrical Engineering in 2010 at University of Southern California in Los Angeles. His thesis work, advised by Prof. John O'Brien, was on photonic crystal nanocavity lasers. He was a postdoc and later a research scientist in the Physics Department of Massachusetts Institute of Technology, where he worked with Prof. Marin Soljačić and John Joannopoulos and collaborated with Prof. Liang Fu. His current research focuses on topological photonics.

Multipole decomposition and nonradiating sources in nanophotonics and metamaterials

Andrey Miroshnichenko
Associate Professor
Nonlinear Physics Centre
Research School of Physics and Engineering
Australian National University
Acton, ACT, 2601, Australia

Email: andrey.miroshnichenko@anu.edu.au
Website: andreysquare.com

Multipole decomposition is indispensable tool in analyzing the optical response of nanoscale structures consisting of finite size elements. In general, there are two complementary approaches based on Cartesian (current) multipoles and Spherical (scattered field) multipoles. For subewavelength elements they produce similar description. But for larger elements certain deviations might occur. In this tutorial, I will provide the basic description of both methods and specify kind of complementary information they provide. I will also introduce the concept of nonradiation sources, provide specific examples of so-called *anapole* modes and demonstrate the importance of toroidal dipole moments.

Biography: A/Prof. Andrey Miroshnichenko obtained his PhD in 2003 from the Max-Planck Institute for Physics of Complex Systems in Dresden, Germany. In 2004 he moved to Australia to join the Nonlinear Physics Centre at ANU. During this time A/Prof. Miroshnichenko made fundamentally important contributions to the field of photonic crystals and bringing the concept of the Fano resonances to photonics. In 2007 A/Prof. Miroshnichenko was awarded by APD Fellowship from the Australian Research Council. It allowed him to initiate the research on a new class of tunable photonic structures infiltrated with liquid crystals. Later, in 2011 he was awarded by Future Fellowship from the Australian Research Council. During this period, he pioneered the research of high-index dielectric nanoparticles in the visible range, including one of the first demonstrations of the optically induced magnetic response in silicon nanoparticles. The current topics of his research are nonlinear nanophotonics, topologiccal photonics, and resonant interaction of light with nanoclusters, including optical nanoantennas and metamaterials.

Plasmonic nanolasers: fundamental, application and challenges

Renmin Ma
School of Physics
State Key Lab for Mesoscopic Physics
Collaborative innovation center of quantum matters
Peking University, China
Email: renminma@pku.edu.cn

Plasmonic nanolasers are a new class of quantum amplifiers that deliver coherent surface plasmons well below the diffraction barrier which brings fundamentally new capabilities to biochemical sensing, super-resolution imaging and on-chip optical communication. In this talk, I will review fundamental, application and challenges of this emergent device.

Biography: Ren-Min Ma is an assistant professor in the School of Physics, Peking University. He received his PhD from Peking University. His dissertation was focused on semiconductor physics and devices in low dimensional structures and received the National Top 100 Ph.D. dissertations of China Award. He was a postdoc researcher at UC Berkeley during 2009-2014. He developed the first room temperature semiconductor plasmon laser, directionally emitted waveguide embedded plasmon laser and applied plasmon lasers to sensing field. His current research interests include nanophotonics and nanomaterials.

The optics of film-coupled nanoparticles: a bridge to the quantum realm

Cristian Ciracì
Center for Biomolecular Nanotechnologies, Istituto Italiano di Tecnologia,
Via Barsanti 14, 73010 Arnesano, Italy
Email: cristian.ciraci@iit.it

Metals support surface plasmons at optical wavelengths and have the ability to localize light to sub-wavelength regions. The film-coupled nanoparticle system—in which plasmonic nanoparticles are separated nanometer distances from a metal film by an insulating spacer—has unique properties that make it useful for a variety of processes depending on the nanoparticle shape. Nanospheres that are coupled to a film, for example, have been predicted to produce enormous field enhancements—as much as thousands of times that of the incident radiation—in the separating region between nanoparticle and film. For the narrowest (<1 nm) gaps, light can be so tightly confined that the nonlocality associated with the dielectric response of the metal and quantum effects can have a strong impact on the scattering properties of the system, placing strict bounds on the ultimate field enhancement.

Another interesting system is that of nanocubes or planar structures, which support transmission line-like modes between the two planar metal contact regions. Collective scattering of film-coupled nanocubes can strongly modify reflectance properties of the underlying surfaces, creating a nearly ideal absorber at desired wavelengths. The controlled reflectance of the surface might provide a means for enhancing nonlinearity, for example by allowing potentially all of a fundamental beam to be converted into higher harmonics. Moreover, we numerically find a sub-nm gap regime in which nonlocal effects can dramatically enhance the nonlinear optical response of the metal by several order of magnitude.

All mentioned structures can be easily and cheaply fabricated using colloidal nanoparticles, surface chemistries, or atomic layer deposition lithography, allowing for near angstrom-scale control over the spacer thickness and large-area uniformity. At the same time, a reliable way to theoretically describe and numerically model optical properties of plasmonic nanostructures with different length scales requires methods beyond classical electromagnetism. In this tutorial I will present an implementation of the hydrodynamic model that takes into account the nonlocal behavior of the electron response by including the electron pressure and it is generalized so that it can describe electron spill-out and tunneling effects, including nonlocal broadening near metal surfaces.

Biography: Cristian Ciracì obtained his BSc in Computer Science Engineering in February 2005 and his MSc in Science for Engineering in July 2007 at Sapienza, University of Rome (Italy). He received his Ph.D. in Condensed Matter Physics from University of Montpellier, France, with honor degree in September 2010. In November 2010 he joined the Center for Integrated Metamaterials and Plasmonics at **Duke University (U.S.)** as a Postdoc. In March 2014 he joined the Center for Biomolecular Nanotechnologies at the **Istituto Italiano di Tecnologia (IIT)**, Italy, where he currently holds a position as Researcher. His main research activities concern numerical modeling and investigation of electromagnetic propagation in complex media, with particular emphasis on nonlinear optical phenomena. During the years of his research activity he has co-authored several publications on top-tier scientific journals and has been invited to several international conferences. In 2012 his work was featured on the **cover of Science Magazine**.

niz@orc.soton.ac.uk

Abstract-Electromagnetic toroidal multipoles can be represented as currents flowing on the surfaces of tori were recently experimentally observed in metamaterials and nanoparticles. They provide physically significant contributions to the basic characteristics of matter including absorption, dispersion, and chirality. They give rise to dynamic anapoles, illusive non-radiating charge-current configurations recently detected in matter. Toroidal excitations also exist in free space as spatially and temporally localized electromagnetic pulses propagating at the speed of light and interacting with matter in a way different from conventional electromagnetic transvers pulses. We discuss these recent findings and the role of localized and propagating electromagnetic toroidal excitations in light-matter interactions, spectroscopy and telecommunications.

Squeezing of Photonic Energy into A Point-like Space

Y. H. Lee[1,*] **and M. K. Kim**[2]

[1]Department of Physics, KAIST, Daejon, Korea

[2]KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, Korea

[*]corresponding author: yhlee@kaist.ac.kr

Abstract – A three-dimensionally tapered metallic nano-gap resonator with modal volume of ~1.0×10^{-7} λ^3 is to be discussed. From a 5-nm-air-gap gold resonator, strong second harmonic signals are generated at a point-like space where electromagnetic energy is highly concentrated. The nonlinear signal is found to be stronger than that from a 100-nm-gap counterpart by a factor of >27,000. Rich nonlinear characteristics observed from quantum dots and nm-scale proteins trapped in the nano-gap will also be discussed.

Metaoptics in the Visible

Federico Capasso

John A. Paulson School of Engineering and Applied Sciences, Harvard University, USA

capasso@seas.harvard.edu

Abstract- Metasurfaces based on sub-wavelength patterning have major potential for arbitrary control of the wavefront of light by achieving local control of the phase, amplitude and polarization and allowing greater functionality and more compact devices. We have introduced a new CMOS compatible technology based on atomic layer deposition of TiO_2 which has enabled high performance metalenses, achromatic lenses, immersion objectives, axicons, vortex plates, holograms and ultracompact spectrometers for a wide range of applications.

Parity-Time-Symmetric Optics, extraordinary momentum and spin in evanescent waves, and the quantum spin Hall effect of light.

Franco Nori [1,2]
[1] *RIKEN, Saitama, Japan.* [2] *University of Michigan, Ann Arbor, USA*

(1) Optical systems combining balanced loss and gain provide a unique platform to implement classical analogues of quantum systems described by non-Hermitian parity–time (PT)-symmetric Hamiltonians. Such systems can be used to create synthetic materials with properties that cannot be attained in materials having only loss or only gain. We report PT-symmetry breaking in coupled optical resonators. We observed non-reciprocity in the PT-symmetry-breaking phase due to strong field localization, which significantly enhances nonlinearity. In the linear regime, light transmission is reciprocal regardless of whether the symmetry is broken or unbroken. We show that in one direction there is a complete absence of resonance peaks whereas in the other direction the transmission is resonantly enhanced, which is associated with the use of resonant structures. Our results could lead to a new generation of synthetic optical systems enabling on-chip manipulation and control of light propagation.

(2) Maxwell's equations, formulated 150 years ago, ultimately describe properties of light, from classical electromagnetism to quantum and relativistic aspects. The latter ones result in remarkable geometric and topological phenomena related to the spin-1 massless nature of photons. By analyzing fundamental spin properties of Maxwell waves, we show that free-space light exhibits an intrinsic quantum spin Hall effect—surface modes with strong spin-momentum locking. These modes are evanescent waves that form, for example, surface plasmon-polaritons at vacuum-metal interfaces. Our findings illuminate the unusual transverse spin in evanescent waves and explain recent experiments that have demonstrated the transverse spin-direction locking in the excitation of surface optical modes. This deepens our understanding of Maxwell's theory, reveals analogies with topological insulators for electrons, and offers applications for robust spin-directional optical interfaces.

Kawata@ap.eng.osaka-u.ac.jp

Abstract
Tip-enhanced Raman scattering (TERS) microscopy as a version of near-field scanning optical microscopy has been widely used for analyzing molecular distribution of nanomaterials and biomaterials In this presentation, mechanisms of super-resolution and field enhancement of TERS microscopy will be discussed and recent progress of TERS microscopy beyond the limits, such as nanometer resolution, 3D imaging, and deep UV imaging, will be shown.

Raman microscopy has been a convenient tool for analyzing and imaging various materials as it provides richer information than other imaging techniques based on topographic information. However, Raman scattering is a weak phenomenon and the spatial resolution in any optical microscopy is usually restricted by the diffraction limit of the probing light. Both these problems can be overcome by use of surface plasmons, which confines optical field in the near field of probe tip [1], resulting in local enhancement of light [2] as well as super spatial resolution [3]. The spatial resolution in imaging is limited around 10 nm due to the necessity of a reasonable diameter of metallic tip to excite collective electron oscillation and due to the contribution of imaginary part of dielectric constant of probe metal in visible range [4]. The factor of enhancement is also limited due to the necessary of covering the spectrally broad band for the excitation and Raman scattering shift of sample [5]. The effective spectral range is also limited to near UV to near infrared for silver and gold. In this presentation, I will show our research progress in TERS microscopy beyond the limitations. The spatial resolution has been drastically improved by applying pressure on to the sample with a tip to introduce the localized structural deformation in sample [6]. The broadband enhancement by cascading the probe antennae [7], the deep UV resonant Raman TERS [8] without photo-degradation wit use of lanthanide ions [0], and 3D Raman imaging with a gold nano-particle inside a living cell [10] will be discussed.

Active Quantum Nanoplasmonics:
From Single Molecule Strong Coupling to Stopped-Light Lasing

O. Hess
The Blackett Laboratory, Imperial College London, Prince Consort Road, London, SW7 2AZ, UK
o.hess@imperial.ac.uk

Abstract- Nanoplasmonic cavities create a unique environment for controlled spatio-temporal dynamics of light strongly coupled with single quantum emitters (molecules, quantum dots) providing a basis for strong coupling at room temperature, strong coupling quantum spectroscopy and paving the way for few- or single-molecule lasing.

Nanoplasmonic (meta-)materials and nanophotonics have the unique ability to confine light in extremely sub-wavelength volumes and thereby strongly enhance the effective strength of electromagnetic fields. Fundamentally, such high-field enhancement can alter the local density of states experienced by a photoactive molecule to unprecedented degrees and control its exchange of energy with light. For a sufficiently strong field enhancement, one enters the strong-coupling regime, where the energy exchange between the excited states of molecules/materials and plasmons is faster than the de-coherence processes of the system. As a result, the excitonic state of the molecule becomes entangled with the photonic mode, forming hybrid excitonic-photonic states. These hybrid-states are part light, part matter and allow for characteristic Rabi oscillations of atomic excitations to be observed. Until recently, the conditions for achieving strong-coupling were most commonly met at low temperatures, where de-coherence processes are suppressed. As a major step forward, we have recently demonstrated room-temperature strong coupling of single molecules in a plasmonic nano-cavity [1] which was achieved using a host-guest chemistry technique, controlling matter at the molecular level. Concurrently, linking nano-spectroscopy of quantum dots with strong coupling allows to lithographically realise a strong-coupling set-up that couples dark plasmonic modes and quantum dots [2]. Remarkably, through strong coupling we obtain spectroscopic access to otherwise veiled states (such as the charged trion state) enabled through a strong-coupling induced speed up of the radiative dynamics of the quantum dot states [2]. Considering the key importance of strong coupling in quantum optics our findings pave the road for a wide range of ultrafast quantum optics experiments and quantum technologies at ambient conditions. Moreover, the pronounced position-dependent spectral changes may lead to new types of quantum sensors and near-field quantum imaging modalities.

Parity-time Symmetry Breaking Lasing and Anti-Lasing

Xiang Zhang
UC Berkeley, USA

Abstract: Optical loss is usually undesirable. Recently, judiciously designed balanced gain and loss structures, so called parity-time (PT) symmetric synthetic materials, are explored due to their extraordinary properties. In this talk I will discuss the notion of PT symmetry in optical systems. Especially I will discuss how to achieve nano-scale spectrometer by designing an anti-Hermitian light matter interactions. This will be also useful for spectrum splitting in solar applications. Finally, I will discuss a single mode lasing scheme using PT symmetric periodically modulation in a micro ring lasers, and lasing and anti-lasing in a single cavity.

Optical Antennas;
Spontaneous Emission Faster Than Stimulated Emission.

Eli Yablonovitch
University of California, Berkeley

Abstract-Antennas emerged at the dawn of radio for concentrating electromagnetic energy into a volume much smaller than the wavelength cubed, allowing for nonlinear radio detection. Such coherent detection is essential for radio receivers, and has been used since the time of Hertz. Conversely, an antenna can efficiently extract radiation from a sub-wavelength source, such as a small cellphone.

Over 100 years after the radio antenna, we finally have tiny "optical antennas" which can extract radiation from molecules and quantum dots. With optical antennas, spontaneous light emission can become faster than stimulated emission. Antenna physics has been poorly covered in education. It does not require plasmonics; nor the Purcell effect.

Towards Scalable Semiconductor Quantum Networks

Dirk Englund
Department of Electrical Engineering and Computer Science, MIT, USA
*corresponding author: englund@mit.edu

Abstract-The Internet is among the most significant inventions of the 20th Century. We are now poised for the development of a quantum internet to exchange quantum information and distribute entanglement among quantum memories (and ultimately quantum computers) that could be great distances apart. This kind of quantum internet would have a range of applications that aren't possible in a classical world, including long-distance unconditionally-secure communication, certain types of precision sensing and navigation, and distributed quantum computing. But we still need to develop or perfect many types of components and protocols to build such a quantum internet. This talk will consider some of these components, focusing on photonic integrated circuits, diamond spin-based quantum memories, and prototype networks. Specifically, the first part of this talk will review our recent progress in adapting one of the leading PIC architectures—silicon photonics—for different types of quantum secure communications protocols. The second part of the talk will consider how photonic integrated circuits technology may extend the reach of quantum communications through all-optical and memory-based quantum repeaters, as well as extensions to modular quantum computers.

Keynote Presentation

Metasurfaces for in-plane plasmonic arbitrary pattern generation

Byoungho Lee
School of Electrical and Computer Engineering, Seoul National University, Seoul 08826, Korea
*byoungho@snu.ac.kr

Abstract- Plasmonic metasurfaces with distributed nanoslits are demonstrated to generate in-plane plasmonic arbitrary patterns based on holographic approach. Utilizing extremely anisotropic scatterings of surface plasmon polaritons (SPPs) at nanoslits, holographic reconstructon and modulation of plasmonic wavefront are achieved by designing spatial distributions and rotations of nanoslits. Polarization-dependent modulations of in-plane SPP wavefront are thoroughly studied for focusing, switching, and multiplexing in-plane plasmonic waves. Moreover, manipulation of complex plasmonic field in terms of phase and amplitude is proposed for complete control of arbitrary holographic SPP patterns.

Plamonics and metasurface are the major research topics which have led the boom of nanophotonics recently. Plasmonics have emerged as a powerful route to subwavelength optical technologies by using surface plasmon polaritons (SPPs) which are surface bound electromagnetic waves propagating along a metal-dielectric interface. Meanwhile, metasurfaces, which are planar metamaterials, have been extensively studied to manipulate properties of light abruptly in anomalous manner. Particularly, as an ultra-thin flat optical component for coherent light manipulation, metasurface has been attracting much interest as a promising candidate to replace conventional bulky optic components. Moreover, metasurfaces have been found to enable coherent control of plasmonic waves as well as light waves propagating in the free space.

In this presentation, metasurfaces for arbitrary plasmonic wavefront generation and polarization dependent modulations will be presented. Firstly, physical mechanisms of nanoslits as anisotropic SPP scatterers will be explained. Then, design methods to assign phase profiles on nanoslit distributions are presented in case of various polarization states [1]. Plasmonic waves are focused, switched, multiplexed, and steered depending on polarization state modulations [1-3]. Lastly, arbitrary complex plasmonic field generation with manipulation of both phase and amplitude is introduced with an example of plasmonic Airy beam generation [4].

Hybrid nanostructures for sub-wavelength imaging, nonlinear optics, and chemistry

S. A. Maier[1]

[1] Imperial College London, London SW7 2AZ, UK

Abstract **– We demonstrate how controlled emission of hot electrons in plasmonic nanoantennas leads to highly localized nanochemistry. This scheme is utilized for the assembly of hybrid metallic nanoantennas consisting both of top-down fabricated elements, and nanosized colloids. The second part of the talk will show new results for dielectric and hybrid metallic/dielectric antennas, based on Si, Ge and GaP, for highly enhanced harmonic generation and surface-enhanced sensing.**

Plasmonic nanoantennas with nanoscale gaps act as efficient transducers of electromagnetic energy from the far to the near field at optical frequencies, creating hot spots of field energy utilized extensively in surface-enhanced spectroscopy and sensing. Using a super-resolution localization scheme, we demonstrate direct imaging of these electromagnetic hot spots via single-molecule emission events, paying careful attention to coupling between molecular emission and antenna modes, in order to determine the true position of the single emitters [1]. We then introduce the notion of "reactivity hot spots" — nanosized regions in plasmonic antennas where hot electrons generated via plasmon decay are emitted. We demonstrate that control over this emission process can lead to highly localized surface chemistry [2], allowing the positioning of colloidal nanospheres around bow tie antennas with high accuracy (Figure 1). A combination of experimental imaging of these reactivity hot spots and ab initio theory will be used to elucidate this process.

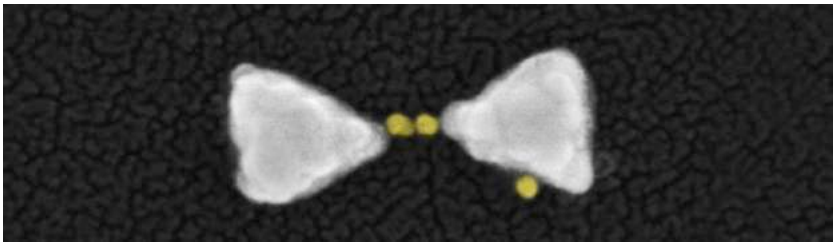

Fig. 1. Gold nanospheres arranged in the gap of a silver bow tie antenna via localized hot electron emission [2]. SEM image false-coloured to distinguish between the two materials. The diameter of the gold spheres is 15 nm.

In the second part of the talk, we will present new results on dielectric and hybrid dielectric/metallic nanoantennas, focusing on highly enhanced harmonic generation and surface-enhanced spectroscopy under low-loss conditions. As an example, GaP nanopillars allow to utilize the advantages of dielectric antennas in terms of low loss and high field confinement throughout the visible regime [3]. We will further show new, unpublished results on hybrid Si/plasmonic antennas, as highly efficient nanoscale sources of third harmonic radiation.

Acoustic omni meta-atom for decoupled access to all octants of a wave parameter space

Sukmo Koo, Choonlae Cho, Jun-ho Jeong, and Namkyoo Park*
Photonic Systems Laboratory, Department of ECE, Seoul National University, Seoul 08826, Korea
*corresponding author: nkpark@snu.ac.kr

Abstract-Although the decoupling of fundamental wave parameters has been envisaged as an ideal platform towards the top–down and deterministic reconfiguration of the meta-atom (Pendry, Science 312, 2006), its feasibility has remained as a plausible idea. In this talk we present our recent proposal for a new design strategy for the meta-atom (Koo et. al., Nat. comm. 13012, 2016). Focusing on an acoustic platform, the criteria for the decoupling of wave parameters are derived, and an omni meta-atom that achieves independent, broad-range access to all octants of the wave parameter space (ρ, B^{-1}, Ξ) is demonstrated. With the precision access for target parameters, we also demonstrate new meta-devices, including bianisotropic meta-surfaces for independent beam shaping of transmission / reflection-waves.

Extreme elastic anisotropy – realization by metamaterials

Yoon Young Kim

Seoul National University
School of Mechanical and Aerospace Engineering
E-mail address: yykim@snu.ac.kr, Tel:02-880-7154

While extreme effective material properties, such as negative or very large density and stiffness, have been explored significantly, studies on the realization of extreme anisotropy has not received much attention. Particularly for elastic media that are characterized by 4^{th}-order tensor field, a wide spectrum of material anisotropy can be envisioned. As illustrative cases of extreme anisotropy, one can make shear modulus equal to or even larger than longitudinal modulus for which unique wave phenomena known as conical refraction or polarization anomaly can take place. Natural materials alone may not achieve the desired anisotropy but specially designed elastic metamaterials made of either single or multiple phases can. In this talk, we discuss a recent progress made towards the design of extreme anisotropic elastic metamaterials. Also, their potential applications will be discussed.

Second order optical nonlinearity in metamaterials

Teruya Ishihara
Department of Physics, Graduate School of Science,
Tohoku University, Sendai, Japan
*corresponding author: t-ishihara@m.tohoku.ac.jp

Abstract-By designing sub-wavelength structure, it is possible to endow a new response that is not obtained in nature. In this paper, various second order optical nonlinearities including second harmonic generation, optical rectification and electro-optic effects are discussed in the same platform for metamaterials.

Even in centrosymmetric materials, second-order optical nonlinearity exists at the surface where permittivity environment changes abruptly. In the oblique incident configuration, surface polarization is excited which generates second harmonic generation (SHG) and photo-rectification. For normal incidence it does not give SHG unless the surface has a structure which breaks the symmetry in the plane. The structure can be endowed by artificially carving the surface by using e-beam lithography for example. This structure can be considered as a new type of metamaterial where second order optical nonlinearity is designed. Earlier we have shown that by breaking the symmetry, it is possible to observe SHG in semiconductor embedded structure [1] and photorectification in metal-based metamaterials [2,3]. Recently sub-wavelength shape dependent SHG was investigated and analyzed in terms of effective susceptibility concept [4-7]. By appropriately design the subwavelength structure, it may be possible to produce extremely nonlinear metamaterial beyond the empirical Miller's rule [8], which sets the ceiling limit for nonlinear response.

In this paper, we will discuss examples of the second order optical nonlinearities in the same platform for artificially designed metamaterial films.

Electronically Tunable Materials and Metasurfaces: Exploring Quantum Materials and Device Designs for Dynamic Wavefront Control

Harry A. Atwater

Thomas J. Watson Laboratory of Applied Physics and Kavli Nanoscience Institute
California Institute of Technology, Pasadena, California 91125, USA
E-mail address: haa@caltech.edu

Abstract- Tuning the complex dielectric function of low-dimensional materials and metasurfaces enables scientific exploration of quantum materials such graphene, phosphorene and topological insulators and, as well plasmonic and nanophotonic device applications for dynamic wavefront control including electronic phase and amplitude modulators for the near infrared (conducting oxides) and mid infrared (graphene). We discuss light-matter interactions in emerging quantum materials and report dynamically tunable metasurfaces in the near-infrared and mid-infrared with $>\pi$ phase modulation and 'perfect' absorption approaching 100%.

We have explored the photonic properties of thin electrostatically gated phosphorene and $(Bi_{1-x}Sb_x)_2Te_3$ topological insulators using mid-infrared spectroscopy measurements. We combine these optical experiments with transport measurements and ARPES to identify the observed spectral modulation as a combination of gate-variable Pauli-blocking of bulk interband optical transitions at higher energies and modulation of intraband transitions associated with both topological surface stated (TSS) and the bulk free carrier density.

In the domain of device applications, we experimentally demonstrate a gate-tunable metasurface that enables dynamic electrical control of the phase and amplitude of plane wave reflection. Tunability arises from field-effect modulation of the complex refractive index of conducting oxide layers incorporated into metasurface antenna elements which are configured in a reflectarray geometry. We measure a phase shift of $>\pi$ and ~ 30% change in the reflectance by applying 2.5 V gate bias. Additionally, we demonstrate modulation at frequencies exceeding 10 MHz, and electrical switching of +/-1 order diffracted beams, a basic requirement for electrically tunable beam-steering phased array metasurfaces.

We further demonstrate electronically tunable mid-infrared transmission that utilizes resonant absorption in graphene plasmonic ribbons to modulate the extraordinary optical transmission effect in subwavelength metallic slit arrays. Resonant absorption in plasmonic modes of nanoscale monolayer graphene ribbons situated inside subwavelength metallic slits can efficiently block the coupling channel for extraordinary optical transmission, leading to a strong suppression of transmission. Full wave simulations predict a transmission modulation of 95.7% via this mechanism. Measurements reveal a transmission modulation of 96%, yielding an experimental realization of 'perfect' absorption in monolayer graphene.

Abstract-In this talk, we report experiments aiming at exploring the physics of surface plasmons in the single plasmon regime. In other words, we revisit quantum optics using surface plasmons: tests of the wave-particle duality of surface plasmons, observation of entanglement between a photon and a plasmon and two photon interference on a lossy beam splitter. In the latter case, we observe both a correlation dip and a correlation peak at the outputs of a beamsplitter.

Chiral plasmonic nanostructures

P. Fischer[1,2,*]

[1]Max Planck Institute for Intelligent Systems, Heisenbergstr. 3, Stuttgart, Germany

[2]Institute for Physical Chemistry, University of Stuttgart, Pfaffenwaldring 55, Stuttgart, Germany

Abstract-How can one see gold nanoparticles in strongly absorbing blood? I will describe that this is possible with plasmonic nanohelices. Moreover, I will show that record local plasmon resonance (LSPR) sensitivities can be achieved when plasmonics and chirality are combined. We use a general fabrication scheme to rapidly grow chiral nanostructures from plasmonic and magnetic materials, in a way that lets us tailor their dielectric function. We thereby realize metafluids whose optical properties can be tuned and dynamically switched.

Ultrafast nanoscopy: imaging structure, function, and dynamics of matter on its natural length and times scales

Markus B. Raschke

Department of Physics, Department of Chemistry, and JILA, University of Colorado, Boulder, USA
*Email address: markus.raschke@colorado.edu

Abstract: I will present the advances in multimodal linear, nonlinear, and spatio-temporal nano-imaging for the study of fundamental optical and plasmonic phenomena, coupled single molecule or quantum dynamics, with unprecedented nanometer spatial and femtosecond resolution, sensitivity and precision [1-6]. To gain the desired *simultaneous nanometer spatial resolution with spectroscopic specificity and femtosecond temporal resolution* we combine plasmonic and optical antenna concepts with ultrafast and shaped laser pulses to precisely control optical excitation on femtosecond time and nanometer length scales from the visible to THz spectral range. In the implementation with scattering scanning near-field microscopy (*s*-SNOM) or other tip-enhanced microscopy modalities with nonlinear, ultrafast, and IR and Raman vibrational spectroscopies, the resulting enhanced and qualitatively new forms of light-matter interaction enable deep-subwavelength spatially resolved imaging of heterogeneities and nano-confinement as they define the properties of most functional materials. I will present several new concepts extending tip-enhanced spectroscopy into the nonlinear and ultrafast regime for nano-scale imaging and spectroscopy of surface molecules and nano-solids. Examples include the adiabatic nano-focusing for nm-resolved imaging of the few-fs plasmon coherence [1] (Fig. 1), ultrafast and nonlinear probing of structure and dynamics in quantum materials [2-4], vibrational nano-imaging of molecular structure, coupling, and dynamics down to the single molecule level [5,6] (Fig. 2), and the transition from classical to quantum plasmonic emitter coupling and femtosecond control for electron wavepackets for ultrafast electron imaging and STM.

Pseudo-spins and their consequences in classical waves

C.T. Chan[1*]
[1]Hong Kong University of Science and Technology, Hong Kong, China
[2]Author Affiliation, Country
[*]corresponding author: phchan@ust.hk

Abstract- Classical wave systems such as photonic crystals and metamaterials can exhibit pseudospin physics. The pseudospin in such systems gives rise to unique transport properties such as super-Klein tunneling. In addition, the conventional Anderson localization picture needs to be revised for waves propagating in 1D disordered systems carrying pseudospins. The localization length in such systems reaches a minimum value at a critical random strength and any additional disorder beyond this critical strength only makes the waves less localized.

Many of the novel properties of graphene can be described by a "massless Dirac equation" with a pseudospin of ½. The term "pseudospin" here refers to the two degrees of freedom given by the two atomic sites in a unit cell of graphene's honeycomb lattice, not to the intrinsic spin of electron,.

The natural question to ask is then whether we can construct systems with a higher pseudospin. Previous work in ultracold atom systems suggested that this is possible in some artificial lattices, and such systems can support striking transport properties. However, ultracold atom systems usually demand extremely low temperature and hence technically difficult to realize in experiments. We find that certain classical wave systems with special dispersions near the zone center correspond to a pseudospin-1 system, which offers the opportunity to study the pseudospin physics in classical wave systems with experimentally realizable materials and in room temperature. Here, the pseudospin of 1 does not refer to the intrinsic spin of photons, but the three degrees of freedom of the spatial wavefunction of photon near the Dirac-like point of the photonic crystal. Interesting properties of such photonic pseudospin-1 system includes "super Klein tunneling" and "super-collimation". While both "Klein tunneling" and "collimation" are known effects for graphene (and pseudospin of ½ in general), these effects become more robust and pronounced when the pseudospin becomes 1.

In addition, the conventional Anderson localization picture needs to be revised for waves propagating in 1D disordered systems carrying pseudospins. In conventional disordered system, localization length decreases with disorder. The localization length in psuedospin systems reaches a minimum value at a critical random strength and any additional disorder beyond this critical strength only makes the waves less localized. More importantly, for pseudospin-1 systems, there exists a sharp transition at the critical random strength which separates the localization behavior into two distinct regimes with different localization characteristics. These novel phenomena have never been seen before in ordinary disordered systems. The localization characteristics are also depends strongly on the details of the disorder potential, which is again not seen in ordinary materials.

We will also compare the localization characteristics of systems carrying pseudospins 1and pseudospins of ½.

Making Structured Metal Transparent for Ultra-Broadband Electromagnetic and Acoustic Waves

Mu Wang
National Laboratory of Solid State Microstructures and Department of Physics,
Nanjing University, Nanjing 210093, China
*Email: muwang@nju.edu.cn

Abstract- In this talk, I will present our recent studies on making structured metals transparency for ultrabroadband electromagnetic waves and acoustic waves via surface excitations. First, I will show the effect that periodic, quasiperiodic, and disordered metallic gratings can become transparent and completely antireflective for extremely broadband electromagnetic waves at oblique incidence. Further, we develop an approach to design oblique metal gratings that are transparent for broadband electromagnetic waves (including optical waves and terahertz ones) with normal incidence. Thirdly, we demonstrate that the principles of broadband transparency for structured metals can be extended from one-dimensional metallic gratings to two-dimensional scenario. Finally we point out that similar phenomena can be observed in sonic artificially metallic structures, demonstrating transparency for broadband acoustic waves. With this series of studies we try to provide guidelines to develop novel broadband metamaterials, which are promising for applications of transparent conducting panels, antireflective conducting solar cells, broadband acoustic imaging and sensing, etc.

Hybrid Optically Active Nanomaterials

Penetration Effect in Uniaxial Anisotropic Metamaterials

K. Vytovtov[1*] and S. Zouhdi[2]

[2]Polytech Paris-Sud, Paris-Sud University, France
[*]corresponding author: vytovtov_konstan@mail.ru

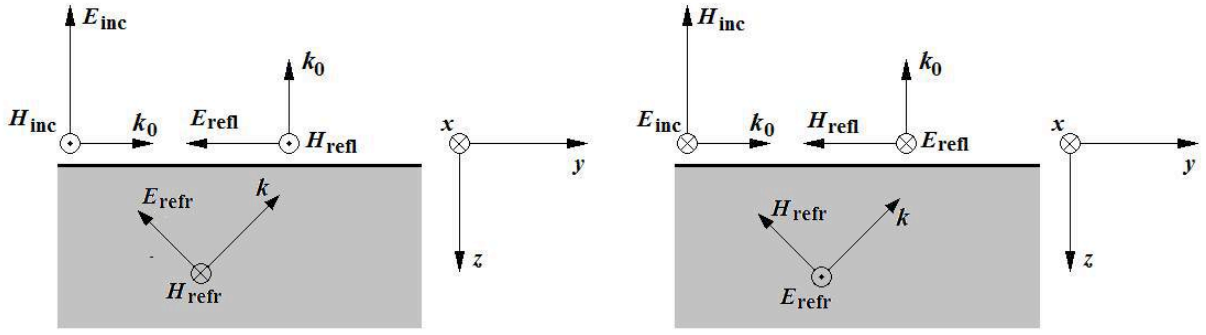
Abstract - We consider a plane harmonic wave propagating parallel to an interface between a standard isotropic medium and an anisotropic metamaterial. It is proved analytically that part of the wave power propagates into the anisotropic metamaterial. Reflection and transmission coefficients are obtained.

An interesting behavior of a plane wave propagating parallel to an interface between isotropic and anisotropic media has been considered in [1]. It has been shown analytically that a bulk wave is excited within the anisotropic medium at grazing incidence. This phenomenon has been defined as the "penetration effect". The hypothesis about reflected wave propagation perpendicularly to an interface was also presented in [2] but this problem has not been studied in detail.

Here we study a semi-infinite uniaxial anisotropic metamaterial described by the permittivity dyadic

$$\overleftrightarrow{\varepsilon} = \begin{vmatrix} \varepsilon_{11} & 0 & 0 \\ 0 & \varepsilon_{11} & 0 \\ 0 & 0 & \varepsilon_{33} \end{vmatrix} \qquad (1)$$

and a scalar permeability μ. Here ε_{11}, ε_{33}, μ have negative values. It is assumed that the anisotropy axis is in the plance of incidence. It is also assumed that a plane harmonic wave propagates parallel to the interface between a standard isotropic medium, free space, and the anisotropic metamaterial. The geometry of the problem is shown in Fig.1.



a) b)

Fig.1. Geometry of the problem: a) for TE-wave, b) for TM-wave

After algebraic transformation we obtain the permittivity dyadic (1) in the *xyz*-system

$$\overleftrightarrow{\varepsilon} = \begin{vmatrix} \varepsilon_{xx} & 0 & 0 \\ 0 & \varepsilon_{yy} & \varepsilon_{yz} \\ 0 & \varepsilon_{zy} & \varepsilon_{zz} \end{vmatrix} \quad (2)$$

which can be considered as a two-dimensional metamaterial. In the general case of a lossy medium, the elements of (2) are complex.

We show that the plane wave propagating parallel to the interface can excite a bulk wave propagating under an arbitrary angle within the anisotropic metamaterial. We found that the normal components of the wave vector and the Poyting vector are non-zero.

To describe the reflected wave behavior one should take into account the fact that the tangential components of the wavenumbers of incident, reflected, and refracted waves must be equal to each other and also equal to wavenumber in the isotropic medium. The reflected wave can propagate along the interface or perpendicular to it. Moreover the magnetic filed of the refracted wave has a tangential component for an ordinary wave and electric field has a tangential component for an extraordinary wave. Therefore these components must be also present in the reflected wave since they were not present in the incident wave.

Based on these considerations, we assume that a reflected linearly polarized wave should propagate perpendicular to the interface between the isotropic and the anisotropic medium. The reflection and transmission coefficients are obtained for this case.

For an ordinary wave the reflection coefficient is equal to zero (R=0) and the transmission coefficient is equal to one (T=0). Thus the reflected wave is absent for this type of waves. The surface current at the interface is also nil.

For an extraordinary wave the reflection and transmission coefficients are:

$$R = \frac{\omega\left(\varepsilon_{yy}\varepsilon_{zz} - \varepsilon_{yz}\varepsilon_{zy}\right)}{\omega\left(\varepsilon_{yy}\varepsilon_{zz} - \varepsilon_{yz}\varepsilon_{zy}\right) - k_z\varepsilon_{zz} - k_y\varepsilon_{yz}} \qquad T = \frac{k_z\varepsilon_{zz} + k_y\varepsilon_{yz}}{\omega\left(\varepsilon_{yy}\varepsilon_{zz} - \varepsilon_{yz}\varepsilon_{zy}\right) - k_z\varepsilon_{zz} - k_y\varepsilon_{yz}}$$

More interestingly, in this case the reflection and transmission coefficients do not depend on the frequency if there is no frequency dispersion in the material parameters. Additionally a surface polarization change occures at the interface. These changes are a result of molecular polarization caused by the electromagnetic field.

Abstract Wearing Pt on Cu nanocubes to form the bimetallic nanocatalysts is demonstrated. By heterogeneous coating of Pt, the ultimate rhombic dodecahedral core-frame nanostructures were obtained. Turning the amount of Pt atoms, the frames evolved at the 100 corners to form the vertex-stretching ones. The corresponding nanoframes could be obtained after removing the Cu cores. The nanoframes showed superior performances in the ORR and the photoreduction of 4-nitrophenol , rendering them the cost-efficient alternatives for noble metal catalysts.

The noble metal Pt was successfully coated on the surfaces of the Cu nanocubes by virtue of efficient thermal reduction. The reduced Pt atoms deposited on the Cu surfaces to form Cu-CuPt core-frame nanocrystals The CuPt alloy frames were generated due to co-reduction of Pt(II) and residual Cu(I) ions in the supernatant of Cu nanocube solution and the diffusion of Cu atoms at the core-shell interfaces. The alloying induced the {100} face evolution on the Cu nanocubes and resulted in the rhombic dodecahedral (RD) shape to minimize the crystal energy. Raising the added amount of Pt precursor, the vertices at the {100} corners of the RD core-frame nanocrystals grew out as stretching tips in that sufficient reduced Pt atoms kept growing into the vertices. After removing the Cu cores from the core-frame nanocrystals, the CuPt alloy nanoframes in regular and vertex-stretching (V-S) RD shape were obtained and verified in the Pt/Cu ratios of 26/74 for the regular RD NFs, and 41/59 for the V-S ones (Figure 1).

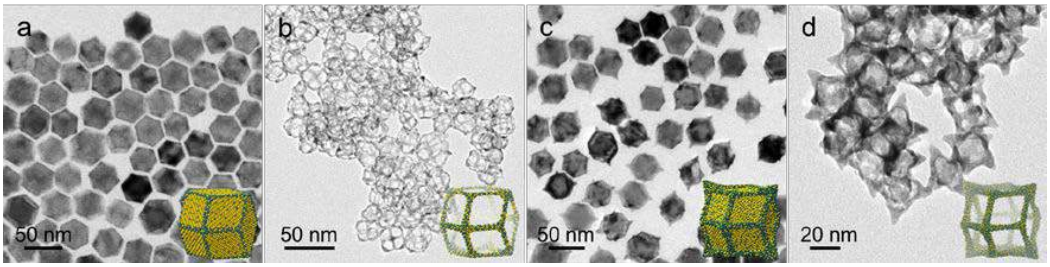

Figure 1. (a) Regular core-frame nanocrystals, (b) regular nanoframes, (c) vertex-stretching core-frame nanocrystals, and (d) vertex-stretching nanoframes in rhombic dodecahedral shapes.

More importantly, abundant surface defects such as terraces and adatoms on both the NFs render them highly active catalysts. In ORR, the V-S NFs showed very superior ECSA activity, 1.3 and 3 times high than those of the regular NFs and the commercial Pt/C. However, it decayed after ADT for 1,200 cycles due to the

surface reconstruction on the defected stretching tips. The Pt mass activity of V-S NFs presented a lower value than that of the regular NFs which indicated the higher content of Pt in the V-S structures. In reduction reactions of 4-nitrophenol, both NFs displayed excellent activities than that of the commercial Pt NPs in dark. Furthermore, their activities were improved at least 1.3 times high under irradiation of visible light, attributed to the effect of SPR enhancement contributed by the nanophase Cu crystal domains in the Cu-rich skeletons.

* ewjfan@ntu.edu.sg

Here, we'll show our simulation results on the electronic structure and optical gain of the $InAs_{1-x}Bi_x/InP$ pyramidal quantum dots (QDs). We have taken the valence band anticrossing (VBAC) model into our calculation following our previous work of $GaN_xBi_yAs_{1-x-y}/GaAs$ QDs[1]. The Hamiltonian of the QD is given by

$$H = \begin{pmatrix} H_{8\times8} & H_{8\times6} \\ H_{6\times8} & H_{6\times6} \end{pmatrix} \qquad (1)$$

Where $H_{8\times8}$ is the Kane Hamiltonian, $H_{6\times6}$ is the Bi-state related Hamiltonian and the $H_{8\times6}$ is the interaction between host material and Bi-states. The optical gain is obtained by

$$G(E) = \frac{\pi e^2 \mathrm{h}}{m_0^2 \varepsilon_0 n_r c E} \sum_{n_c, n_v} \frac{1}{V} \left| M^{cv} \right|^2 \left(f_c + f_v - 1 \right) B_{cv}(E - E_{cv}) \qquad (2)$$

All details of the theoretical model can be found in our previous paper [1]. The parameters in model are taken from Refs [2],[3].

FIG.1 shows the variation of conduction band (CB), valence band (VB) and band gap energy with the concentration of Bi and the height of QD. It is clearly shows that the band gap can be tuned less than 400 meV which means that the wavelength of photon will exceed 3μm when the concentration of Bi is more than 7% for the QD with height of 20 in unit of lattice constant. The VB increases obviously when more Bi atoms are incorporated due to the VBAC effect. The CB decreases slowly as compared with VB, resulting from the combination of strain effect and virtual crystal effect. Although the compressive strain effect introduced by Bi drives the CB to go up, the virtual crystal effect drives the CB to go down more quickly. Quantum size effect can be seen as the band gap decreases with the increasing the height of the QDs.

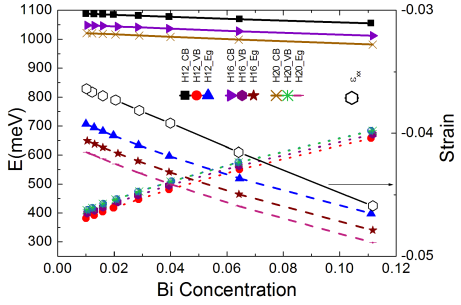

FIG.1. The variety of CB, VB and Eg with the Bi concentration and the height of QD.

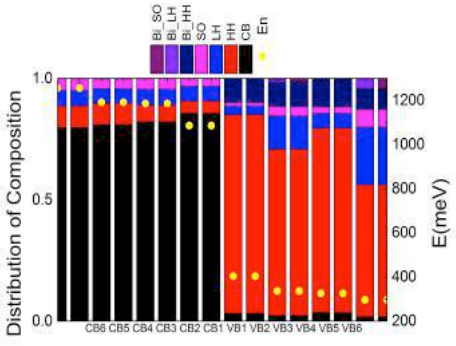

FIG.2. Distribution of compositions for the first six CBs, VBs of H12 QD with Bi of 1.6%.

FIG.2 shows the composition of the first six CBs and VBs. The majority of VB states are the HH states and some Bi_HH states also are mixed.

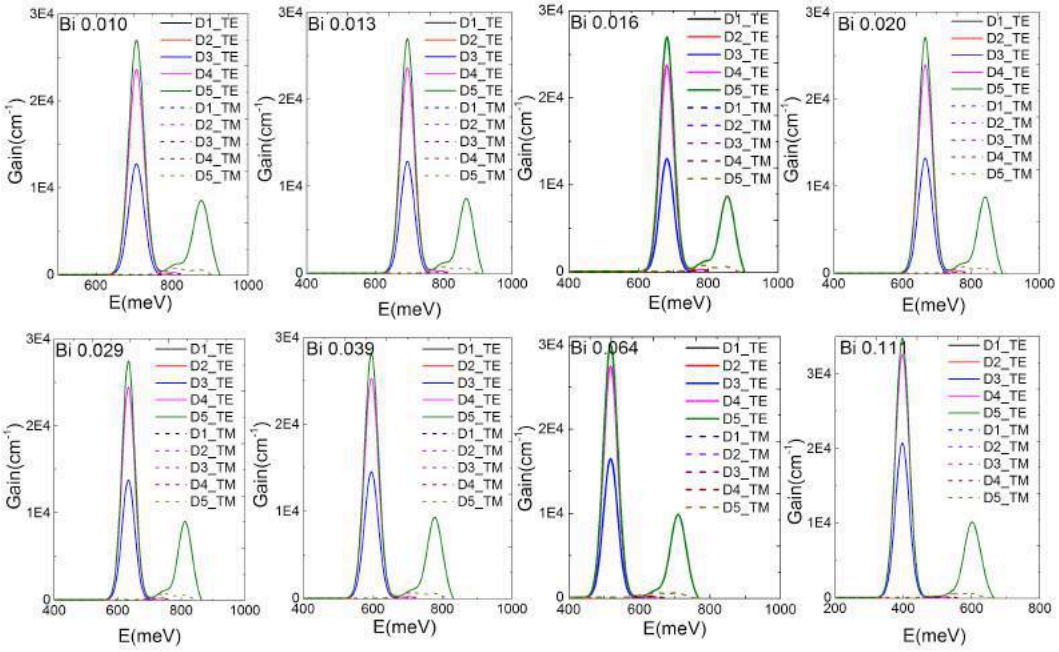

FIG.3. The optical gain of the H12 QDs for different carrier densities and different Bi composition. Here the D2_TE means that the carrier concentration is 2 X10^{18}cm^{-3} for TE mode.

FIG.3 shows the optical gain of the QD for TE and TM modes with different carrier densities in the unit of $10^{18}\mathrm{cm}^{-3}$ and different Bi concentration. The location of the primary peak is red-shift as the concentration of Bi increases. The photon wavelength will exceed 2μm when the concentration of Bi is larger than 3% for the H12 QD. For the sufficiently high carrier density, we obtain a secondary peak in addition to the primary peak.

In summary, the Bi indeed decreases the band gap of the $InAs_{1-x}Bi_x$/InP pyramidal QDs and thus may achieve the 2 and 3μm laser emission. This is important for 2 and 3μm laser devices. The wavelength can be tuned by controlling the concentration of Bi.

Chirality, the property of an object to lack mirror symmetry and thus be able to exist in two non-superimposable mirror image forms, is a ubiquitous property in nature. Indeed, the building blocks of life, amino acids and sugars are chiral, and this sense of handedness propagates in to the complex structures of life. In this talk I will discuss how near fields with chiral asymmetries, generated by light scattering from chiral nanostructures, can uniquely characterise higher order biological structure which is invisible to conventional spectroscopy. I will demonstrate how the interaction of chiral nanostructures and biomaterials can be understood using concepts from physical chemistry and atomic and molecular physics; orbital hybridisation and quantum interference phenomenon such as electromagnetic induced transparency (EIT).

Nanoplasmonics for ultra-high resolution colours prints and DNA-programmable nanoplasmonics

Abstract- Metal nanostructures can be designed to exhibit specific plasmonic resonances in their optical reflectance spectra through the control of nanostructure material and geometry. This unique spectral control and tunability is attractive for ultra-high resolution colour printing, or for producing security elements for anti-counterfeiting. Their enhanced sensitivity can be combined with the programmability of DNA to develop active plasmonic systems. Here, economical ways of making high resolution colour prints and integrating lithographically-defined nanostructures on solid substrates with DNA will be discussed.

Plasmonic nanostructures can support highly efficient, resonances within gaps or cavities [1-3]. The strong dependence of this phenomenon on geometry and local environment has been exploited for nanoscale manipulation of electromagnetic fields, allowing for extreme local field confinement and enhancement. By lithographically defining nanostructures, one can tune their characteristic resonances to produce wide colour tunability in the visible spectrum. Previously, we demonstrated an approach to ultra-high resolution colour printing in arrays of dielectric pillars capped with a thin layer of metal [4-6]. Multiple layers of optical information can also be encoded within the same area by employing different shapes and/or orientations of nanostructures illuminated by orthogonally polarised light to elicit Surface-Plasmon-induced changes in the colour spectra [6]. This unique spectral control and tunability is particularly attractive for applications such as ultra-high resolution colour printing or for producing unique security elements in anti-counterfeiting technologies.

The enhanced sensitivity afforded by plasmonic nanostructures can further be combined with the programmability of DNA to develop new-generation DNA-based active plasmonic systems. Practical means for active control of these nanoplasmonic systems will open up vast possibilities for downstream applications, such as plasmonic-electronics and solid-state chemical and biological sensing, but has remained elusive. While DNA has previously been shown to enable control over plasmonic resonances in nanoparticle-based systems, the lack of means for precise spatial positioning of these nanoparticles presents challenges for systems integration and readout. The use of programmable DNA to actively control the nanogap between nanoparticles and lithographically defined nanostructures is a strategy that can potentially provide a sensitive plasmonic platform for biomolecule detection as well as a means of dynamically controlling plasmonic colours. Here, I will discuss results including economical ways of making high resolution colour prints, plasmonic pixels that can encode dual images, and combining lithographically-defined nanostructures on solid substrates with DNA programmability towards DNA-nanoplasmonic hybrid systems.

Abstract

Controlling and understanding the assembly of colloidal nanoparticles remain a challenging issue for optimizing magnetic-plasmonic devices for various applications including sensors, displays, bio-imaging and therapy. A magnetic field is successfully utilized to induce the fabrication of multidimensional structures composed of magnetite coated silver core/shell ($Ag@Fe_3O_4$) particles, which exhibit intriguing optical properties. Also we report a proof-of-concept experimental results using biocompatible FeSe QDs and femtosecond infrared laser, leading to remarkable excitation-dependent photoluminescence in two-photon luminescence (2PL). An effective and highly controlled dip-coating technique for fabrication of one-dimensional (1D) structure of magnetoplasmonic particles on large-area surface is proposed by combining electrostatic and magnetic dipole interactions. This technique is demonstrated to be a very powerful approach to modulate optical properties of magnetoplasmonic particles. Moreover, a magnetic-field assisted coating technique for fabrication of two-dimensional (2D) amorphous photonic crystal (APC) film of the magnetoplasmonic particles on a filter membrane is proposed. The magnetoplasmonic 2D APC exhibits strong dual reflected colors caused by structural scattering and plasmon resonance scattering.

Plasmonic Liquid Marbles for In-situ Monitoring of Picoliter-scale Reactions

Xing Yi Ling

Division of Chemistry and Biological Chemistry, School of Physical and Mathematical Sciences, Nanyang Technological University, 21 Nanyang Link, Singapore 637371.

*corresponding author: xyling@ntu.edu.sg

Abstract- Current microscale tracking of chemical kinetics is limited to destructive ex-situ methods, which are also unable to provide real-time reaction monitoring at a molecular level. In this talk, I will discuss our group's development using highly flexible plasmonic liquid marbles as pico-liter analytical sensors. By using the ultrasensitive surface-enhanced Raman scattering (SERS) capability imparted by the plasmonic shell of the Ag nanoparticles of the liquid marbles, the liquid marbles are capable of quantitative examination of multiple analyte(s), even at trace level. Simultaneous two-phase analyte detection at the interfacial of aqueous and organic solvents can also be achieved using our marble. Recently, we extend the usage of our flexible liquid marbles as picoreactor, which is also capable of providing in-situ identification of reaction dynamics in their native reaction environment and at molecular level. One unique property of the liquid marbles is that they can be submerged at liquid–liquid interface. We exploit the interfacial property to monitor the interfacial reaction of dimethyl yellow (p-dimethylaminoazobenzene (DY)) across aqueous and organic phases. Using this soft plasmonic platform, we have successfully resolved the presence of two isomeric products with very similar physical properties, which would otherwise be indiscernible by other analytical methods. Ultimately, our ability to precisely decipher molecular-level reaction dynamics sketches new horizons to develop more efficient processes in synthetic chemistry and nanotechnology.

Ultrafast optical responses of photoexcited electrons and excitons in hybrid nanomaterials

G. P. Wiederrecht[1]
[1]Center for Nanoscale Materials, Argonne National Laboratory, Argonne, IL 60439, USA
[*]corresponding author: wiederrecht@anl.gov

Abstract- The ultrafast optical responses of two types of hybrid nanomaterials are described. The first is the ultrafast hot electron response of plasmonic gap mode metamaterial nanostructures, in which two plasmonic nanostructures are separated by a thin layer of semiconducting or insulating material, with impact on understanding and using energetic electrons. The second describes ultrafast exciton generation and migration in porphyrin-based self-assembled biomimetic nanomaterials, with ramifications for optical light harvesting in self-healing structures.

In this talk I will describe the ultrafast optical responses of two types of hybrid nanomaterials. For the first topic, optically excited plasmonic nanostructures can produce energetic, hot electrons before thermalization that are of great interest for driving new photophysical or photochemical processes. However, new approaches are needed to generate hot electrons with higher efficiency and to easily detect them optically. It is also important to understand their decay processes in order to better harness extremely energetic hot electrons for applications before losing energy to thermalization. I describe our advances in this area using gap-mode plasmonic metamaterials that incorporate atomic layer deposition of semiconductor or insulating materials to precisely control the gap distance in the hybrid structures.[1] The gap modes create unusually high electromagnetic fields that are efficient at creating energetic electrons. New approaches to spectroscopically recognize the presence of hot electrons as well as to model the kinetics of hot electron decay are described.

Second, I describe the study of porphyrin-based biomimetic hybrid nanostructures that self assemble into structures capable of supporting exciton migration and excitonic light harvesting behavior. The ultrafast transient optical absorption and emission responses are monitored in order to characterize exciton migration. The importance of the environmental structural response in realizing efficient and long-range exciton transport is described. Sensitization of the porphyrin-based system with excitonic nanostructures to utilize a broader portion of the solar spectrum is also found to significantly enhance the yield of mobile excitons. The ability of these structures to operate as light harvesters with self-healing properties is evaluated.

Abstract-Refractory titanium nitride (TiN) is an emerging alternative plasmonic material with resonances in the visible and near-infrared. Its exceptional stability in corrosive chemical environment and its durability at high temperature enable the use of TiN for a wide range of solar energy conversion applications. We will present our recent results on the use of plasmonic TiN for photocatalysis, solar/thermophotovoltaics, and our progress on the large-scale fabrication of refractory plasmonic nanostructures.

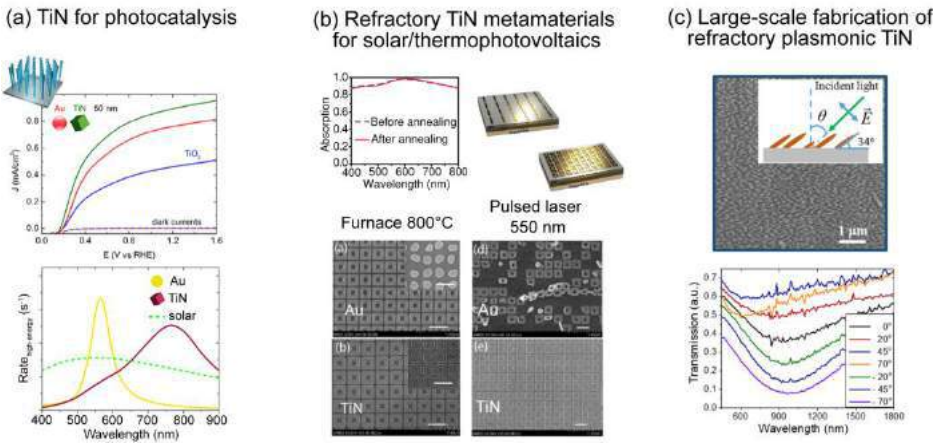
The use of plasmonic nanostructures in solar energy conversion has recently attracted great attention.[1,2] Recent demonstrations have been mainly limited to nanostructures made of gold and silver. While they show excellent optical properties for plasmonic applications, major issues are related to their high cost, poor chemical (Ag) and thermal stability (Au, Ag). Aluminum is an alternative plasmonic material that provides high optical performance at low cost [3] Nevertheless, its low melting point (around 300-400°C for nanostructures) and its poor chemical stability under alkaline conditions preclude Al from operating under either thermal or chemical harsh conditions.

On the contrary, transition metal nitrides such as titanium nitride (TiN) and zirconium nitride (ZrN) exhibit optical properties similar to Au and can be utilized as plasmonic materials in the visible and near-infrared regions. [4] Combining refractory material properties with plasmonic properties, transition metal nitrides offer a unique solution to material-related problems in applications where high temperature durability and/or chemical stability are needed. We will present the use of colloidal plasmonic nanoparticles of TiN in solar water splitting, lithographically-patterned TiN metamaterials for solar/thermophotovoltaics (STPV), and a newly-developed approach for the large-area fabrication of plasmonic TiN nanostructures.

In particular, we will present our recent results on superior photocurrent generation for solar water splitting by using TiN nanoparticles (NPs) on TiO_2 nanowires (NWs) as compared to using gold (Figure 1a). Through a combined experimental and theoretical approach, we will show that the superior performance of TiN is due to the broadband hot electron generation and improved electrical junction at the metal-semiconductor interface.[5] The design and implementation of refractory TiN metamaterials for STPV applications will be also discussed. This technology requires extremely high temperatures and suffers from material thermal stability. Refractory TiN metamaterials can be a solution to this limitation. Recent results on TiN nanostructures for broadband absorption and selective emission for STPV will be discussed.[6] The schematic of our design and a comparison on the thermal stability of TiN over Au are shown in Figure 1b. Finally, our recent results on large-scale fabrication of refractory plasmonic nanostructures will be discussed.[7] Figure 1c shows the morphology plasmonic resonances of tilted TiN NWs obtained by using a TiO_2 NWs array precursor deposited through

glancing angle deposition. We will also show that plasmonic TiN can be obtained after nitridation of TiO_2 nanoparticles, lithographically-patterned TiO_2 and more complex TiO_2 nanostructures highlighting the potential of this approach, not only for solar energy applications, but also for lasing and flat nanophotonics.

Our results show that plasmonic TiN enable enhanced performance for solar energy conversion holding promise for its implementation in stable and cost-effective devices.



Figures 1: (a) Increased plasmon-enhanced water splitting in TiN/TiO_2 over Au/TiO_2 (upper plot) due to a broadband hot electron generation of plasmonic TiN nanoparticles (NPs) (lower plot).(25) (c) A plasmonic TiN metamaterial for solar/thermophotovoltaics. TiN survives at both high temperatures and more intense light illumination than Au. (c) Large-scale fabrication of novel plasmonic TiN nanostructures from TiO_2 nitridation.

Abstract- Metallic nanoparticles, dielectric nanoparticles and metal-dielectric hybrid dimers have been investigated for fluorescence enhancement. Results show that the metallic nanoparticles have better fluorescence enhancement in high-index media (e.g. water), whereas the dielectric nanoparticles have higher fluorescence enhancement in low-index media (e.g. air). The hybrid dimers show 40% higher electric field enhancement comparing with dielectric dimers and 30% lower loss comparing with metallic dimers, yielding a fluorescence enhancement 30% higher than that of the pure dielectric dimers.

Fluorescence is a wide spread optical technique for the detection of molecular analytes in chemistry, biology and medicine[1]. The optical signal from a single fluorophore is generally weak, limiting the sensitivity. Metallic nanoparticles have been proved to be a versatile platform in fluorescence enhancement due to surface plasmon resonance. Up to date, over three-order fluorescence enhancement by the metallic nanoparticles has been achieved. However, the metallic nanoparticles suffer from parasitic losses, decreasing the quantum yields and resulting in the quenching of the fluorophores when they close to the metal surface. As an alternative, high permittivity dielectric nanoparticles are recently proposed to enhance the fluorescence. They can also generate the field enhancement near the nanoparticles although the physical mechanism is different. The lossless nature of dielectric material does not compromise the fluorescence quantum yield. The question is which are better, metallic or deictic nanoparticles? A dimer nanoantenna has demonstrated unprecedented capabilities to confine light into deep-subwavelength regime[2], which is promising for a variety of emerging applications. To simultaneously satisfy the growing demand in both high electric field enhancement and low loss features, a natural way is to construct a metal-dielectric hybrid dimer that automatically integrates the advantages of both platforms.

We will first present a comprehensive evaluation on the capabilities and applicability of the mettalic and dielectric nanoparticles in the fluorescence enhancement, including the different physical mechanisms of the fluorescence enhancement by the two material platforms, the investigation of the nanoparticle enhancement for different fluorophores in both air and water media, and a fair comparison between the respective optimized situations where the resonance wavelengths of both dielectric and plasmonic nanoparticles are shifted to the same. The results show that the metallic nanoparticles have better fluorescence enhancement in the higher index medium (e.g. water), whereas the dielectric nanoparticles have higher fluorescence enhancement in the lower

index medium (e.g. air)[3].

Then we integrate the metallic and dielectric nanoparticles to enhance the fluorescence with hybrid dimers. When the hybrid dimer under plane wave excitation, we discovered that the coupling between metal plasmonic mode and dielectric electric-dipole-mode creates a hybridized mode due to the direct electric-electric dipole-dipole interaction between the nanoparticles. Between the plasmonic mode and dielectric magnetic-dipole-mode, there is no direct but indirect coupling, which happens between the primary resonances excited by the incident light and the secondary resonances induced by the primary resonances. When the hybrid dimer is radiated by a quantum emitter, we found that the electric/magnetic dipole selectively excites the electric/magnetic (magnetic/electric) resonances of the dimer when the emitter orients parallel (perpendicular) to the dimer axis.

By placing fluorescence dyes to the low loss dielectric side of the hybrid dimer, 40% higher electric field enhancement comparing the dielectric dimer and 30% lower loss comparing with the metallic dimer can be simultaneously achieved, yielding a fluorescence enhancement 30% higher than that of the pure dielectric dimer. On top of that, the hybrid dimer directs 20% more radiation towards the dielectric side due to its unique asymmetrical structure (e.g. permittivity and size contrast between the constituent nanoparticles), thereby significantly enhancing the antenna directivity.

Our studies show that both metal and dielectric have their own advantages, and the hybrid dimer possesses the potential to be an optical antenna simultaneously achieving high field enhancement, low loss and good directivity features. The fundamental coupling mechanism between metallic and dielectric nanoparticles can also be extended to other structures, paving the way in the design of complex hybrid systems.

Blinking surface-enhanced Raman scattering and fluorescence from polyamino acid or dye molecules on the same silver nanoaggregate

Y. Kitahama
[1]Department of Chemistry, Kwansei Gakuin University, Japan
[*]corresponding author: kitahama@kwansei.ac.jp

Abstract Blinking of surface-enhanced Raman scattering (SERS) and surface-enhanced fluorescence (SEF) from the same silver nanoaggregate with poly-L-lysine or thiacarbocyanine were simultaneously observed at different wavelengths. Intensities of the SERS were plotted against those of the SEF at the same times. The SERS of poly-L-lysine was emitted while no SEF of silver atomic cluster on the silver surface was observed. This result suggests single molecule detection. We compared the blinking statistics of poly-L-lysine to that of the dye molecules.

SERS and SEF can be applied a sensitive measurement enough to detect a single molecule adsorbed on a noble metal, because enhanced electromagnetic (EM) field is induced at a junction of the metal nanoaggregate by excitation light via localized surface plasmon resonance (LSPR). At single molecule level, blinking is observed. It has disturbed an application of SERS and SEF in terms of a reproducibility of the spectra and a tracking of the emitter. It is thought that the blinking is induced by the molecule goes in and out of the enhanced EM field. However, there is a possibility that the reason of the blinking is fluctuation of the EM field.

We observed blinking SERS and SEF from silver nanoaggregate with poly-L-lysine or thiacarbocyanine. The silver nanoaggregate were dispersed on glass slide by spin coating and then were excited by using a diode-pumped solid-state laser beam (λ = 532 nm). The signal were collected with an objective lens of an inverted microscope and was split into a short and long wavelength area through W-VIEW Gemini (Hamamatsu) in which a dichroic mirror and band-pass filters were inserted. Then, the video was taken by an inverted microscope coupled with a cooled digital CCD camera (ORCA-AG, Hamamatsu).

For poly-L-lysine, intensities of the signal in the short wavelength area were plotted against those in the long wavelength area at the same times as shown in Fig. 1. They express “L”-shaped distribution; namely, the SERS was emitted while no SEF was observed. In the spectrum of poly-L-lysine, the SERS peaks are attributed to poly-L-lysine, while the broad band in the long wavelength area is assigned to fluorescence due to emissive silver atomic cluster, which formed by photo reduction of silver oxide on the nanoaggregate [1]. Thus, when poly-L-lysine goes into the junction of the nanoaggregate, the silver atomic cluster cannot enter the EM field. It is noted that the result suggests single molecular detection.

Also for thiacarbocyanine, the intensities of the signal in the short wavelength area were plotted against those in the long wavelength area at the same times. They express “/”-shaped distribution. Thus, the SERS was emitted while the SEF was observed, because the SERS and SEF in the spectrum originate from the same dye molecule. In the case of the dye molecules formed J-aggregate, the variances of the plotted intensities of SERS against those of SEF are different from those for the dye formed H-aggregate. The result may be due to different adsorption between the dye molecules formed J- and H-aggregate [2], because the intensities of SERS and SEF are influenced by distance from the metal surface; the latter is quenched by an energy transfer to the surface.

In a similar way of the previous our studies [3], statistics of the blinking SERS and SEF were analyzed by a truncated power law. The probability distributions for duration of the bright and dark event against the duration $P_{on/off}(t)$ are fitted by

$$P_{on}(t) = At^{\alpha_{on}} \quad (1)$$

and

$$P_{off}(t) = Bt^{\alpha_{off}} \exp(-t/\tau), \quad (2)$$

where $\alpha_{on/off}$ is the power law exponent for bright/dark events, respectively, and τ is the truncation time. These parameters for the blinking SERS were plotted against those for the blinking SEF from the same nanoaggregates. For the dye formed J-aggregate, the power law exponents, which are influenced by a random walk model of the molecule on the metal surface, for the SERS were derived to be more various values than those for the SEF. On the other hand, the opposite trend was shown for the dye formed H-aggregate. The truncation times for the SERS of poly-L-lysine are longer than those for the SEF, while those for the SERS of thiacarbocyanine molecules are shorter than those for the SEF. In the present case, the truncation time is affected not by a speed of the molecule, but by an energy barrier from the dark state to the bright state of SERS and SEF, which are different in the enhancement process.

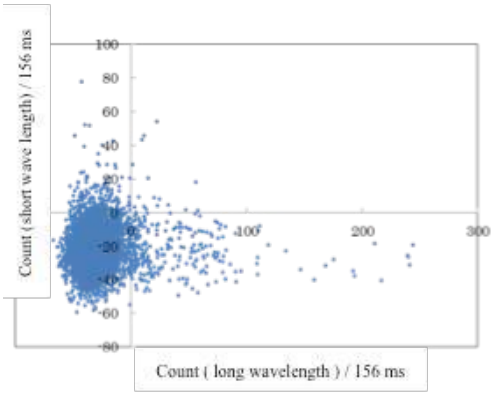

Fig. 1 Signal intensities observed simultaneously in the short and long wavelength area from the same blinking spot.

Abstract-We report a generalized theory for the Foerster-type nonradiative energy transfer (NRET), which includes the derivation of the effective dielectric function due to the donor in different confinement geometries and the derivation of transfer rates distance dependencies due to the acceptor in different confinement geometries, including mixed dimensionality in arrays. These accounts for the transfer rates in all possible combinations of different confinement geometries and assembly architectures. Thus, we obtain a unified picture of NRET in assembled nanostructures arrays.

To obtain the confinement effects of the dielectric function on the Förster-type nonradiative energy transfer (NRET), the effective dielectric function, in the long distance approximation, for the spherical geometry (Nanoparticle (NP) case), cylindrical geometry (Nanowire (NW) case) and planar geometry (Quantum well (QW) case) were obtained (Table 1) by calculating the electric potential for these geometries.

α-direction	NP	NW	QW
X	$\varepsilon_{eff_D} = \frac{\varepsilon_{NP_D} + 2\varepsilon_0}{3}$	$\varepsilon_{eff_D} = \frac{\varepsilon_{NW} + \varepsilon_0}{2}$	$\varepsilon_{eff} = \varepsilon_0$
Y	$\varepsilon_{eff_D} = \frac{\varepsilon_{NP_D} + 2\varepsilon_0}{3}$	$\varepsilon_{eff} = \varepsilon_0$	$\varepsilon_{eff} = \varepsilon_0$
Z	$\varepsilon_{eff_D} = \frac{\varepsilon_{NP_D} + 2\varepsilon_0}{3}$	$\varepsilon_{eff_D} = \frac{\varepsilon_{NW} + \varepsilon_0}{2}$	$\varepsilon_{eff} = \varepsilon_0$

Table 1. Effective Dielectric Function Summary: Effective dielectric constant expressions for the cases of NP, NW and QW in the long distance approximation.

The NRET rate was calculating using equation (1)

$$\gamma_{trans} = \frac{2}{\mathrm{h}} \mathrm{Im}\left[\int dV \left(\frac{\varepsilon_A(\omega)}{4\pi} \right) \mathbf{E}_{in}(\mathbf{r}) \cdot \mathbf{E}_{in}^{*}(\mathbf{r}) \right] \tag{1}$$

where the integration is taken over the acceptor volume, $\varepsilon_A(\omega)$ is the dielectric function of the acceptor, and $\mathbf{E}_{in}(\mathbf{r})$ includes the effective electric field created by an exciton at the donor side. The average NRET rate (at room temperature) is calculated as

$$\gamma_{trans} = \frac{\gamma_{x,trans} + \gamma_{y,trans} + \gamma_{z,trans}}{3} \tag{2}$$

where $\gamma_{\alpha,trans}$ is the transfer rate for the α-exciton $(\alpha = x, y, z)$. We found that the energy transfer rate is

$$\gamma_{trans} \propto \frac{1}{d^n} \tag{3}$$

where *n = 6, 5, 4* and *3* for 3D confinement (QD case), 2D confinement (NW case), 1D confinement (QW case) and 0D confinement (bulk case), respectively.

In conclusion, we present a complete picture and unified understanding of the nonradiative energy transfer for nanostructures of mixed dimensionality and in assembled nanostructures arrays. We obtain the analytical expressions for the energy transfer rate in the long distance approximation. Our findings show that the acceptor quantum confinement dimension sets the generic NRET distance dependence and the donor geometry dimension modifies the effective dielectric function. This generic distance dependence can be remodified by arraying (stacking) the nanostructures. Therefore, the functional distance dependency of the NRET rate is determined by the quantum confinement as well as array stacking dimensionality of the acceptor. The NRET results obtained in this work can be used to design and optimize new solid-state devices for high efficiency light generation and harvesting. The formalism developed here is convenient to estimate the NRET rates in experimental studies involving assembled nanostructure arrays.

Observation of Isotopic Effect on Hydrogen Evolution Process using *In-situ* Electrochemical Surface Enhanced Raman Scattering.

Hiro Minamimoto*, and Kei Murakoshi
Department of Chemistry, Faculty of Science, Hokkaido University, North 10 West 8, Kita-ku, Sapporo, Hokkaido 060-0810, Japan
*corresponding author: minamimoto@sci.hokudai.ac.jp

Abstract- *In-situ* electrochemical surface enhanced Raman scattering measurements were performed for the investigation of the isotopic effect for the hydrogen evolution reactions. Using various mixed ratio of H_2O and D_2O, curious behavior for the heavy water was observed depending on the electrode potential. Through the analysis of the obtained SERS spectra, it was revealed that the highly ordered structures of water molecules formed at the surface of the electrode during hydrogen evolution process.

The strong optical field is generated by the excitation of the localized surface plasmon resonance (LSPR) under the light illumination onto plasmon active nano-metal structures.[1] It is well known that the generated strong optical field leads several interesting phenomena such as chemical reactions or surface-enhanced Raman Scattering (SERS). SERS is a very useful tool for observing a small number of molecules in the progress of the electrochemical reactions with ultra-high sensitivity.[2] Up to date, several groups have been focusing on the water molecule behavior during electrochemical hydrogen evolution reactions using electrochemical SERS measurements. In their great efforts, it was found that SERS intensity depends on the metal species, electrode potentials, and the supporting electrolyte species.[3] Although various studies have been reported, there is a still room for discussion, such as scattering enhancement mechanism.

Hydrogen evolution reactions (HER) is the one of the well examined electrochemical reactions. Especially for the case of the HER in the mixed solution of H_2O and D_2O, the ratio for the generated H_2 and D_2 depends on the over potential, the mixed ratio, or solution temperature. Although, various examinations have been carried out, at the present stage, the specific factor for the control of the isotopic effect for HER is still unclear. In this study, we have investigated the isotopic effect for HER process via *in-situ* electrochemical SERS measurements. Through the use of various mixed ratios and electrode potential, several new and curious phenomena were observed.

The silver and gold wire electrode were used for SERS measurements. Before SERS measurements, two oxidation reduction cycle (ORC) procedures were performed in order to obtain the atomically roughened surface. Electrochemical SERS measurements were conducted with the electrochemical three electrode cell as shown in Fig. 1. The electrolyte solution was 0.1 M Na_2SO_4 aq. which was halide free solutions. All electrochemical Raman spectra from the surface of roughened metal electrodes

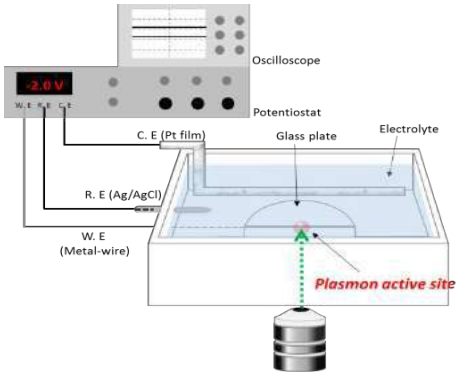

Fig.1 Schematic illustration for *in-situ* electrochemical SERS measurement system.

were obtained by the inverse Raman microscope. The excitation wavelength for acquiring spectra were 514 (2.41 eV) and 785 (1.58 eV) nm.

SERS spectra obtained from the mixed solutions of H_2O and D_2O on Ag electrode surface were shown in Fig. 2. The excitation wavelength was 514 nm. The broad bands at around 500 and 3400 (2400) cm^{-1} are assigned to the libration and OH (OD) stretching mode (σ(OH)). The representative Raman band for SERS of water is the sharp band at 1600 (1400) cm^{-1} corresponding to the OH (OD) bending mode (δ(OH)) which appears in only HER over potential region. It should be mentioned that the scattering intensities for water/ deuterium band becomes relatively weak with the case for Au electrode or λ_{ex} = 785 nm. Apparently, the scattering intensity becomes stronger as the negative potential polarization. This behavior can be explained by the charge transfer effect to induce effective resonance of the scattering. Generally, the scattering intensity of each Raman band reflects the composition of the bulk solutions. However, in the present case, the scattering intensity for σ(OH) ignores the mixed ratio of the bulk solution. From this result, it can be said that the composition of the bulk solution drastically changed at the localized position during the process for HER. In addition to this result, we have observed the various highly ordered structures of deuterium oxide during the HER process. Through the all attempts, we have confirmed that the very unique behavior of the deuterium oxide at the strong optical field during HER process. The present results would be the key for understanding the principle of the isotopic effect on HER.

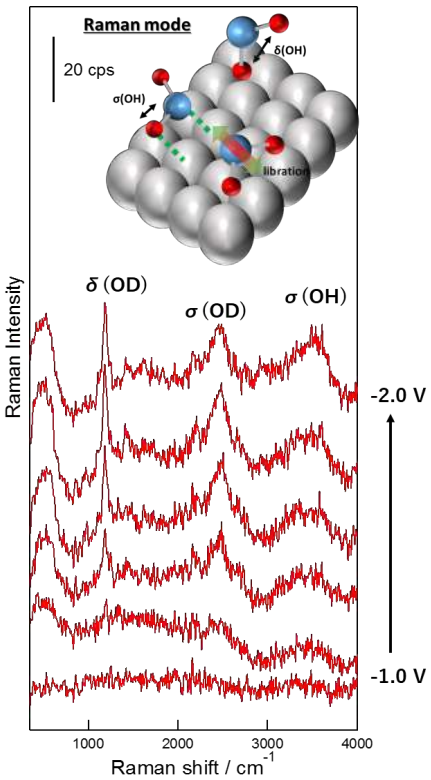

Fig. 2 *In-situ* electrochemical SERS spectra obtained from mixed solution. The ratio of H_2O and D_2O was 1 to 10. The electrode potential was scanned from −1.0 to −2.0 V vs. Ag/AgCl from bottom to top. The electrode and excitation wavelength were Ag and λ_{ex} = 514 nm, respectively.

Exciton-plasmon coupling of single quantum dots and a metal nanowire

Hong Wei*
Institute of Physics, Chinese Academy of Sciences, Beijing 100190, China
*corresponding author: weihong@iphy.ac.cn

Abstract-We studied the coupling of single quantum dots and a metal nanowire. By exciting a single quantum dot, single surface plasmons are generated in the nanowire with the quantum efficiency dependent on the distance between the quantum dot and the nanowire. The single quantum dots can also be excited by the propagating surface plasmons in the nanowire. We demonstrate the selective excitation of two quantum dots within diffraction-limited area by modulating the electric field using the interference of surface plasmons.

Benefiting from the subwavelength confinement feature of surface plasmons (SPs), plasmonic waveguides can perform the function of optical fibers at the deep subwavelength scale and construct plasmonic devices for nanophotonic circuitry. Metal nanowires (NWs) can support multiple SP modes, which are the physical origins of various phenomena for the propagating SPs in the NWs. The electric field confinement and propagation of the SPs also make metal NWs attractive for investigating light–matter interactions in NW-emitter coupled systems. The coupling of single quantum emitters and a metal NW generates single SPs propagating in the NW, opening the prospects of using quantum optical techniques to control single SPs and designing novel quantum plasmonic devices.

We studied the exciton-plasmon interaction in the coupled system of single quantum dots (QDs) and a silver nanowire [1, 2]. The decay rates of all the exciton recombination channels were experimentally obtained. Thus we obtained the quantum efficiency of single QD exciting single SP. By using Al_2O_3 film of different thickness to control the QD-NW separation, we revealed the distance dependence of the exciton decay rates and the SP quantum yield. We also show that the intensity and lifetime of the QD emission can be modified by creating a nanogap between the silver NW and a silver nanoparticle with the QD located in the nanogap. Moreover, the QD on the NW can be excited by the propagating SPs, enabling a remote excitation technique. By using the interference of SPs to modulate the electric field on the NW, we demonstrate the selective excitation of two QDs within diffraction-limited area.

Abstract- Silicon waveguides functionalized with non-linear organic cladding material are a versatile integrated platform to provide long-range interaction of high-intensity confined light with non-linear material. Here, we show that such waveguides can be utilized for high efficiency, integrated and compact THz sources based on non-linear frequency mixing. Light-matter interaction in these systems is modelled and optimized by analytical and numerical means.

THz science is a rapidly growing filed with applications in information and communications technology, biology and medical sciences, non-destructive evaluation and quality control, security, environmental monitoring and more [1,2]. Despite the recent progress in the field, it still remains challenge to produce continuous wave THz radiation with integrated, compact, room-temperature stable and tunable devices [3].

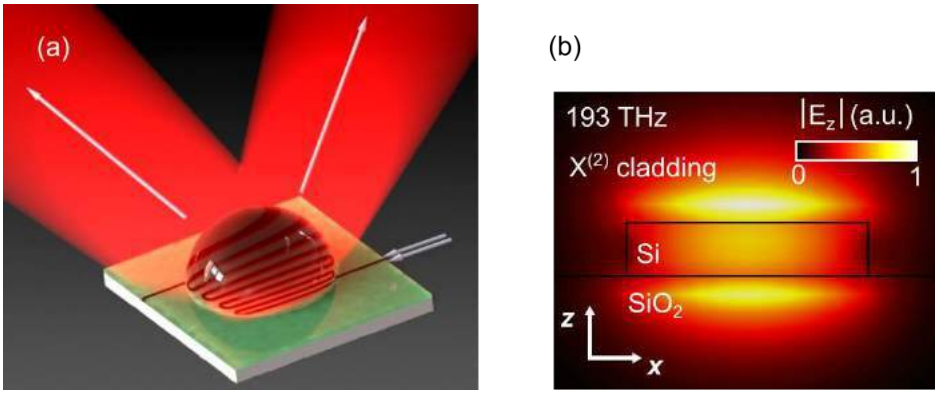

Figure 1. (a) folded silicon waveguide covered with non-linear material (green) and a half-spherical high-index THz lens. Two inclined THz beams are emitted from the device. (b) Mode profile of an optical TM-mode at NIR Frequency in a silicon waveguide covered with organic non-linear cladding material. A large percentage of the optical field intensity is confined in the non-linear material leading to strong light-matter interaction.

Here, we present concept for high- efficiency integrated THz sources. The concept is based on non-linear frequency mixing of two near infrared (NIR) modes guided in the same silicon waveguide that is cladded with non-linear organic polymers. Such materials can be well combined the with silicon photonic platform [4]. In the non-linear cladding material, evanescent fields of the two (NIR) modes mix and produce the difference frequency which can be tuned to any deliberate frequency in the THz range.

A high-index half-spherical THz lens is for phase matching in a Cherenkov scheme (cf. Fig. 1 (a)). Compact devices can be obtained by folding waveguides into a meander line structure. Due to the large refractive index contrast, silicon waveguides strongly confine light with low optical loss which can be exploited to realize a long interaction length of high-intensity light with the non-linear cladding material (cf. Fig. 1 (b)).

The non-linear conversion efficiency, besides phase matching considerations and the intensity of the input light, is governed by the optical environment of the polarization sources at THz frequencies - an effect that is often referred to as Purcell effect. Employing numerical [5] and analytical tools we show that the emitted THz power can be increased as a result of the Purcell effect by appropriately choosing the refractive index of the coupling material and the dispersion of the optical waveguides. We find that a THz output power in the order of 1μW (CW) can be obtained as a consequence of the long interaction length provided by the low-loss silicon waveguide and the engineered Purcell effect in the system.

Improving the photocatalytic water reducing activity of $LaTi_2O_7$ by tuning the crystal facets and composing with plasmonic Au

Junying Zhang
Department of Phyiscs, Beihang University, Beijing 100191, China
e-mail:zjy@buaa.edu.cn

The photocatalytic activity of $La_2Ti_2O_7$ (LTO) is limited by the large band gap and poor electron mobility. These problems can be conquered by hybridization with materials with visible-near infrared (vis-NIR) light absorption and high charge carrier transport. Firstly, we synthesized a 2D composite with g-C_3N_4 nanosheets and nitrogen doped LTO nanosheets (NLTO). The composite exhibited high photocatalytic activities for H_2 production under UV and visible light irradiation [1]. Secondly, Au/LTO was composited with black phosphorus (BP). The broad absorption of BP and plasmonic Au contribute to the enhanced photocatalytic H_2 production in the visible and NIR light regions [2].

LTO nanosteps (NSP) with successive surface heterojunctions were synthesized, which have high photocatalytic hydrogen generation performance. The LTO NSP uniformly packed with MoS_2 shell exhibited further improved activity and good stability. Moreover, UV to NIR light induced photocatalytic water reduction was achieved by introducing plasmonic Au nanorods to LTO NSP.

Abstract-Self-assembled hyperbolic metamaterials comprised of gold nanorod arrays deposited via anodic aluminium oxide templates have received significant attention due to the broad tunability of the optical properties due to the template geometry and the scalable fabrication approach. In this work we describe a method to create ultrasharp nanocone arrays using the broad beam argon ion milling of gold nanorod metamaterials. Such materials support localized plasmonic resonances characterized by strong electromagnetic field enhancement at the cone apex.

Plasmonic metamaterials fabricated using bottom-up approaches are inherently scalable and inexpensive. Template based fabrication benefits from low size dispersity and the ability to finely tune the dimensions of the porous structure over a wide range (inter-rod separation 55–100 nm, diameter>9 nm and thickness from 20–500 nm).[1] This flexibility enables the production of large area arrays of metallic nanorods with user specified dimensions providing designer optical properties.[1] The spectral position of the dipolar plasmonic resonances in such arrays depend both on the geometry of the individual nanorods but also on their separation; the electromagnetic coupling between adjacent rods modifies the field intensity distribution which reaches a maximum between the rods.[2] Due to their high refractive index sensitivity these materials have been used as optical sensors for biological molecules[3], ultrasound[4] and hydrogen[5] and the ability to engineer all-optical control of their optical properties makes these suitable candidates for ultrafast active devices.[2]

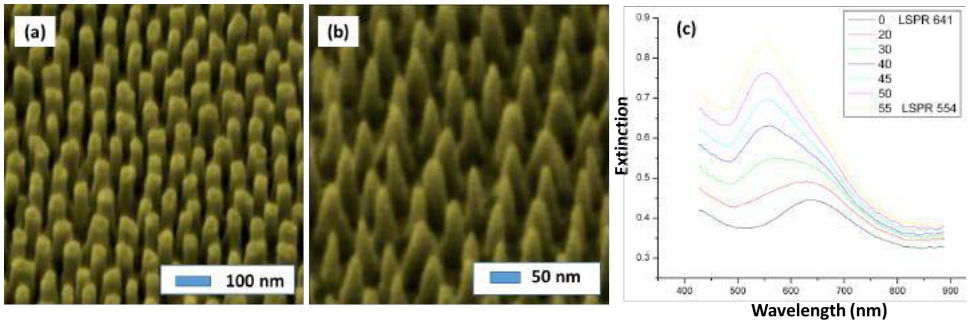

Figure 1: SEM images of (a) Nanorods having a diameter of 45 nm and separation of 90 nm after the removal of the alumina matrix and (b) Nanocone metamaterial formed from (a) after oblique incidence argon ion milling. (c) Extinction spectra of the nanocone metamaterial acquired with TM polarized light at various angles of incidence (legend).

In this paper we present a new type of optical metamaterial based on large area arrays of ultrasharp

nanocones. Notwithstanding the scalable fabrication process, such nanostructuring provides an extra degree of freedom to tailor the optical properties of the arrays, which support localized plasmonic resonances that can be tuned in wavelength, by varying the nanocone geometry, and that exhibit high electromagnetic field enhancement at the cone apex. Here we will describe the fabrication process and optical properties of these materials, highlighting the spectral tunability of the resonances and the achievable field enhancement. Prospects for the use of these novel metamaterials in nonlinear and reactive devices will be elaborated.

Enhancement of the Activity of Plasmonic Photocatalysts

J. Zhang[1], J. P. Claverie[1*], X. Yu and L. Razzari[2]

Abstract-Plasmonic photocatalysts are widely popular as they permit an efficient utilization of the solar spectrum in photocatalysis. However, they usually require a noble metal component, which precludes a large scale deployment of such devices. We present here two strategies to increase their activity, and thus to reduce the amount of noble metal.

Semiconducting metal oxides, such as TiO_2, form an important class of photocatalsyts, as they are widely available at low cost, they are quite stable, but they are usually only active in the ultraviolet (UV) and lower wavelength part of the solar spectrum. Plasmonic photocatalysts constituted of metal nanoparticles exhibiting surface plasmon resonance (SPR) and a semiconducting metal oxide have been extensively investigated, because they can extend the activity of the photocatalyst to higher wavelength illumination. However, from an economic point of view, the large-scale use of such photocatalysts will be curtailed by the prohibitive cost and availability of noble metals. We propose here two strategies to reduce the amount of such metals.

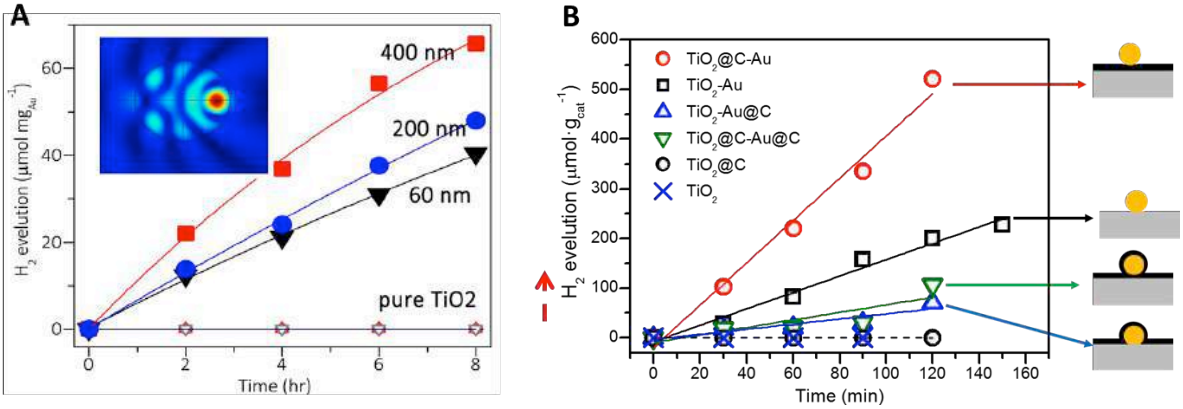

Figure 1. A. Hydrogen evolution from a TiO_2 sphere of increasing diameter (60, 200 and 400 nm) decorated with one Au nanoparticle (d = 60 nm).[1] The inset shows the WGM induced EM field (mode 4) within a 400 nm TiO_2 sphere. B. Hydrogen evolution from a plasmonic Au-TiO_2 photocatalyst decorated with carbon, for various arrangements of C, Au and TiO_2.[2] All experiments are performed with the same amount of Au, TiO_2 and C, under the same conditions.

In the first one, we demonstrate that the activity of the photocatalyst can be tuned by exploiting whispering gallery mode (WGM) resonances expressed within the semiconductor (Fig. 1a). Using the right size and architecture combination for TiO_2 and Au nanoparticles, the activity of the photocatalyst can be enhanced by a factor of fourty. The role of these WGM resonances is to enhance the absorption and interfacial field of the plasmonic Au NPs in Au−TiO_2 hybrids. Thus, by exploiting the combination of WGM resonances and SPR, one

can easily construct photocatalysts that are active in a broad spectral range, for example, from 400 up to 800 nm and further.

In the second one, we demonstrate that carbon can play a synergestic role in the development of the photocatalytic activity of an Au-TiO_2 composite plasmonic photocatalyst (Fig. 1b). We prepared three TiO_2-C-Au structures with different Au and C arrangements, but keeping the same amount of each component. Remarkably, the activity of the photocatalyst is not only highly dependent of on the architecture of the catalyst, but also on the type of reaction investigated. Photocatalytic degradation of dyes, PEC and IPCE measurements all point toward the fact that a sandwich structure, whereby Au is sandwiched between graphene leaflets at the surface of TiO_2, gives the highest activity. However, for hydrogen production, the TiO_2@C-Au catalyst exhibits an activity which is five times greater than TiO_2@C, indicating a synergistic action of plasmonic Au NPs and graphene. Thus, although the presence of carbon can result in a significant increase of the activity of the catalyst, this increase can only be achieved if the spatial arrangement of the Au and C on TiO_2 is finely controlled.

Ultrahigh Enhancement of Electromagnetic Fields by Exciting Localized Surface Plasmon with Propagating Surface Plasmon

Shuzhou Li[1*]
[1]School of Materials Science and Engineering, Nanyang Technological University, Singapore
[*]corresponding author: li@ntu.edu.sg

Abstract-We demonstrated that the localized surface plasmon resonances of a gold sphere can be excited by the extended surface plasmon of a silver thin film. The finite-difference time domain simulations have shown that the electromagnetic field enhancement in this configuration can be up to three orders higher than direct plane wave excitation. This huge enhancement has also been observed in surface-enhanced fluorescence and surface-enhanced Raman spectroscopy. These results show high potential for enhanced spectroscopic sensing and other optoelectronic application.

Excitation of localized surface plasmons (LSPs) of metal nanoparticles (NPs) residing on a flat metal film has attracted great attentions recently due to the enhanced electromagnetic (EM) fields found to be higher than the case of NPs on a dielectric substrate. In the present work, it is shown that even much higher enhancement of EM fields is obtained by exciting the LSPs through extended surface plasmons (ESPs) generated at the metallic film surface using the Kretschmann-Raether configuration. We show that the largest EM field enhancement and the highest surface-enhanced fluorescence intensity are obtained when the incidence angle is the ESP resonance angle of the underlying metal film. The finite-difference time-domain simulations indicate that excitation of LSPs using ESPs can generate 1-3 orders higher EM field intensity than direct excitation of the LSPs using incidence from free space. The ultrahigh enhancement is attributed to the strong confinement of the ESP waves in the vertical direction. With this unique configuration, we also found that an array of particles shows a critical importance of the inter-particle gap on the enhancement factor, which was confirmed experimentally using surface-enhanced Raman scattering (SERS). A monomolecular layer of 4-Aminothiophenol sandwiched in between the silver film and the gold nanoparticles showed SERS enhancement factor of the order of 10^{10} per molecule in the hotspots. It is demonstrated that the ultra-high SERS enhancement does occur only when the ESP is coupled to the LSP at an optimized inter-particle gap. Further, highly sensitive detection of glycerol in ethanol is demonstrated using the optimum structure with detection limit of the order of 10^{-12} to the weight percentage of ethanol, which is equivalent to a few molecules detection. This ultrahigh enhancement is useful in realizing various highly sensitive biosensors when strong enhancement is required as well as in highly efficient optoelectronic and energy devices.

Abstract-We propose a full time-dynamical and space-dependent theoretical description of the optical response of plasmonic nanoparticles coupled to gain (active medium) in two geometries homogeneous spheres immersed in a gain medium, and gain core-metal shell nanoparticles. We are able to calculate the lasing threshold and the initial stages of the lasing instability, and for the latter geometry, we solve the long-term dynamics which we show to be only dipolar, calculating the emission width of the nanolaser as well as exploring other relevant features of the system.

We here explore the features of nanolasers using, for the first time, a time-dependent model, which integrates a quantum formalism to describe the gain and a classical treatment for the metal. Our model also fully takes into account the influence of the system geometry (shape of the plasmonic resonator).

We start with studying the case of a homogeneous, metallic, spherical nanoparticle immersed in an active medium (gain) using a fully multipolar approach [1,2]. We calculate the lasing threshold value for all multipoles of tthe spaser, as well as the onset of the lasing instability, in the linear dipolar regime, with and without external field forcing. We also calculate the behaviour of the system *below* the lasing threshold, with the external field, demonstrating the existence of an amplification regime where the nanoparticle's plasmon is strongly enhanced but stable: this corresponds to partial loss compensation. Figure 1 shows the initial temporal evolution of the dipolar moment of the nanoparticle, in a stable case (below the threshold), displaying plasmon amplification, and in the unstable case, above threshold. Finally, for later, non-linear stages of the dynamics and the approach to the steady-state of the spaser; in particular, it is shown that, for the considered geometry, the spasing is necessarily multi-modal, i.e., multipolar modes are always activated, irrespective of how small the nanoparticle is with respect to the wavelength [2].

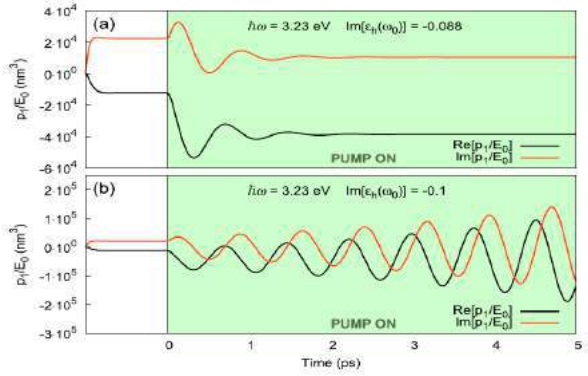

Figure 1. (a) Amplification regime below threshold: the dipole moment converges to a stable state with values which are greater in absolute value than those observed when the pump is off ($t < 0$). **(b)** Unstable lasing state, obtained above threshold.

We then move on [3] to a geometry closer to actual experiments and practical applications: a nanoparticle containing an active core and a plasmonic shell. It can be demonstrated that, in this case, the emission is mono-modal with only the dipolar mode activated. We then study the lasing threshold as well as the rise of the instability when gain values exceed it. For later times, however, significant differences appear with respect to the previous case, the most prominent one being that higher-order modes are never activated. We then solve the full time dynamics and look for non-linear, long-term states which are dominated by the interplay the nanolaser emission and the depletion of the population inversion in the active medium, which will then limit the growth of the laser. This leads in most cases to stationary states, which are reached via damped oscillations on the emission. We sometimes also observe, in restricted areas of the parameter space, richer features like bistability, where the system hesitates between a linear attractor state and a non-linear attractor. Figures 2 shows the normalized intensity value of the field calculated near the particle surface as the gain level is varied in the system.

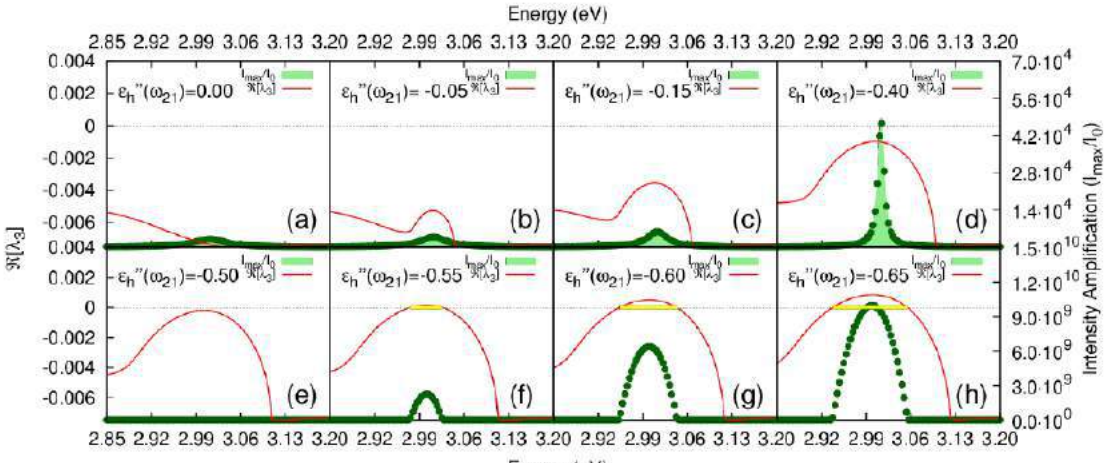

Figure 2. (a) Green points: intensity near the particule surface for increasing gain values in the particle's core from (a) to (h). From (a) to (d) the response is linear with partial loss compensation, while on (e) the lasing threshold is attained. From (f) to (g), one can observe the nonlinear emission state, and calculate the spectral width.

Abstract- Different fabrication approaches for nanostructured localized surface plasmon resonance (LSPR) sensors will be presented and their sensitivities evaluated. A miniaturized setup based on gradient index lenses will be shown.

Plasmonic nanostructures can be used as sensors for the local index of refraction. Under illumination, localized surface plasmon resonances (LSPRs) occur depending on the permittivity of the surroundings. The sensing concept relies on the high sensitivity of the LSPR wavelength to changes of the refractive index in their immediate vicinity. Such optical resonance-shift sensing can offer a marker-free alternative to e.g. fluorescence based detection [1]. Shifts in the intensity maximum of the LSPR spectrum can be evaluated to determine the refractive index of a bulk liquid of known composition, as e.g. demonstrated in Figure 1. While the method as such is unspecific, it can be made selective by functionalizing the nanostructure surface. In this case, the local refractive index can e.g. be changed by receptor-antibody-binding processes.

In this presentation the nanofabrication and plasmonic modes of arrays of nanodiscs, nanorods and vertical dimers will be discussed [2]. The nanostructures are implemented in microfluidic channels within fluidic PDMS cells. Examples for resonance-shift sensing based on changes of the refractive index of the bulk liquid will be shown. The biosensing capability is demonstrated by functionalizing the nanostructure surface and observing resonance-shifts due to the specific binding of testosterone antibody from solution. The overall setup is miniaturized by preparing nanostructures directly on the planar surfaces of gradient index lenses, which are then integrated within the fluidic cells as the optical detection element.

Abstract: The main goal of our work is to develop new types of inorganic nanoparticulate materials possessing optical activity and chirality, study their properties, investigate their nature and explore their applications. We have developed new chiral nanomaterials including chiral II-VI semiconducting nanoparticles (quantum dots) and chiral nanoparticles of technologically important metal oxides. We have also demonstrated potential applications of chiral quantum dots for chiral recognition and luminescent chemo- and bio- sensing.

Symmetry and chirality are properties commonly found throughout the natural world. Chirality is one of the most important factors in molecular recognition, with chiral compounds having a major role in chemistry, biology and medicine. Chirality has also been envisaged to play an important role in nanotechnology. Over the last years the area of chiral nanoparticles has received a great deal of attention due to the range of potential applications offered by these materials [1-5].

The main aim of our work is to develop new types of technologically important inorganic nanoparticulate materials possessing optical activity and chirality, study their properties, investigate their nature and explore their applications (Figure 1).

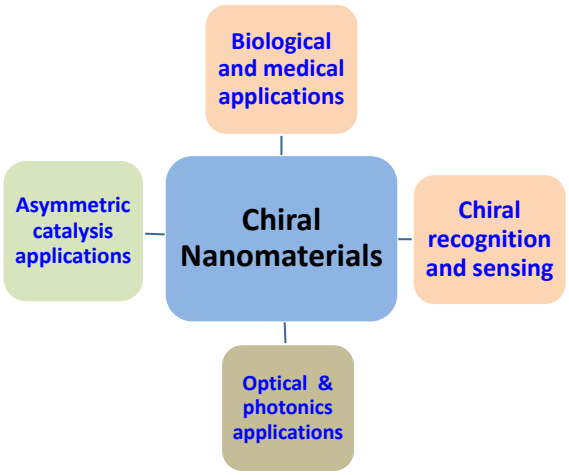

Figure 1. Potential applications of chiral nanomaterials.

We have developed new chiral nanomaterials including chiral II-VI semiconducting nanoparticles (quantum dots) and chiral nanoparticles of technologically important metal oxides. In addition we started to explore the properties of novel anisotropic chiral nanomaterials. The new nanomaterials have shown a very interesting optical activity and unusual chiral morphologies which were confirmed by various instrumental techniques. We have found that in some nanocrystals (e.g. CdSe/ZnS QDs and quantum rods) the chirality and corresponding optical activity are intrinsic features that can occur even without the presence of chiral ligands. The intrinsic chirality of the CdSe based nanocrystals is caused by the presence of intrinsically occurring chiral defects such as dislocations or point defects in these nanostructures. The use of chiral ligands enabled us to separate these nanostructures into different phases and enhance their chiroptical activity. We have also demonstrated potential applications of chiral quantum dots for chiral recognition and luminescent chemo- and bio- sensing. We have also found that live cells demonstrate an enantioselective uptake of chiral quantum nanostructures. It is expected that chiral nanomaterials will find applications in sensing, nanomedicine, asymmetric synthesis, catalysis and other areas.

Abstract- The optical responses of core/shell nanostructures composed of silica cores and numerous small silver nanoparticles composing an outer shell are studied with a finite-difference time-domain (FDTD) approach. Light scattering cross sections are decomposed via a multipolar analysis in order to reveal their magnetic and electric multipolar character. The analysis is presented for core-shell structures illuminated by a variety of scalar and vector incident light beams, showing how various modes can be selectively excited.

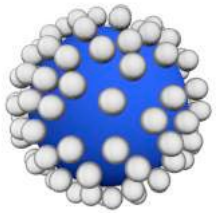

Figure 1. A core-shell nanostructure. In this work we typically study silica cores with diameters of 330 nm surrounded by up to 160 silver nanoparticles with diameters of 40 nm.

Creating negative-index metamaterials requires both negative permittivity and permeability at the excitation frequencies of interest and this is tantamount to creating strong electric and magnetic resonances. Core-satellite structuresare known to exhibit magnetic modes at optical frequencies and their characterization is relevant for the development of metamaterials and metafluids[1].

We study the optical responses of silica-silver nanoparticle core/shell nanostructures (**Figure 1**) using the FDTD method. We introduce a method of multipolar analysis for FDTD simulations and apply it to better understand the interaction of both linearly polarized or scalar and vector beams with silica-silver core-satellite structures at a new level of detail[2]. The method can be used to identify the multipolar nature of scattering peaks and provide angular scattering intensity for better comparison to experimental results. The types of vector beams considered have radial, azimuthal or shear polarization.

Azimuthally polarized light is shown to selectivity excite the magnetic modes of the core-satellite nanostructures, in addition to enhancing their scattering intensity and spatially rotating the mode. Similarly, radially polarized light selectively excites and enhances the electric modes and shear polarized light selectively excites and enhances quadrupolar and higher order modes. We also find that linearly and azimuthally polarized light excite magnetic dipolar and magnetic quadrupolar modes that can spatially interfere with each other, which can be an important consideration for experimentally-observed angular scattering. In addition, nanoparticle placement and arrangement is shown to be an important aspect of scattering by these systems.

Abstract- Controlling plasmonic systems with nanometre resolution over large non-planar areas with high flexibility and speed is of strategic importance for spreading their use in various industrial fields. Using light to trigger self-organization processes controlled by non-linear feedback mechanisms is a unique strategy to meet this challenge. Here, we open a new route for the ultrafast laser-induced self-organization of metallic nanostructures in 3D, we characterize the self-organization processes through time-resolved polarization imaging and we demonstrate that this laser marking technique offers a powerful tool for the engineering of plasmonic colors.

Different strategies have recently been developed to create plasmonic colors based on the control of localized surface plasmon resonances, such as gap plasmons and hybridized disk–hole plasmons.[1] Most of them have been implemented by electron beam lithography, a powerful tool to produce well-controlled nanostructures but still prohibitive in terms of time and cost for many applications. Other techniques such as nanoimprint or self-assembly are more appropriate for producing large-scale nanostructured materials, but they lack versatility. In contrast, laser techniques offer the advantage of controlling plasmonic systems over large non-planar areas with high-speed and flexible processes. We especially demonstrated that cw laser light could trigger self-organization processes of metallic nanoparticles in thin films resulting in plasmonic nanopatterns exhibiting singular dichroic colors.[2]

In this presentation we demonstrate the high efficiency of ultrashort laser pulses to produce a full range of plasmonic colors while controlling thermal effects. The laser color marking technique is based on triggering self-organization processes of metallic nanoparticles in a protective thin inorganic film. Beyond the generation of planar nanostructures, we show that 3D self-organization can be activated and controlled in nanocomposite films by ultrashort laser irradiation, resulting in plasmonic nanostructured films with highly regular periodic lattices located at different depths. Such a 3D self-organization is shown to originate from the simultaneous excitation of independent optical modes at different depths in the film and to be activated by the plasmon-induced charge separation and thermally-induced NP growth mechanisms. We implement time-resolved polarization imaging to characterize the different self-organization processes that appear to occur at different time scales at different depths depending on local phase changes or diffusion limited growth processes.

Optical chirality generation and amplification in achiral plasmonic nanostructures assembled with chiral biomolecules

Dangyuan Lei[1,2]

[1]Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, China

E-mail: dylei@polyu.edu.hk

Abstract – I will discuss our recent study on the generation and amplification of optical chirality in achiral metal nanostructures assembled with chiral biomolecules. I will show how an individual plasmonic nanostructure interacts with chiral biomolecules, which enables switching and amplifying the molecular optical activity and probing the conformational evolution of the chemisorbed molecules. I will also show how a cluster of plasmonic nanostructures can be assembled with chiral molecules to produce plasmon-induced circular dichroism response in both UV and visible-NIR regions.

Main text – Recent studies demonstrate that conjugation of noble metal nanoparticles (NPs) with chiral molecules can switch the molecular optical activity, which is usually located in the UV region, to the visible wavelength region. The new circular dichroism (CD) response appears at the localized surface plasmon resonance (LSPR) band of the metal NPs and thus is termed plasmon-induced CD [1]. This phenomenon is of particular importance for determining and manipulating the optical chirality and activity in the visible and near infrared (NIR) regions and has numerous applications in the fields of biochemical sensing, enantioselective catalysis, biomedicine chirality separation, and chiroptical nanodevices. In this talk, I will show how an individual plasmonic nanostructure interacts with chiral biomolecules, which enables switching and amplifying the molecular optical activity and, more importantly, probing the conformational evolution and structural rearrangement of the chemisorbed molecules on the nanostructure surface, thus constituting a promising stereo-chemically attuned nano-sensor. I will also show how a cluster of achiral plasmonic nanostructures can be assembled with chiral molecules to produce plasmon-induced CD response in both UV and visible-NIR regions. The induced CD resonance position can be adjusted from ~340 nm to above 900 nm through altering the aspect ratio and/or the assembling pattern of the hybrid nanostructures. Detailed theoretical calculations elucidate the electromagnetic interaction mechanisms responsible for the observed CD in both cases.

Circularly Polarized Luminescence from Chiral Lanthanide Phosphate Nanocrystals

U. Hananel, A. Ben Moshe, and G. Markovich*
[1]School of Chemistry, Tel Aviv University, Tel Aviv 6997801, Israel
*corresponding author: gilmar@post. Tau.ac.il

Abstract- We prepared colloidal chiral lanthanide phosphate nanocrystals using chiral molecular templates and studied their chirality through circularly polarized luminescence at the lanthanide emission lines. Some of these emission lines exhibited very large degree of circular polarization, up to ~50%. High enantiomeric purity of the nanocrystals was obtained using tartaric acid molecular templates.

Following our recent work on enantioselective synthesis of α-HgS,[1] and Te, Se nanocrystals,[2] using thiolated chiral ligands (cysteine, penicillamine, glutathione), we have moved to a very different system of inorganic nanocrystals of chiral space group: lanthanide phosphate hydrates (Rhabdophanes, $LnPO_4 \cdot H_20$). We synthesized Eu^{3+} doped $TbPO_4 \cdot H_2O$ nanocrystals, which correspond to a chiral space group ($P3_121$), in the presence of chiral ligands. We have measured circularly polarized luminescence (CPL) at the lanthanide emission lines (see Figure 1). On using pure L- or D-tartaric acid ligands we observed substantial CPL values for these nanocrystals, of up to 20-50% for certain emission lines. Surprisingly, on preparing the nanocrystals with L- and D-tartaric acid mixtures at different enantiomeric excess values, we observed almost complete enantioselectivity in the product nanocrystals already at ~20-30% enantiomeric excess of the tartaric acid. The sensitivity of the resulting nanocrystal handedness to the enantiomeric excess of the tartaric acid depended on the synthesis temperature and pH.

The successful control of nanocrystal handedness by the tartaric acid molecules probably indicates collective effects involving a large number of ligand molecules at the nucleation stage or at the handedness determining stage in the growth of these nanocrystals.

This is an interesting model system for studying the formation and handedness control of chiral crystals. The CPL is a very useful tool for studying the formation of such chiral crystals and following their evolution kinetics.

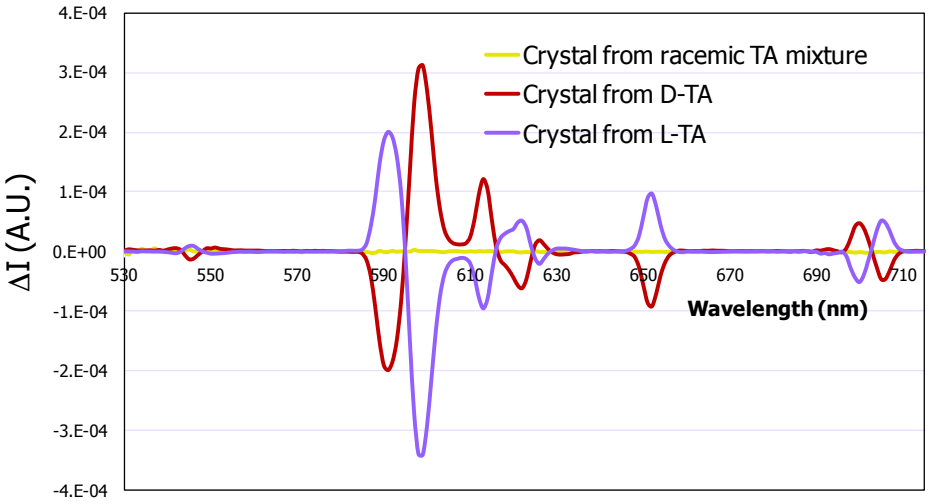

Figure 1. CPL spectra of the Eu^{3+} doped $TbPO_4 \cdot H_2O$ nanocrystals prepared with pure L- and D-tartaric acid (L-TA and D-TA) and with a racemic mixture of the two.

Abstract- we investigated light spatial localization in an infrared nanoantenna consisting of a gold trimer. The study is based on two-photon molecular motion in azobenzene-containing photopolymers. It is shown that different electromagnetic hot spots can be tuned and controlled, on demand, with an external plane wave. 4-digit plasmonic combination was also discussed.

Metallic Nanostructures (MN) offer the possibility of strong spatial confinement, down to the nanometer scale. In this context, easy remote control of electromagnetic hot spot constitutes an important challenge. In particular, rational control of MN geometry and incident beam shaping (including phase and angle of incidence) can produce a large variety of near-field distribution that can be exploited in the future, e.g. for photonic computing.

Recently, It was theoretically demonstrated that that symmetric and antisymetric modes can be excited, on demand by a propagating plane wave in a linear trimer of identical gold nanoparticles[1]. In this paper, we experimentally demonstrate this effect on plasmonic infrared trimer nanoantenna. Two novelties are emphasized. First, we report direct near-field observation of mode balancing and localization of hot spots in trimer plasmonic nanoantenna. Second, we have used for the first time two-photon absorption in azobenzene moieties for plasmonic nano-imaging of infrared nanoantenna, opening the route to near-field investigation of coupled systems based on molecular probing. The studied nanostructure is shown in Fig. 1(a).

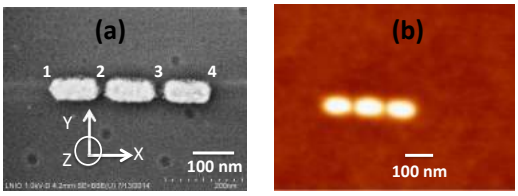

Figure 1. Studied gold nanotrimer

To investigate the optical near-field, we used a specific approach that has been developed over the past decade[2].

Azobenzene molecules that are covalently attached to a polymeric backbone are used as optically driven molecular nanomotors. After exposure to the light, an atomic force microscope (AFM) is used to measure the resulting topography that is related to the near-field intensity pattern to be characterized. Fig. 1(b) shows the plasmonic structure after photopolymer deposition, before any exposure. Figure 2 shows examples of AFM images taken after exposure (at λ=900 nm) with different incident angles and polarizations. Topographical depletions correspond to electromagnetic hot spots that triggered molecular migration. The results were analyzed and compared with electrodynamics calculation allowing us to discuss field spatial localization.

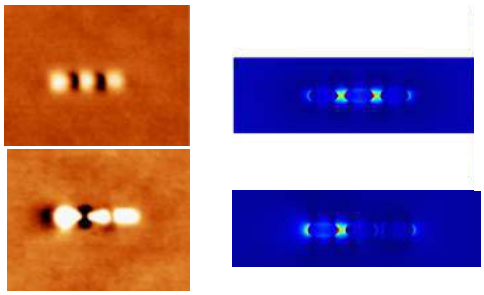

Figure 2. Examples of hot spot localization. Left: AFM images taken after exposure (λ=900 nm). Right: corresponding calculated field maps.

Interestingly, by considering hot spots at both cavities and trimer extremities (named 1, 2, 3, 4 in Fig. 1(a)), we demonstrated the partial activation of a four-digit plasmonic code (cf. example in Fig. 3)
This study opens the avenue to near-field plasmonic circuits and information that are controlled by simple far-field optical commands.

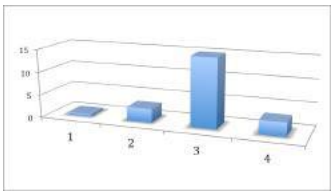

Figure 3. Example of 4-digit plasmonic configuration. 1, 2, 3, 4 stand for the locations pointed out in Fig. 1(a). The heights correspond to depletions in nm observed at each location.

III-V Semiconductor Nanowires for Optoelectronics Applications

Chennupati Jagadish
Electronic Materials Engineering
Research School of Physics and Engineering
The Australian National University, Canberra, ACT0200, Australia
Email: c.jagadish@ieee.org

Semiconductors have played an important role in the development of information and communications technology, solar cells, solid state lighting. Nanowires are considered as building blocks for the next generation electronics and optoelectronics. In this talk, I will introduce the importance of nanowires and their potential applications and discuss about how these nanowires can be synthesized and how the shape, size and composition of the nanowires influence their structural, electronic and optical properties. I will present results on axial and radial heterostructures and how one can engineer the optical properties to obtain high performance optoelectronic devices. I will discuss the role of surface non-radiation recombination and how the quantum efficiency of these nanowires will be discussed. I will also present the crystal phase control of nanowires and implications for polarization properties of these nanowires.

Plasmonic cavities and how one can enhance the quantum efficiency of nanowires using plasmonic cavities will be discussed.

I will present results on room temperature operation of GaAs/AlGaAs nanowire multi quantum well lasers and also wurtzite InP nanowire lasers.

I will also present results on GaAs/AlGaAs and InP nanowire THz detectors. These detectors have shown excellent signal to noise ratio similar to bulk ZnTe detectors despite sub-wavelength dimensions. Bandwidth of these detectors will be discussed.

Nanowire solar cells have drawn considerable attention in recent times and I will present results on nanowire solar cells and identify the challenges in improving the efficiency of the solar cells.

I will discuss how Nanowires can be used to engineer neural networks towards creating brain on a chip.

Future prospects of the semiconductor nanowires will be discussed.

Metal nanostructures characterization by digital holography: applications to thermoplasmonics and electrochemistry

A. Lalisse[1,3], V. Brasiliense[1,2], M.C. Nguyen[1,2], P. Berto[1], R. Kuszelewicz[1], F. Kanoufi[2], J. Plain[3], G.Tessier[1]

Abstract- Heterodyne digital holography is a powerful tool to study optically scattering objects. It allows the reconstruction of 3D images, and the superlocalization of individual objects with 3x3x10 nm^3 precision. Associated to heterodyning, it can also measure modulated phenomena like the scattering efficiency changes thermally induced by the modulated excitation of plasmonic nanoantennas. We will illustrate the possibilities of this technique to study electrochemical processes in single metallic nanoparticles, and to obtain quantitative thermal mapping in thermoplasmonics.

Heterodyne digital holography is an interferometric technique which gives access to both the amplitude and phase of the optical field, allowing the reconstruction of 3D images. We have recently shown that the concept of superlocalization, initially proposed to pinpoint the position of fluorescent molecules, can be applied to the coherent field scattered by metallic nanoobjects: using holography, individual nanoparticles separated by more than the width of the microscope point spread function can be localized in 3D with an accuracy of 3x3x10 nm^3 over relatively large volumes. Real-time holograms are reconstructed in order to superlocalize and track several individual NPs, which finds interesting application in electrochemical nanoimpacts monitoring.

This emerging field of research is based on the time-resolved detection of stochastic collisions of individual NanoParticles, (NPs) on micro-electrodes or in nano-confined electrochemical cells [1] to measure electron transfer processes associated to single NP impacts. We will illustrate the possibilities of this coupled system in several chemical systems, where 3D particle tracking can provide a NP size estimate during the Brownian approach of the particle (through its mean square displacement). During chemical reactions on the metal interface, we will show that holography and spectroscopy, associated to an optical model of the scattering, give access to relevant information on the size, position, and chemical composition of the NPs [2].

Associated to heterodyning, digital holography also allows the study of rapidly modulated phenomena. This includes the modulated optical excitation of nanofabricated plasmonic nanoantennas, which induces a localized heating in lossy metals, and a refractive index change. The optical and thermal properties of these objects strongly depend on the morphology of the nanostructure and its dielectric environment. Both can be efficiently monitored by digital holography, which provides the 3D optical scattering pattern of the structures and gives access to quantitative thermal imaging. We will illustrate the possibilities of the method on various nanofabricated systems, with the aim of modelling, characterizing and optimizing the thermal properties of metallic nanostructures.

Hybrid plasmonic-dielectric metamaterials for enhanced nonlinear response

Hayk Harutyunyan[1,*]
[1]Department of Physics, Emory University, Atlanta 30322 GA, USA
[*]corresponding author: hayk.harutyunyan@emory.edu

Abstract- Since its discovery in the 1960s, nonlinear optics has revolutionized optical technologies and laser industry. Development of efficient nanoscale nonlinear sources will pave the way for new applications in photonic circuitry, quantum optics and biosensing. However, nonlinear signal generation at dimensions smaller than the wavelength of light brings new challenges. These include the reduced light-matter interaction volume, the overlap of the fundamental and the nonlinear modes at the nanoscale and the outcoupling of the nonlinear signal to the far-field. Here, we develop hybrid plasmonic – dielectric metamaterials that overcome these limitations and demonstrate ~10^{-4} nonlinear signal conversion efficiency at visible frequencies.

In the first part of my talk I will introduce new type of 3-dimensional, non-planar plasmonic metasurface and demonstrate 3 orders of magnitude enhancement of second harmonic generation (SHG) compared to doubly-resonant plasmonic nanowire gratings. The metasurface consists of an array nanowires with characteristic plasmonic and photonic (diffraction grating) resonances. The geometry of the metamaterial design minimizes the destructive interference of nonlinear emission into the far-field, provides independently tunable resonances both for fundamental and harmonic frequencies, a good mutual overlap of the modes and a strong interaction with the nonlinear material [1,2]. In the second part of my talk I will describe our recent efforts to combine localized plasmon modes with propagating photonic waveguide modes. The hybridized mode that is formed as a result of such coupling can exhibit the desirable feature of plasmonic modes such as high Purcell factors and large field enhancement but with reduced losses.

Our findings can enable the development of efficient nanoscale single photon sources, integrated frequency converters and other nonlinear devices.

Abstract-We report on the strong plasmon–exciton coupling in monolayer WS_2 coupled to individual plasmonic gold nanorods. Due to the high oscillator strength and larger binding energy of the 2D exciton of WS_2, we have obtained large Rabi splitting energy of 91 meV ~ 133 meV at ambient condition which was associated with only 5 ~ 18 excitons. In addition, the strong coupling can be dynamically tuned either by electrostatic gating or temperature scanning.

Strong light–matter coupling of quantum emitters with optical cavities have attracted much interest for its importance in the fundamental cavity quantum-electrodynamics research and great potentials in quantum information applications. In the strong coupling regime, the rate of energy exchange between the exciton transition and photon is faster than both of their dissipation rates, which results in the formation of hybrid light-matter states manifested by a Rabi splitting energy. Metallic plasmonic nanocavities have been shown as an excellent platform to realize the strong coupling at room temperature with dye molecules or quantum dots due to their ability to confine light at the deep subwavelength.[1,2] On the other hand, two-dimensional semiconducting transition-metal dichalcogenides (TMDs) have recently emerged as promising candidates for facilitating the light–matter interaction due to the high oscillator strength and large banding energy of their tightly bound 2D excitons. Although several studies have reported the strong coupling in TMD monolayers integrated with optical microcavities as well as plasmonic nanostructures, they all involved plenty of excitons due to the large size of the optical cavities.[3,4] Furthermore, active control on the strong coupling by taking advantage of the exceptional excitonic properties of the TMDs has yet to be demonstrated. Here, we investigate all-solid-state, room-temperature strong coupling with active control in heterostructure composed of monolayer WS_2 and an individual plasmonic gold nanorod.

Figure 1a schematically shows the gold nanorod–WS_2 monolayer heterostructure studied in our work. The single-crystalline monolayer WS_2 flake was grown by chemical vapor deposition (CVD) method with the thickness of ~ 1 nm and exhibited an exciton emission centering at 1.95 eV with a narrow linewidth (γ_{ex}) of 57 meV (Figure 1b). The gold nanorods were synthesized with different aspect ratios to enable the spectral overlap with the exciton transition, and Figure 1c shows the scattering spectrum of a typical gold nanorod with aspect ratio of 2.2, which exhibits a longitudinal plasmon resonance with the plasmon resonance energy of 1.97 eV with and linewidth (γ_{pl}) of 149 meV (Figure 1c). A well-defined mode splitting can be observed in the scattering spectrum from the gold nanorod coupled to the WS_2 monolayer with the formation of the high- and low-energy hybrid states (Figure 1d), which indicates the coherent plasmon–exciton coupling. Furthermore, we have

observed the anti-crossing behavior on the scattering energy diagram of the heterostructures by measuring the spectra of various gold nanorods with different detunings between plasmon frequencies and exciton transition. The Rabi splitting energy, $\hbar\Omega$ is ~ 106 meV, which fulfills the criterion where the strong coupling can occur ($\hbar\Omega > (\gamma_{pl} + \gamma_{ex})/2$). Due to small mode volume of gold nanorod and 2D structure of the monolayer WS_2, the plasmonic field is strongly confined and enhanced at the WS_2 surface, with the strongest enhancements locating near the two apexes of the nanorod (Figure 1e), which is occupied by few excitons since the WS_2 exciton extends several unit cells (Figure 1f). The Rabi splitting energies can be tuned from ~ 133 meV to ~ 91 meV by precisely reducing the nanorod volume while fixing the plasmon resonance frequency at the exciton energy, which only involve 18 to 5 excitons. Most importantly, the WS_2 excitons are sensitive to external stimulus, which enables the active control on the strong coupling via electrostatic gating as well as temperature scanning.

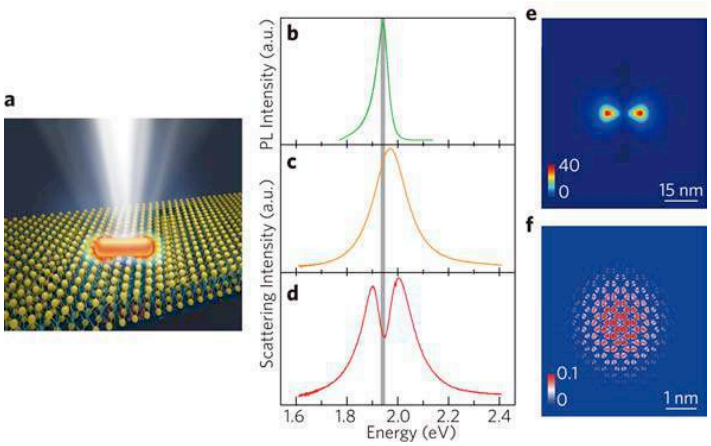

Figure 1. a) Schematic showing the heterostructure composed of an individual gold nanorod coupled to the WS_2. **b)** Photoluminescence spectrum of the monolayer WS_2. Scattering spectra of **c)** individual gold nanorod, and **d)** nanorod coupled to the WS_2. **e)** Near-field enhancement contour of an individual gold nanorod placed onto the WS_2 monolayer. The electric field contour is drawn on the WS_2 plane underneath the gold nanorod. **f)** Modulus-square of the real-space wavefunction of the WS_2 exciton.

In summary, we have demonstrated all-solid-state, room-temperature, and active controllable strong coupling in monolayer WS_2 coupled to a single plasmonic gold nanorod. This strong coupling system hold a great promise for future on-demand quantum optics devices.

Abstract- Liquid marbles have been studied extensively as isolated microreactors, as micropumps, and in sensing. However, current liquid-marble-based sensor and reactor are limited to qualitative colorimetry-based detection and ex-situ characterizations, respectively. Herein we fabricate plasmonic liquid marble[1] (PLM) as a substrate-less surface-enhanced Raman spectroscopy (SERS) platform for multiplex and ultrasensitive molecular detections simultaneously across two separate phases, with detection limits as low as 0.3 fmol. PLM also serves as a multi-functional reactor for in-situ and non-invasive reaction monitoring.

1. Introduction

Optical manipulation of small biomolecules is an important issue in bioscience. Plasmon-based optical tweezers (POT) has attracted significant interests as a novel efficient trapping method, since it enhances a radiation force and enables us to trap smaller biomolecules. Recently, we have demonstrated POT of DNA. A micro-ring of optically trapped DNAs was formed on a plasmonic substrate upon resonant light irradiation. Also, we found that the micro-ring was permanently fixed on the substrate [1, 2]. Presumably, the micro-ring formation originates from four physical phenomena:

① Radiation force (trapping DNAs as an attractive force)
② Thermophoresis (carrying DNAs from hotter to colder regions)
③ Thermal convection (supplying DNAs from outside of plasmon excitation area to inside)
④ Coulomb's force (fixing DNAs onto a plasmonic substrate)

Since radiation force and thermophoresis strongly depend on the size of DNAs, DNAs with different base pairs (bp) should be optically separated and then fixed as micro-rings with different diameters on a plasmonic substrate. In the present study, we discuss a mechanism of the micro-ring formation and propose a new separation technique of DNAs with different number of bp (plasmonic chromatography, Fig. 1).

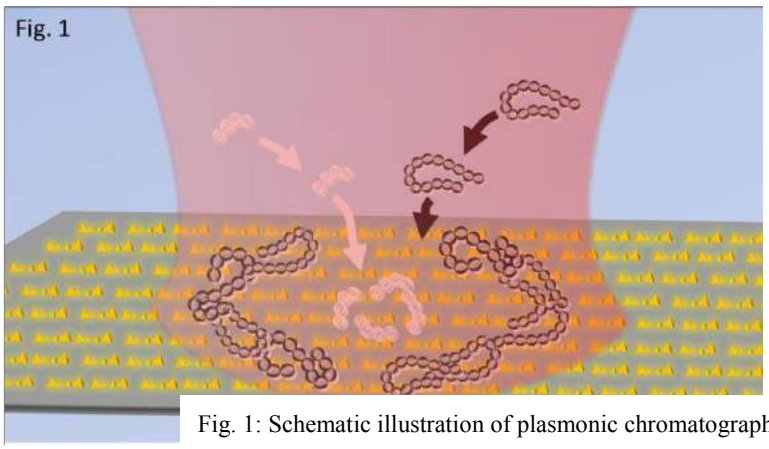

Fig. 1: Schematic illustration of plasmonic chromatography for DNAs. DNAs with different number of base pairs trap at desired positions, leading to multiple-rings formation.

2. Experiments

For a plasmonic substrate, we fabricated gold nanopyramidal dimer arrays on a glass substrate. The plasmonic substrate has a broad absorption band around 800 nm that is ascribed to a gap-mode plasmonic resonance. As trapping targets, λ-DNA (48 kbp) was labelled with YOYO-1 (λ_{em} = 509 nm) and T4-DNA (166 kbp) was labelled with DAPI (λ_{em} = 461 nm), respectively. These DNAs were mixed in an aqueous buffer solution. We used a cw near-infrared (NIR) laser (λ = 808 nm) for LSP excitation and a cw near-ultraviolet and visible lasers (λ = 375, 473 nm) for fluorescence excitation. Trapping behavior was followed using a fluorescence microscope.

3. Results & discussion

The plasmon excitation resulted in formation of two micro-rings (inner and outer rings) on a plasmonic substrate as shown in Fig. 2(a). These rings were permanently fixed on the substrate. Fluorescence spectra of the inner ring were safely assigned to YOYO-1, indicating that the inner ring consisted of λ–DNA (Fig. 2(b)). On the other hand, fluorescence spectra of the outer ring were surely assigned to DAPI, showing that the outer ring consisted of T4-DNA (Fig. 2(c)).

The position of micro-ring formation depends on the intensity of thermophoresis (repulsive force) and radiation force (attractive force). Thermophoresis repelling from the focal spot exerted DNAs, while radiation force exerted DNAs for trapping. Thermophoresis exerted DNA significantly increase with increasing the number of base pairs. As a result, DNAs with different number of base pairs formed the double micro-rings.

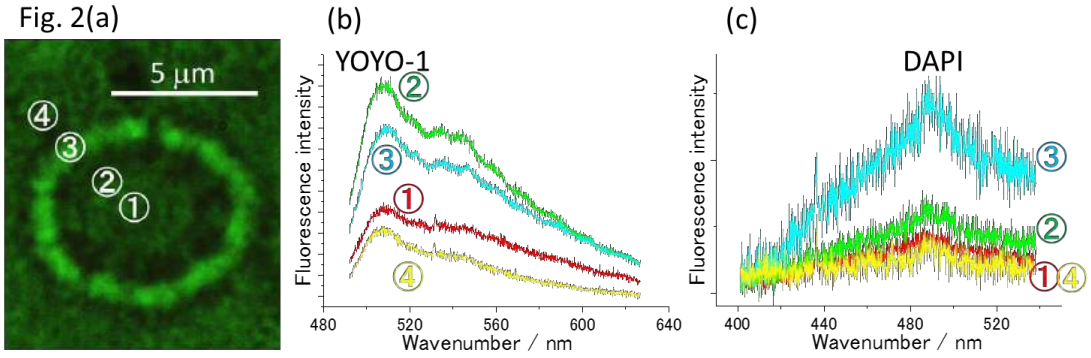

Fig. 2: (a) Optical micrographs of two micro-rings (②: inner ring, ③: outer ring) fixed on a plasmonic substrate by near-infrared laser irradiation. (b), (c) Fluorescence spectra at each positions of a plasmonic substrate. (b): YOYO-1 in λ-DNA (c): DAPI in T4-DNA

4. Conclusion

We successfully separated and fixed DNAs with different number of base pairs on a plasmonic substrate using plasmonic optical tweezers.

Abstract. One of the grand challenges in nanotechnology is controlling the organization of nanoparticles into scalable superlattices with tunable crystal structures. Here, we present a bottom-up approach to direct the self-assembly of shape-controlled plasmonic nanoparticles into multiple large-area 2-dimensional (2D) and 3-dimensional (3D) metacrystals. Using Ag octahedra and nanocubes, we demonstrate the ability to assemble each particle morphology into 3 distinct 2D metacrystals with areas larger than 50 cm^2. We further show the importance of crystal design in surface-enhanced Raman scattering.

Shape-controlled nanoparticles can be assembled into structurally diverse superlattices. However, it remains challenging to control the organization of one nanoparticle morphology into multiple superlattices over large areas. In this presentation, we demonstrate the concept of 'one nanoparticle, multiple plasmonic metacrystals' using Ag octahedra and nanocubes. We tailor the nanoscale surface chemistry of the Ag octahedra [1] and nanocubes [2] using a family of thiol-terminated molecules, enabling us to control their surface wettability. Subsequent assembly of these nanoparticles at the oil/water interface gives rise to multiple plasmonic metacrystals (Figure 1). Increasing the surface hydrophobicity of the nanoparticle surfaces leads to increasingly open metacrystals with packing densities as low as 33 %. At this packing density, the nanoparticles are standing on their vertices in their respective plasmonic metacrystals. Notably, we can achieve large areas of these plasmonic metacrystals despite their structural instability.

Our ability to achieve such large-area plasmonic metacrystals also enable a structure-to-function characterization for these metacrystals. We find that the lowest packing density metacrystals generates the highest surface-enhanced Raman scattering (SERS) enhancement factors for both the metacrystals of nanocubes and octahedra. Numerical simulations indicate that this strong enhancement arises from the large-area field delocalization within the metacrystals (Figure 1). Our findings here indicate the importance of crystal design in creating efficient SERS substrates. Furthermore, our findings imply that packing the highest number of nanoparticles within a given area will not always generate the strongest SERS enhancement. With these findings in mind, we proceed to build 3D plasmonic metacrystals possessing dual structures within a single supercrystal and demonstrate its superiority over a uniform supercrystal in SERS.

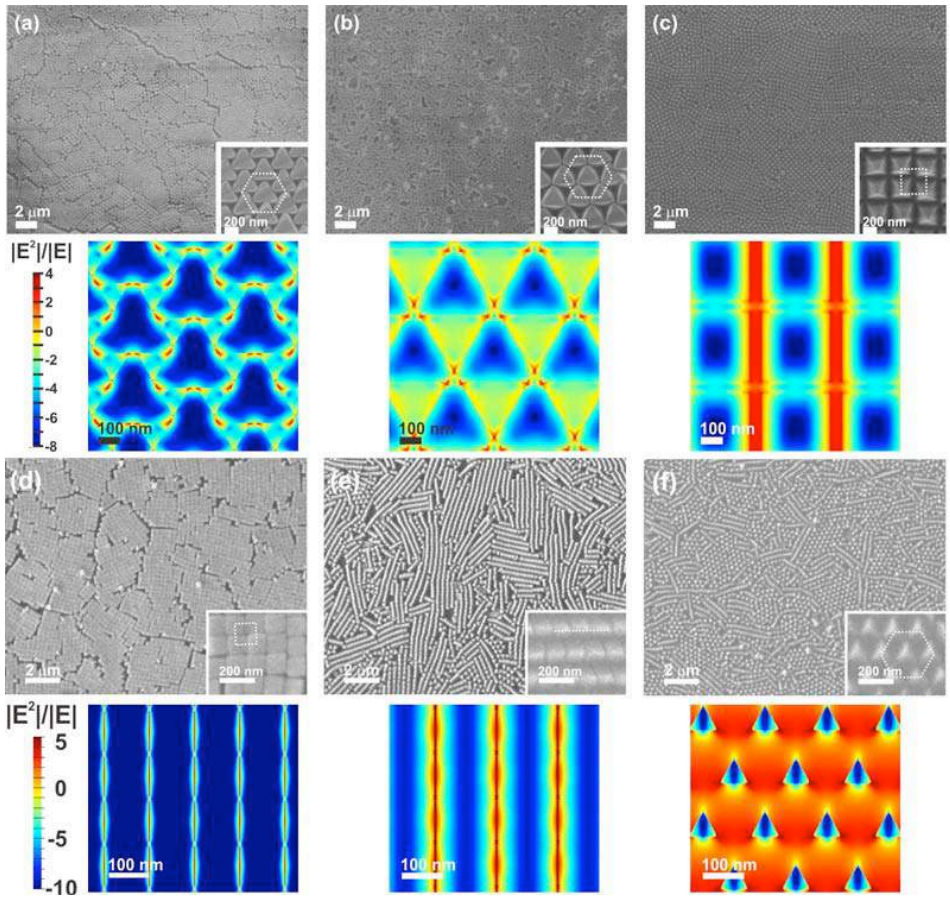

Figure 1. One nanoparticle morphology, multiple plasmonic metacrystals. Ag octahedra assemble into (a) hexagonal close-packed, (b) open hexagonal, and (c) square metacrystals, together with their corresponding local electromagnetic field enhancements at 532 nm. Ag nanocubes assemble into (d) square planar, (b) wire-like, and (f) hexagonal metacrystals, together with their corresponding local electromagnetic field enhancements at 532 nm. In (c) and (f), nanoparticles are standing on their tips within the metacrystals.

Nitrogen fixation using plasmonic photoanode composed of n-semiconductor and metal nanostructures

T. Oshikiri[1*]
[1]Research Institute for Electronic Science, Hokkaido University, Japan
[*]corresponding author: oshikiri@es.hokudai.ac.jp

Abstract-Ammonia has received considerable attention as a potential energy carrier and as a fuel in addition to its use as a fertilizer because it is a non-carbon-based chemical that is easily condensed into a liquid. In this study, we introduce the nitrogen fixation to obtain ammonia using plasmonic photoanode composed of n-semiconductor and gold nanostructures. The plasmonic photoanode can synthesize ammonia from nitrogen, water, and visible light.

Plasmon-induced charge transfer has been studied as one mechanism for plasmonic energy conversion. When plasmonic metallic nanostructures make intimate contact with n-type semiconducting materials, the localized surface resonance(LSPR)-excited intraband and interband transitions of electrons can be directly injected from the plasmonic metallic nanoparticles (NPs) into the conduction band of the semiconductor, via overcoming the Schottky barrier between the metallic NP and semiconductor. One of the attractive features of this approach is the circumvention of the semiconductor bandgap-limited absorption energy band edge by harvesting the energy of photoelectrons ejected from plasmonic metallic NPs. This discovery has led to the widespread development of photocurrent generation[1-3] and photoelectrochemical water splitting systems[4,5] using visible light energy.

Ammonia has received considerable attention as a potential energy carrier and as a fuel in addition to its use as a fertilizer because it is a non-carbon-based chemical that is easily condensed into a liquid. Previously, we achieved plasmon-induced ammonia synthesis via photoelectrochemical reduction of nitrogen using a strontium titanate photoelectrode loaded with gold nanoparticles (Au-NPs) and co-catalyst via plasmon-induced charge separation.[6,7] However, the electric properties and the reaction mechanism are still unclear because the previous study only analyzed the chemical products. Furthermore, the reaction efficiency was still poor because of the limitation of ion and electron transport path. In this study, we report on a quantitative evaluation of ammonia photoelectrochemical synthesis on a two-electrodes system with the Au-NPs loaded strontium titanate as a plasmon photoanode and a zirconium as a cathode.

The photoelectrochemical nitrogen reduction device using Au-NPs/niobium-doped strontium titanate (Nb-$SrTiO_3$) plasmon photoanode was fabricated as follows. Au-NPs were fabricated on a 0.05wt% Nb-$SrTiO_3$ single crystalline substrate (110) using a sputtering and annealing method. The nitrogen reduction device comprised reaction cells with two reaction chambers separated by ion exchange membrane. The Au-NPs/Nb-$SrTiO_3$ photoanode was installed in the one chamber, and a zirconium coil as a co-catalytic cathode was put in another chamber. The both chambers were filled with an H_2SO_4 aqueous solution without a sacrificial donor. The Au-NPs/Nb-$SrTiO_3$ photoanode was irradiated by a xenon lamp using the visible light, and the cathodic chamber was bubbled with nitrogen gas during the reaction. The photoelectric properties and chemical products of the reaction were monitored simultaneously.

As the results, we have successfully evaluated ammonia photoelectrochemical synthesis quantitatively, such as bias effect, stoichiometry, and intermediate. Also, a novel reaction mechanism of plasmon-induced ammonia

synthesis is proposed.

Surface-enhanced Raman spectroscopy of single-molecules at nanometer and at angstrom-scale

Hyun-Hang Shin, Gyujin Yeon, and Zee Hwan Kim*

Department of Chemistry, Seoul National University

*corresponding author: zhkim@snu.ac.kr

Abstract : A common wisdom of surface-enhanced Raman scattering (SERS) is that the optical property is *completely* determined by the overall geometry of nanostructures (sizes, shapes, and gap-distances) and dielectric constants, despite the fact that real metallic surfaces have atomic surface defect structures and diffuse electron densities extending beyond metallic boundaries. This classical picture of plasmonics leads to the belief that plasmonic length-scale (size of localized field distribution) cannot usually go below ~10 nm. I will demonstrate the use of single-molecule SERS to follow individual chemical reaction events[1], and also spectroscopic evidences that the plasmonic hotspots can be as small as 1 angstrom. I will further discuss its implication in molecular spectroscopy, photochemistry, and nano-scale imaging.

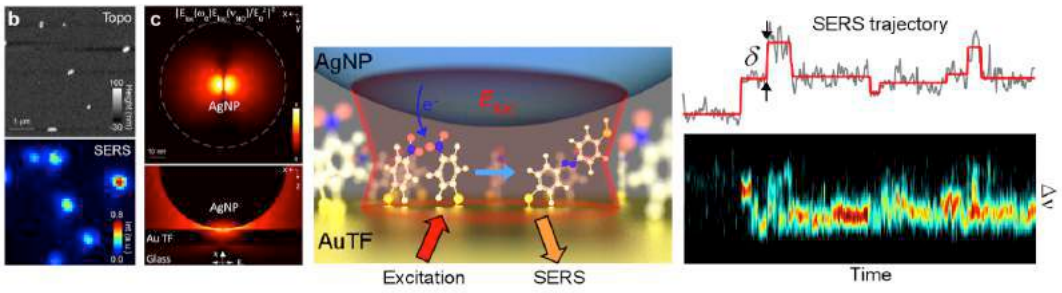

Figure1: Surface-enhanced Raman scattering of individual molecules driven by a plasmonic gap of nanoparticle and a thin film.

Abstract

Composite materials with ordered honeycomb-patterned morphology containing Ag^0 nanoparticles on the surface of carboxylated nitrocellulose matrix were fabricated by a simple solvent-evaporation method at the air/water interface. By annealing initial honeycomb composite structures, thin ordered films of silver nanoparticles were formed. The simulation of optical properties of the obtained structures was carried out and compared to measured spectra.

1. Introduction

Microstructured honeycomb polymer films are of great interest for such fields as microelectronics, biotechnology, and optics, in development of new catalytic systems, sensor devices, and membranes for various functional purposes [1–3]. Honeycomb-structured films with uniform cell size, based on macromolecular compounds, can be prepared by such methods as lithography and microcontact printing [4]. They are based on transfer of a definite pattern from one support to another using a phototemplate or a master [4]. The main advantage of this approach is good reproducibility of the results. However, the process is time-consuming, requires sophisticated expensive equipment and a template, and in the case of lithography is also power-consuming, which restricts its application. It is more promising to prepare honeycomb-structured films by self-assembly of water microdroplets under the action of humid air on a liquid polymer film formed on the water surface [1–3].

Nanoheterogeneous composite materials with metal nanoparticles entrapped in the dielectric polymer matrix deserve attention in electronics and photonics due to their unusual photo- and electric properties caused by the mutual influence of the matrix and nanoparticles. The methods for forming metal coatings on polymeric materials are quite varied: thermal vacuum [5], electrolytic [6], and chemical deposition of metals [7]. One of the promising methods is the chemical metallization, which allows to obtain a uniformly thick coating on the surface of products of not only planar, but of complex form, as well as to apply a metal by selective surface activation.

2. Fabrication procedure

Honeycomb-patterned polymer films were prepared by water-assisted method [8] from carboxylated nitrocellulose (CNC). On the first stage, CNC solution (2 wt.%) in binary solvent (*i* amylacetate:*n*-buthanol at a volume ratio 3:1) was cast on a surface of cooled water (1-3°C), spread and formed thin polymer film on the water surface. On the second stage, formed liquid polymer film was blown by humid air (relative humidity was 75 %). Water microspheres are formed by the condensation of water microdroplets from humid air at the air:polymer solution interface. The honeycomb-like porous structure of polymer appears after complete evaporation of organic solvent. Such hexagonal packing results from the tending of the system to free surface energy minimization.

Deposition of silver nanoparticles on the surface of honeycomb films was carried by electroless plating. Polymer film was immersed into silver nitrate solution (10 mg/ml, 5 min) followed by the reduction of the adsorbed Ag^+ by sodium tetraborate (0.5 mg/ml, 5 min):

$Ag^+ + BH_4^- \rightarrow Ag^0 + BH_3$.

Morphology of formed films was studied by atomic force microscopy (AFM) using scanning probe microscope (Multimode III, VEECO Metrology Group, USA) in tapping mode. Scanning conditions: TappingMode Etched Silicon Probes with stiffness in the 20-80 N/m, a resonance frequency of 330 kHz and tip radius of 8 nm. Scanning electron photomicrographs of the samples was obtained on microscope S4800 (Hitachi, Japan), equipped with a module for X-ray fluorescence analysis (XRF, Avalon-8000, Japan).

3. Structural characterization

Realization of honeycomb structure is a result of self-organizing process during condensation of water microdroplets on the evaporative cooling surface of the polymer solution. Because of the larger density of water than a polymer solution, microdroplets are dipped into a

liquid polymer film and kept in it by surface tension forces. The water microspheres pack in hexagonal array on the surface of polymer solution in self-organization process induced by thermocapillary convection in the evaporating polymer solution. Figure 1 shows an AFM image of the obtained honeycomb film having open spaced hexagonal structure. The structure consists of circular pores of nominal pore diameter about 0.8 μm, separated by a distance about 0.5 μm (Fig. 1).

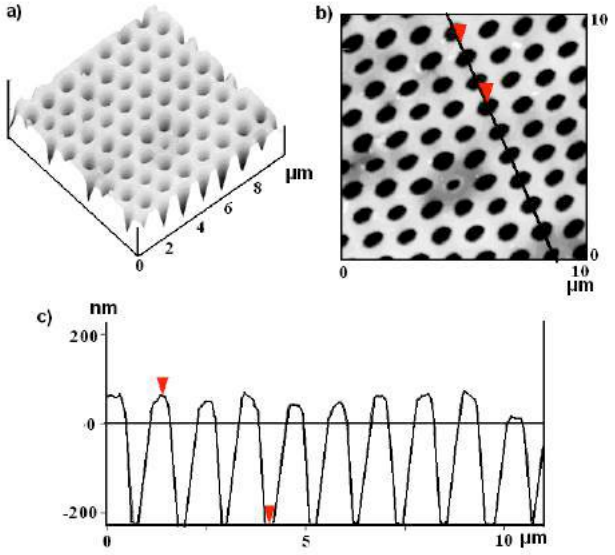

Figure 1: 3D (a) and two-dimensional (b) AFM images of an ordered honeycomb film along with a section profile of surface (c).

The surface of formed ordered honeycomb film was modified with silver nanoparticles by chemical reduction of Ag^+, adsorbed on the polymer matrix (Fig. 2). It was determined that a key factor which affects the selectivity of the Ag^0 deposition on the surface of honeycomb film is the duration of its treatment with $AgNO_3$ solution. Thus, the optimal conditions of modification of ordered honeycomb films by silver nanoparticles are the treatment the initial polymer films with silver nitrate solution for 5 minutes with subsequent treatment with reducer (sodium tetraborate) for 5 min. Such composite films represent the honeycomb polymer matrix the surface of which is covered with a uniform layer of silver nanoparticles.

According to atomic force microscopy (AFM) data the obtained composite samples represent polymer film coated with silver nanoparticles having the pore size of 700-800 nm, the depth of the cells of 650-700 nm and the distance between them 450-490 nm (Fig 2a). Silver nanoparticles with a diameter of ~ 20 nm are also visualized on the surface of the polymer honeycomb films on scanning electron micrographs of the modified samples (Fig. 2b).The presence of silver nanoparticles is also confirmed by X-ray fluorescence analysis. As compared with the XRF spectrum of the initial polymer honeycomb film, in the spectrum of modified sample appears characteristic lines of silver (Fig. 3).

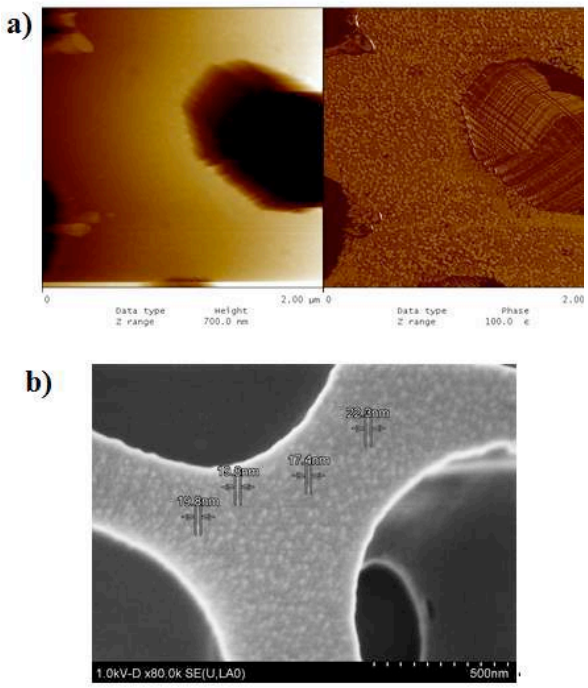

Figure 2: AFM (a) and SEM images of composite honeycomb CNC film with Ag nanoparticles

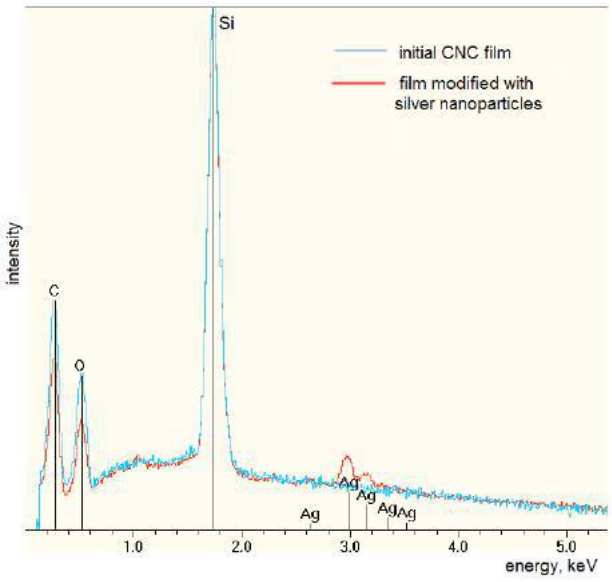

Figure 3: XRF spectra of initial and modified by silver nanoparticles honeycomb CNC films

Thermal decomposition of the polymer matrix results in forming of single-layer film of silver nanoparticles. Thus, after the annealing of honeycomb CNC film modified with

Ag nanoparticles at 200 ºC for 1 hour a layer of silver (thickness is about 15 nm) we produced a nanoparticle distribution that had periodic pattern replicating the projection of initial ordered structure of polymer film on a substrate (Fig. 4).

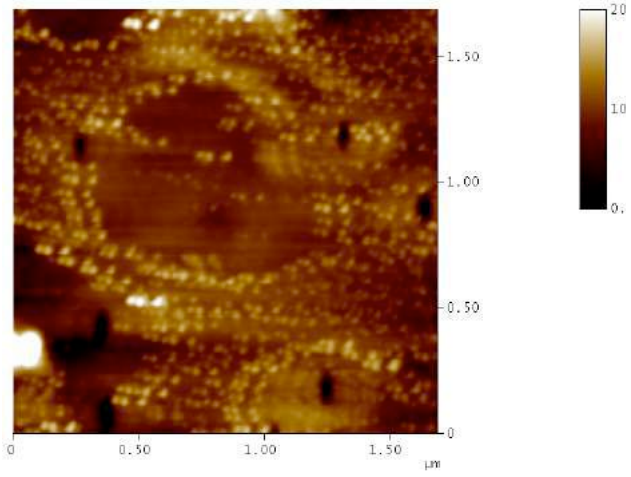

Figure 4: AFM-image of CNC film modified with Ag nanoparticles after annealing at 200 ºC for 1 hour

4. Simulation

Simulation of optical characteristics of the structure was made using FS in CST with periodical boundary conditions. The configuration of an elementary cell with a periodic structure is shown in Fig. 5.

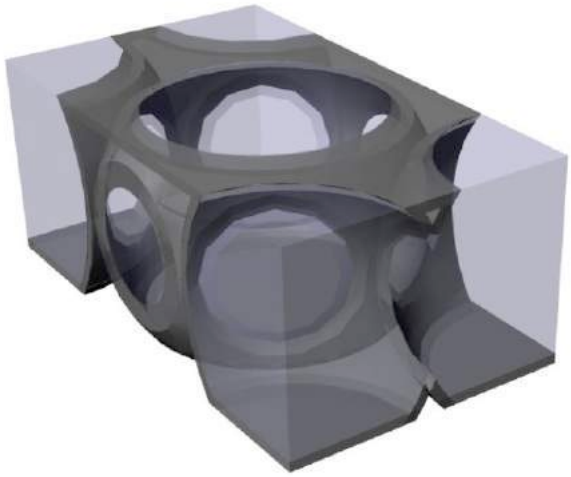

Figure 5: 3D model of polymer carcass coated with silver for simulation of optical properties

The structure is a polymer carcass with spherical crossing pores inside. The carcass is coated with the silver layer with the thickness of 20 nm. The model design describes the structure presented in Fig. 2.

In reflection and absorption spectra (Fig. 6) small region of total absorption within the wavelength of 500-550 nm is presented. For wavelengths smaller than 500 nm resonance peaks are observed, which are conditioned by the ideal periodicity of the simulated structure, and will not be observed in experimentally obtained samples having random deviations in pore gratings.

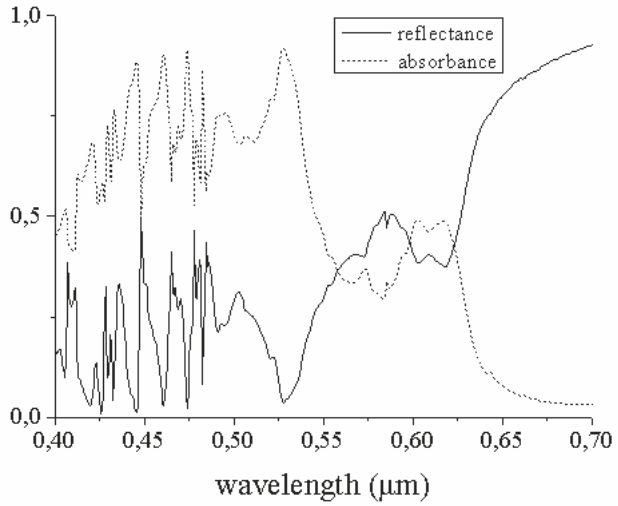

Figure 6: Reflectance and transmittance spectra for the structure shown in Fig. 5

After annealing the particles settle the substrate and form a pattern, which repeats the configuration of pores. The design of an elementary cell, which shows the structure after annealing, is given in Fig. 7.

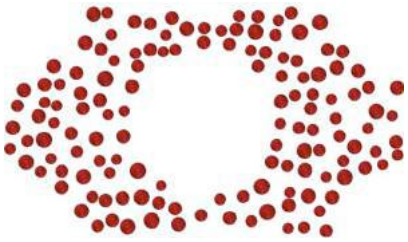

Figure 7: Model of unit cell for simulation optical properties of annealed structures

The diameter of silver particles varied within the region of 40-60 nm. Reflection and transmissions spectra of the structure on the basis of silver nanoparticles were calculated (Fig.7). Using these spectra the efficient refraction coefficient was calculated (Fig.8.).

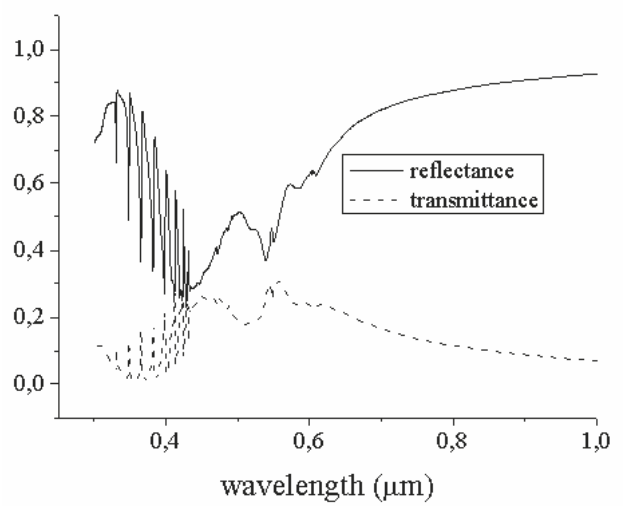

Figure 8: Simulated reflectance and transmittance spectra for the structure shown in Fig.7

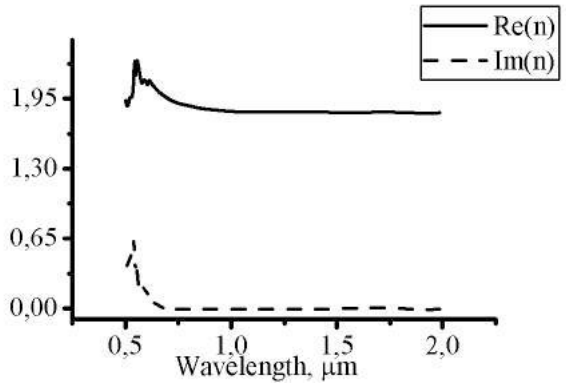

Figure 9: Simulated effective refractive index of the structure after annealing.

In plots (Fig. 8, 9) the structure on the basis of a monolayer of nanoparticles does not possess the expressed resonance peculiarities. In the plot in Fig. 9 it is seen that in infra-red region the structure behaves as a dielectric with efficient refraction index of about 1.8. To increase extremum of the refraction index within the region of 0.5-0.55 μm it is necessary to enhance the concentration of silver in the structure.

5. Conclusions

Using the solvent-evaporation method composite materials with ordered honeycomb films based on carboxylated nitrocellulose and silver nanoparticles were fabricated. For simulation of optical properties of the obtained structure 3D model of polymer carcass with silver was used.
Simulated reflectance and transmittance spectra for the model structure were compared with the measured spectra.

Recent Advances in Complex Materials and Nanophotonics

A controlled-NOT gate based on THz metamaterials

F.-F. Ren*, W.-Z. Xu, and J.-D. Ye

School of Electronic Science and Engineering, Nanjing University, Nanjing 210093, China
*corresponding author: ffren@nju.edu.cn

Abstract- We demonstrate a double-layer bi-anisotropic metamaterial showing strong asymmetric polarization rotation, which can realize a controlled-NOT gate logical transformation between two orthogonal linear polarizations around 0.53 THz. Such a 3D chiral metamaterial opens up new opportunities for the construction of high efficiency optical logic processors towards ultrafast data transmission and information processing.

Logical operation based on polarization encoding of light is important for future data transmission and information processing [1]. However, in the terahertz (THz) region, chiral materials with large optical activity are not available in nature, and achieving effective manipulation of polarization states remains challenging [2]. In this work, we propose and demonstrate a 3D asymmetric THz polarizer composed of a double-layer metamaterials by the combination of a planar spiral structure and a cut-wire structure, separated by a highly stable and low-loss polyimide dielectric layer. The excellent transformation properties between polarizations transmitted through this structure demonstrate a superior CNOT gate functionality [3], which offers a new approach for future all-optical ultrafast computing technology.

Theoretical design and device fabrication. The transmission properties of coherent light through the proposed asymmetric metapolarizer can be studied in terms of a complex Jones matrix [4]. To realize asymmetric polarization rotation and its application as a polarization-encoded CNOT logic gate, a possible way is to have $|T_{yx}| > |T_{xy}|$ when $|T_{yy}| \approx |T_{xx}|$. Based on simulations with the commercial software CST MICROWAVE STUDIO, the designed parameters can be chosen and optimized. The fabrication procedure is performed on on 500 μm-thick quartz substrate with standard photolithography and lift-off technique. which is quite simple and importantly compatible with processing techniques used in traditional semiconductor industries.

Asymmetric transmission measurement. The transmission coefficient measurements were conducted with Advantest TAS7500SP THz TDS system utilizing two femtosecond lasers. The transmitted THz signal was collected by a photoconductive antenna-based THz detector, in which the pulse component was synchronized with another femtosecond laser pulse. When THz radiation propagates along the +z direction, the simulated cross-polarization transmission coefficient |Txy| in the spectral range from 0.4 to 0.7 THz is compressed below 0.22 and reaches its minimum value of 0.06 at 0.53 THz. At the same time, the cross-polarization transmission coefficient |Tyx| yields a transmission peak at the frequency of 0.53 THz with maximum value of 0.62, indicating effectively asymmetric transmission of linearly polarized waves.

Properties of the CNOT gate. On the basis of the characteristics of transmission spectra, the potential application of the metamaterials as a basic optical CNOT gate can be explored. For each of the four possible

logical basis input states |C>|T>=|CT>=|00>, |01>, |10>, and |11>, the output states would be |00>, |01>, |11>, and|10> correspondingly, which indicates that the behaviors of our scheme satisfies the criteria for two-qubit optical logic gate and works as a CNOT gate very well.

Abstract-Understanding and controlling the light-matter interaction is of fundamental importance for science and technology. Scenarios involving nanoemitters and nanoantennas are nowadays routinely measured in the lab. However, interpretation of the observations is not always straightforward. We will show here how conformal transformation can be used to provide an analytical description of the commonly used bowtie nanoantenna and its trimer counterpart.

Most recent effort in nanophotonics and nanoplasmonics has been directed toward fabrication advancements. Very complex structures have been realized experimentally and their properties are routinely measured [1]. In combination with simulations the community has gained significant insight on the physics at the nanoscale [2],[3]. However, further insight could be gained if analytical descriptions of practical scenarios are laid down. In addition, an analytical frame would speed up the design procedure.

Transformation optics attracted the attention of the research community when it was used as a design tool for invisibility cloaking [4]. More recently, this technique has shown great promise to understand plasmonic nanoantennas [5], bridging the void of analytical tools at the nanoscale. Motivated by this, we looked at conformal transformation to provide an analytical description of two-dimensional bowtie nanoantennas [6]. Here, we extend this work on bowtie nanoantennas and investigate the underlying physics in trimers. We restrict ourselves to two-dimensional nanoantennas operating in quasi-statics to keep the analytical character of the results.

The bowtie nanoantenna and its trimer counterpart are complex geometries to handle analytically. However, by applying the conformal transformation $z = \ln(z')$, where z and z' are the spatial coordinates in the transformed and original frame respectively, the nanoantennas are mapped into an infinite array of metal slabs. If the nanoantennas are excited by a single nanoemitter modelled as a line dipole, such line dipole is transformed into an array of line dipoles; for the bowtie, the unit cell with periodicity 2π in the transformed space will be comprised of two metal slabs, whereas for the trimer, it will include three metal slabs. By virtue of the conformal transformation and the quasi-static treatment, the power dissipated in the original and transformed frames are identical. The latter can be computed by simply evaluating the electric field at the dipole position:

$$P_{nr} = P_{abs}^{(x',y')} = P_{abs}^{(x,y)} = -\frac{1}{2}\omega \mathrm{Im}\{p_x E_{1x} + p_y E_{1y}\} \quad (1)$$

where P_{nr} is the nonradiative power emission by the dipole, ω is the angular frequency, p_x and p_y are the components of the emitter dipole moment along x and y directions, and E_{1x} and E_{1y} are the components of the electric field along x and y in the region of the z plane where the line dipole is located.

Figure 1 shows the nonradiative Purcell enhancement (P_{nr} normalized to the 2D dipole radiation $P_0 = 1/16\omega^3\mu_0|p|^2$; μ_0 is the free-space permeability and $|p|$ the magnitude of the dipole moment) for an aluminum bowtie and its trimer counterpart as a function of the nanoemitter orientation. The extra arm of the trimer yields a significant increase of the nonradiative Purcell enhancement and makes the nanoantenna more robust to the dipole orientation [7].

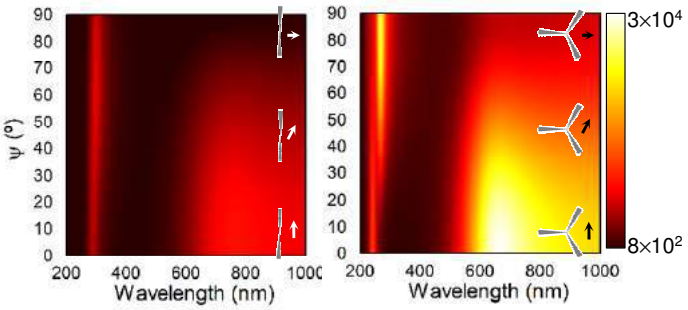

Figure1. Nonradiative Purcell enhancement spectra for an 8nm-arm aluminum dimer (left) and trimer (right) under different emitter orientation excitation.

Non-reciprocal optical effects in nanostructured materials.

T. Verbiest*, T. Swusten, and W. Brullot
University of Leuven, Chemistry department, Belgium
*corresponding author: Thierry.verbiest@fys.kuleuven.be

Abstract-We will discuss nonreciprocal optical effects that we have observed in (chiral) nanostructured materials composed of Au, Ag and Fe_3O_4 nanoparticles.

Hybrid nanomaterials that combine different functionalities are currently of great interest. We recently developed a self-assembly method to prepare multi-layered nanostructures composed of Ag, Au and Fe_3O_4 nanoparticles that are linked together by organic molecules. Such structures combine plasmonic and (superpara)magnetic properties and they can show unusual optical properties that cannot be observed in classical materials (1).

We are particularly interested in nonreciprocal optical effects such as Faraday rotation. In this case an external magnetic field is used to induce optical rotation. The effect is non-reciprocal since the optical rotation adds up when the light travels back and forth through the sample. Faraday rotation is heavily used in optical isolators. We will show that our hybrid materials exhibit extremely strong Faraday rotation due to the presence of the superparamagnetic iron oxide and strong plasmonic enhancement due to gold and silver. Possible applications are extremely small optical isolators or magnetic field sensors.

Faraday rotation is not the only nonreciprocal optical effect that can be observed. Another one is asymmetric light transmission i.e., the dependence of optical transmittance on the direction of light propagation in the material. The effect is induced by the presence of strong quadrupolar interactions in these plasmonic materials and no magnetic field is required. We observed asymmetric transmission effects as large as 10%. The effect can be used in optical isolators or photonic circuits.

When the hybrid structures are impregnated with chiral molecules, additional nonreciprocal optical effects can be observed: in addition to natural optical rotation (which is reciprocal) we also observed a nonreciprocal optical rotation component that is of the same order of magnitude as the natural optical rotation. Like for asymmetric transmission, the origin of the nonreciprocal natural optical rotation is the existence of strong quadrupolar interactions in the material.

Exploiting complex media with random nanoparticles with the principle of inverse scattering

Y. K. Park[1*]
[1]Department of Physics, KAIST, Daejeon, Republic of Korea
[*]corresponding author: yk.park@kaist.ac.kr

Abstract- We will present the applications of inverse scattering principles with digital holography. Scattering of light in complex media or biological samples can be reversed and controlled by actively controlling the wavefront of incident beams. Utilizing multiple light scattering on purpose, we demonstrate 3-D holographic microscopy, the sub-wavelength focusing and imaging, the reference-free optical phase conjugation, the reference-free holographic camera, and ultra-high definition dynamic 3D holographic display

In this talk, we will present the applications of inverse scattering principles with digital holography. First, I will present the recently developed 3-D holotomography setup using a dynamic mirror device, which is an optical analogous to X-ray computed tomography. In particular, I will discuss the visualization of 3D refractive index distributions of biological cells and tissues measured with the 3-D holotomography using the transfer function method. For a weakly scattering sample, such as biological cells and tissues, a three-dimensional refractive index tomogram of the sample can be reconstructed with the inverse scattering principle from multiple measurements of two-dimensional holograms. The outcome demonstrates outstanding visualization of 3D refractive index maps of live. In addition, we also discuss the applications of inverse scattering principle for highy scattering layers. With wavefront shaping techniques using digital holography, we demonstrate ultra-high-definition dynamic holographic display exploiting large space-bandwidth in volume speckle. Exploiting light scattering in diffusers, we also demonstrate the holographic image sensor which does not require for the use of a reference beam.

Abstract- The resonant properties arose from the electric and magnetic interactions between the vertical split-ring resonators (VSRRs) and light are theoretically and experimentally studied. Particularly, the magnetic resonance plays a key role in plasmon coupling in VSRRs. We perform several VSRR-based metadevices for practical applications in optical communication frequency such as Fano-resonance, highly sensitive nanoplasmonic sensor, isotropic absorber *etc*.

Split-ring resonator (SRR), a kind of building block for metamaterial unit cell, has attracted wide attentions due to both the electric and magnetic dipolar responses can be excited under proper conditions. Here, different from prior works, fundamental resonant properties and potential applications in novel three dimensional vertical split-ring resonators (VSRRs) are theoretically and experimentally studied. Beside a single VSRR [1], tuning the structural configuration of VSRR unit cells is able to generate various coupling phenomena in VSRRs, such as plasmon hybridization and Fano resonance [2, 3]. Subsequently, the VSRR-based refractive index sensor will be demonstrated. Due to the unique structural configuration, the enhanced plasmon fields localized in VSRR gaps can be lifted away from the dielectric substrate, allowing for the increase of sensing volume and enhancing the sensitivity [4]. We further perform a VSRR based metasurface for light manipulation at optical communication frequency, in which the 2π phase modulation is from the changing of prong length along z-direction [5]. Finally, isotropic VSRRs are introduced by optimizing the structural arrangement within a unit cell for realizing isotropic VSRR-based perfect absorbers [6, 7].

Translation Matrix for Anisotropic Metamaterials

K. Vytovtov[1*], S. Zouhdi[2] E. Barabanova[1]

Abstract-Stratified anisotropic metamaterials with *N* cells within a period were *N* is an arbitrary number are studied in this paper. Bandgap structure of such materials is under our consideration. The accurate analytical method of investigating is obtained for the first time. The new sign-functions are introduced. It is found that change of the arrangement of cells doesn't affect bandgap structure of metamaterials. It also is shown that boundaries between passband and stopband are resonance characteristics of plane parallel resonator filled by stratified metamaterial. Moreover change of a layer arrangement doesn't affect the resonance characteristic of a device. Analogous properties are observed in Bragg filters and periodic waveguide structures.

Periodic anisotropic metamaterial are very important to produce various microwave, optical devices, and nanostructures [1,2] therefore investigation of these is relevant now.

To study various anisotropic periodic structures the translation matrix method is most widely used. However the matrix has been obtained and analyzed in detail for double-layered period as rule. The translation matrix for a *N*-layered isotropic structure has been presented in [3] and for a longitudinal magnetized ferrite it has been given in [4]. Bianisotropic stratified media have been described by using such a matrix in [5].The translation matrix for a stratified anisotropic metamaterial structure has been offered in [6]. However in that work the matrix has been written for a single layer. Moreover the authors have considered uniaxial anisotropy only. But metamaterials obviously are bi-axial anisotropic. It is very important advantage that the method presented here is accurate analytical and the translation matrix is obtained in elementary functions.

In this paper we study wave behavior within stratified anisotropic metamaterial. Each sell of a structure is described by the dyadics

$$\bar{\bar{\varepsilon}} = \begin{vmatrix} \varepsilon_{xx} & \varepsilon_{xy} & 0 \\ -\varepsilon_{yx} & \varepsilon_{xx} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{vmatrix} \quad \bar{\bar{\mu}} = \begin{vmatrix} \mu_{xx} & \mu_{xy} & 0 \\ -\mu_{yx} & \mu_{xx} & 0 \\ 0 & 0 & \mu_{zz} \end{vmatrix} \tag{1}$$

with negative components ε_{xx}, μ_{xx}, ε_{zz} and μ_{zz}. In general case the dyadic components can be complex values. Note that here we take into account the effective parameters of a medium only.

In our work the translation matrix in the accurate analytical form is presented for the first time. The offered method can be used for various metamaterial structures as the translation matrix of a single sell is the same for them. The translation matrix is written here as the sum of the 2^N matrix group. Each group contains the 2^{N-1} matrix. Therefore we can say about 2^{2N-1} independent waves within a structure that is devided in 2^N group. On other words we can say about a *q*-th independent wave of a *p*-th group. Let us call these waves as equivalent waves. The contribution of each wave is presented by the coefficient that we call as the contribution rate. Here we also use two sign-functions

$$f_{q,j} = \text{sign}\left\{\sin\frac{\pi}{2^{N+1-j}}(2q-1)\right\} \quad (2)$$

$$F_{p,j} = \frac{1}{2}\left(1 + (-1)^{k_j+1} \times \text{sign}\left\{\sin\frac{\pi}{2^{N+1-j}}(2q-1)\right\}\right) \quad (3)$$

The function (2) has been described in [3] in detail by us. The function (3) has been introduced in [5], but it will be described here for the first time. The equivalent waves are the result of interaction of sell eigenwaves as the electromagnetic thicknesses of these are the algebraic sum of the thicknesses of the eigenwaves. Herein two eigenwaves of a same sell don't interact with each other. The function (3) establishes the arrangement of eigenwave interaction. Within each group, the wave electromagnetic thickness and the contribution ratios are different. These values are depended on a sign, which is taken for the sell electromagnetic thickness. It is obtained that within each group the signs vary in binary law. These changes take into account by the sign function (2).

Here it is found that change of sell arrangement does not affect bandgap structure if a period length is invariable. The analytical proof of this phenomenon for an isotropic medium has been presented in [6]. Now we also have obtained the accurate analytical foundation of this property for an anisotropic metamaterial.

The property described for an infinite anisotropic metamaterials can find the practical applications. Indeed Bragg filter based on an anisotropic metamaterial is a periodic structure and wave behavior in such a structure can be described by the differential equations. Therefore bandgap structure can be found from analysis of eigennumbers of the translation matrix. It is important that geometry of a studied filter can be more complicate than it has been studied early. Here a period is N-layered. Analogously a waveguide with variable section and a waveguide filled by periodic anisotropic metamaterial are described by constitutive relations (1) can be described by the obtained translation matrix.

It is found that the boundaries between passband and stopband are the resonance characteristics of a plane parallel resonator filled by inhomogeneous anisotropic metamaterial. Accurate mathematical proof of this property will be given here.

Abstract: We present a wide-field, high-throughput optical technique for locating solid-state quanutm emitters with <10 nm accuracy, and apply it in the creation of micropillar sources with near-optimal single-photon emission.

Solid-state quantum emitters, especially epitaxial quantum dots (QDs) with large optical oscillator strength, are a promising candidate for future on-chip quantum devices. However, the deterministic creation and eventual scalability of single QD devices greatly suffers from the random nature of the QD positions produced in their self-assembled growth. To address this, a variety of approaches for locating such QDs prior to device fabrication have been reported, and mostly rely on scanning techniques (such as confocal microscopy [1] or cathodoluminescence [2]), resulting in relatively low throughput and long acquisition time. Among different positioning methods, photoluminescence imaging is particularly appealing as it can combine high accuracy, short integration time, and wide-field capability in a simple setup [3, 4]. Here, we present a new high-performance system for nanoscale location of QDs based on photoluminescence imaging. This system exhibits improved positioning uncertainty and shorter acquisition time (3× lower and 100× shorter, respectively) than the first generation setup reported in Ref. [4]. We demonstrate its use in the creation of state-of-the-art single-photon sources, based on micropillar cavities, that emit bright, pure, and Purcell-enhanced indistinguishable photons [5, 6].

In our approach, schematically depicted in Fig. 1(a), a 630 nm LED is used to excite all of the QDs within the system's field of view (typically $\approx$ 60 μm × 60 μm), while a long wavelength LED simultaneously illuminates the sample. Emitted light from the QDs and reflected light off the sample are directed through one or more filters to reject light from the short wavelength LED before going into a sensitive electron-multiplied charge-coupled device (EMCCD) camera, or are coupled into a single mode fiber and sent to a grating spectrometer for spectral analysis. Placing the objective in close proximity to the sample allows for the use of a high NA (0.9), which both increases the solid angle over which emitted photons are collected, and also increases the LED intensity at the sample, ensuring that

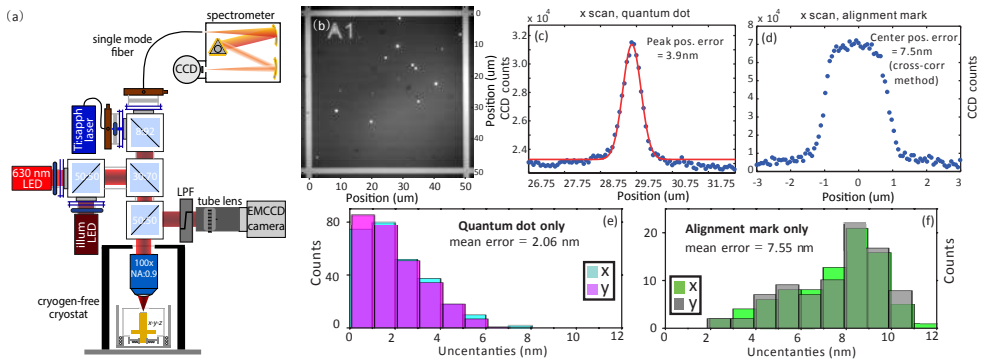

Fig. 1. (a) Schematic of the photoluminescence imaging system. The sample is on a x-y-z positioning stack within a 4 K closed-cycle cryostat. Hanging above the sample, within the cryostat, is a 100× magnification, 0.9 NA microscope objective. Two different color LEDs are combined on a 50:50 beamsplitter and sent into the objective to excite the quantum dots (QDs) and illuminate the sample, respectively. (b) Typical image of the QD photoluminescence and alignment marks taken by the setup. (c)-(d) One-dimensional line cut (along the x-axis) of the (c) QD emission and (d) light reflected off an alignment mark. (e),(f) Histograms of the uncertainties in the QD and alignment mark locations across multiple samples.

saturation of all QDs within the field of view can be achieved. Furthermore, the absence of optical windows between the objective and the sample leads to higher quality imaging. One example of an optical image used for positioning is shown in Fig. 1(b), where the image is taken within 1s and without EM gain. Figures 1(c)-(d) show horizontal line cuts through the QD and alignment mark from the image. Through maximum likelihood estimation and a cross-correlation method, uncertainties of 3.9 nm and 7.5 nm in the center positions of the QD and alignment mark have been obtained, respectively. We also show the statistics of our positioning technique in Fig 1(e),(f), where the mean uncertainties for QD and alignment mark are 2.06 nm and 7.55 nm respectively.

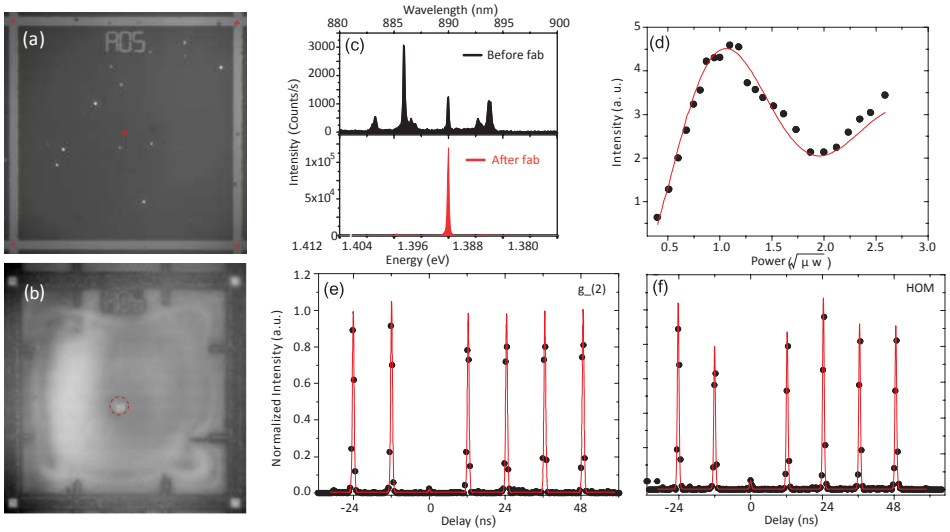

Fig. 2. (a) Photoluminescence image for quantum dot (QD) position extraction. The four alignment mark centers and center of the field are denoted by the red crosses and star, respectively. (b) Photoluminescence image of a micropillar highlighted by the red circle with a single QD in the center. (c) Spectra of the selected QD before (above) and after (below) fabrication of the micropillar. (d) Measured count rate on the spectrometer versus the pulse area of the resonant driving laser field. (d) 2^{nd} order autocorrelation histogram for pulsed resonant excitation with a π-pulse. (e) Histogram of HOM interference with the 12.2 delay time. Photons with parallel polarization are prepared here.

We apply our approach to the creation of micropillar cavities that contain a single QD in their centers, for use in triggered single-photon generation. Figure 2(a)-(b) shows the optical images of our device before and after the micro-pillar etching process. Before fabrication, individual QDs can be clearly identified while only the selected QD is located in the center of the pillar after the dry etching process (this QD was chosen based on its spectral location corresponding to the expected resonance location of the micropillar cavity). A direct comparison of micro-photonluminescence spectra of the positioned dot before and after fabrication suggests that the targeted exciton emission is greatly enhanced by the micropillar cavity structure, as shown in Fig 2(c). Lifetime measurements (not shown) further support this point, with a radiative lifetime of $\approx$ 100 ps corresponding to a Purcell factor of $\approx$ 7.8. Resonantly exciting the QD with a picosecond pulse, we observe characteristic Rabi-oscillation behavior as a function of the square root of the pump power, which is the key signature for the pulsed coherent driving of the two level system, shown in Fig. 2(d). Figures 2(e)-(f) present the second-order correlation and Hong-Ou-Mandel (HOM) interference measurements of the emitted single-photon pulses from the fully population-inverted QD excited by π-pulses at a repetition rate of 83 MHz. $g^{(2)}(0) = 0.015 \pm 0.009$, indistinguishability of (98.5 ± 3.2) %, and an extraction efficiency of (49 ± 4) % within the same device confirms an accurate placement of the QD in the center of the micropillar.

Abstract- In this report, we provide the first experimental demonstration that silicon-based nanoantennas can either enhance or inhibit spontaneous emission from fluorescent molecules at the nanoscale. Using scanning probe microscopy, we analyse quantitatively the near-field interaction between a fluorescent nanosphere and silicon nanodisks in three dimensions.

Mie resonators, or high-index dielectric nanoparticles, have recently been proposed as new building blocks to produce metamaterials[1], metasurfaces[2] or optical antennas[3]. However, all prior studies have focused on the passive resonant scattering properties of dielectric particles without demonstrating their influence on active materials, a property that is crucial for nanoscale photon management. In this report, we provide the first experimental demonstration that silicon-based nanoantennas can either enhance or inhibit spontaneous emission from fluorescent molecules at the nanoscale (**Figure 1**).

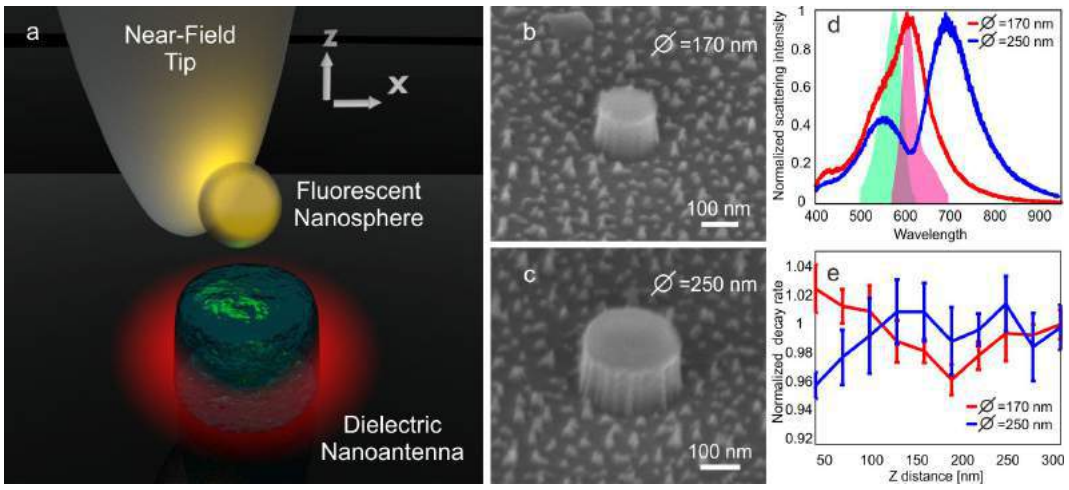

Figure 1: (a) Principal of the experiment: a fluorescent nanosphere is attached at the end of a near-field tip and placed in close proximity to a dielectric photonic antenna. (b, c) Two dimensions of dielectric antennas are considered to be either on resonance or out of resonance at the emission wavelength of the fluorescent nanosphere (d). (e) Enhancement or inhibition of the fluorescent nanosphere spontaneous emission in the vicinity of the dielectric nanoantennas.

Using scanning probe microscopy, we analyse quantitatively the near-field interaction between a fluorescent nanosphere and silicon nanodisks in three dimensions and at the nanoscale. Furthermore,

in this study we highlight the ability of dielectric nanoantennas to increase the far-field collection of spontaneously emitted photons, in excellent agreement with numerical simulations. These results are an essential contribution to the new field of Mie resonators, at the crossroads of plasmonics and dielectric microcavities, as they demonstrate the ability of high-index dielectric nanostructures to manipulate solid-state emitters at the nanoscale and at room temperature.

Abstract— We present recent advances in direct laser writing (DLW) of 3D nanostructures. These require on the one hand sophisticated control of all optical parameters in a DLW system, especially the excitation mode, on the other hand detailed knowledge of the photosensitive material and the structure formation process within this material. Here, we introduce our recent efforts on both: the optics side, including automated aberration correction and stimulated-emission-depletion DLW; the material side, encompassing proximity effect characterization and direct additive metal printing.

Direct laser writing (DLW) [1] – already one of the most versatile technologies for fabrication of 3D nano- and microstructures – has enabled a variety of structures encompassing a large range of applications, including but not restricted to metamaterials, photonic crystals and micro-optics [2]. It is based on tightly focussing a laser beam into a photo sensitive material where via two photon absorption a material change takes place and a structure forms. Despite already being widely applied, there is a demand of yet higher resolution, finer feature details, greater design fidelity, more robustness and specific material properties of these structures. Therefore, ongoing effort is put into improving the DLW system, especially the optical modes [3] (physical approach), and into understanding all processes that lead to structure formation [4] as well as into the development of new photo sensitive materials - the chemical approach.

Here, we present selected routes followed in our group that encompass both, the physical as well as the chemical approach.

On the physical side we introduce a spatial-light modulator (SLM) into the DLW setup. The phase shaping capabilities of the SLM allow sophisticated control of the focal mode. We present automated aberration correction which is applicable in high numerical aperture DLW systems. The iterative correction routine takes the intensity measured in the focal volume as feedback and pre-compensates all major aberrations present in the system using the SLM. We show that the aberration corrected excitation mode allows for substantially increased resolution of grating structures compared to the uncorrected mode.

The SLM not only enables aberration correction of the excitation mode but may be used in stimulated-emission-depletion (STED) inspired lithography. There, a second STED laser mode is overlayed with the excitation mode [5]. The STED mode locally depletes the excited photo initiator and thus locally prevents structure formation. By specifically shaping these modes into, e.g., so-called doughnut or bottle beam modes, finer feature details and higher resolution may be obtained. Here, we show that both, shaping the depleting modes as well as aberration correction of these modes, is possible using the SLM, and that both is necessary to obtain the desired resolution increase in the final structure.

On the chemical side we make use of SLM generated multi foci [6] to take a closer look at the proximity effect. We show that feature sizes and resolution is not only determined by the excitation mode. Rather, the proximity effect plays an important role and contributes to feature sizes in a distinct diffusive spatial and temporal manner [4].

Finally, we present our recent efforts in DLW of metal structures. Hereby, photo sensitive metal salt solutions are developed that undergo a photo induced reduction to neutral metal which then locally agglomerates to form a metal structure [7]. A number of effects, such as charge of metal particles, thermal heating of and scattering by the evolving structure, need to be precisely controlled or avoided.

In conclusion, SLM-based DLW enables accurate control and automated improvement of excitation and depletion modes leading to higher resolution and finer feature details of nanostructures. Furthermore, it allows for determination of spatio-temporal characteristics of the proximity effect which follows a diffusive characteristic in various photo resists. In addition, DLW systems may be used for additive manufacturing of metal structures. There, the reaction leading to the metal structure needs to be photo-initiated and thermal heating needs to be controlled.

Abstract - We demonstrate extremely efficient second harmonic generation (SHG) from monolithic aluminum gallium arsenide (AlGaAs) nanoantennas suspended on a transparent aluminum oxide substrate. When exciting with a pump laser centered at 1554 nm, we obtained SHG with a conversion efficiency of about 10^{-5} for a 1.6 GW/cm^2 pump intensity.

Metal-less nanophotonics has recently raised an increasing interest because the optical response of high-permittivity dielectric nanoparticles exhibits negligible dissipative losses and strong magnetic multipole resonances [1–3] in the visible and near-IR. Here we propose all-dielectric $Al_{0.18}Ga_{0.82}As$-on-AlOx nanodisks, on which we measure second harmonic generation (SHG) with conversion efficiency up to 10^{-5} for a 1.6 GW/cm^2 pump in the optical telecom wavelength range [4].

Our samples were fabricated from a [100] GaAs wafer, with a 400nm layer of $Al_{0.18}Ga_{0.82}As$ on top of an aluminum-rich substrate (see Fig. 1a). The result is an array of nanopillars on an aluminum-oxide (AlOx) substrate. The linear and nonlinear optical response of such nanoantennas are modeled by using frequency-domain finite element simulations in COMSOL [5]. We numerically predict a SH conversion efficiency higher than 10^{-5} for a pump wavelength between 1500 nm and 1700 nm. To experimentally investigate the nonlinear properties of the fabricated nanopillars, we excited them with an ultrafast Erbium-doped fiber laser centered at 1554 nm (150 fs pulses, 80 MHz repetition rate).

The SHG signal was collected from an array of nanocylinders with radius varying from 175 to 225 nm, using single-photon avalanche photodiodes. The dependence of the detected SHG on the radius of the nanocylinders is in excellent agreement with the numerical simulations (see Fig. 1b). The polarization of the emitted SHG, reported in Fig. 1c as a function of the nanodisks radius, is also in very good agreement with the numerical simulations (see Fig. 1d), demonstrating the strong dependence of the SHG polarization from the nanocavity modes involved for specific nanostructures dimensions [6-7].

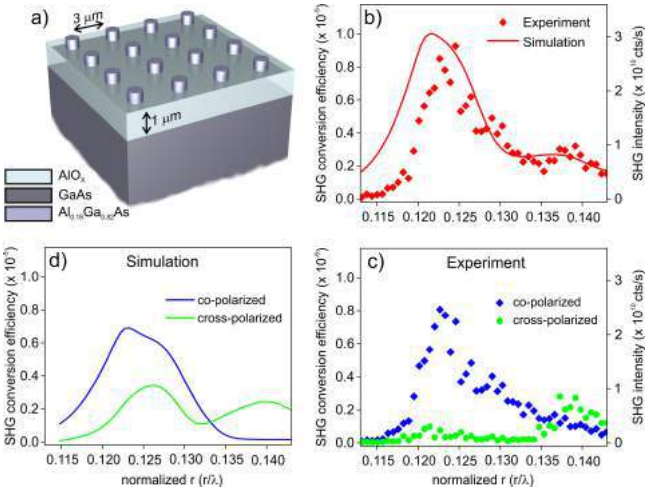

Figure 1. a) Scheme of the fabricated sample of AlGaAs nanodisks on top of a transparent (AlOx) layer. b) SHG conversion efficiency (left) and overall SHG intensity emitted by the nanodisks as a function of the normalized radius (r/λ). Polarized experimental (c) and simulated (d) SHG conversion

Our results allow gaining further insight in the mechanisms underlying the polarized nonlinear emission in these systems, showing the potential of AlGaAs-on-insulator all-dielectric platforms in the nonlinear manipulation of light properties at the nanoscale.

Abstract: We present recent results in the field of hybrid quantum systems. Single photons generated by the resonant pumping of a semiconductor quantum dot are interfaced with alkali atoms in order to realize an efficient variable delay up to a record value of 28 ns. After delaying, two successive single photons are used to perform quantum interference measurements: when only one photon is delayed the indistinguishability is fully conserved while when both are delayed the two-photon interference visibility further increases.

Hybrid quantum systems are attracting increasing attention thanks to their capability of merging the strengths of different complementary fields. In the present case, semiconductor quantum dots (QDs) are interfaced with alkali atoms. QDs are well known to be bright sources of on-demand single and indistinguishable photons. A crucial limitation is set by the relatively short coherence time that can be overcome by using alkali atoms, which display a very long coherence time and can take advantage from the properties of QD-based non-classical light sources [1].

In this direction, we have recently proven an efficient QD-to-atom interface, by filtering two consecutive single photons generated by a resonantly excited QD using of a Cs-based Faraday anomalous dispersion optical filter (FADOF) [2]. The intrinsic tunability of the Mollow triplet allowed tuning the two sidebands in resonance with the Cs-D_1 transition: a simultaneous filtering of both spectral features with more than 10% transmission was achieved, while suppressing all other components below the noise level.

The present study [3] represents a step further in the hybrid QD-atom interface, where the Cs vapor is used as variable optical delay. A tunable, resonantly excited QD is used as source of on-demand single photons, in resonance with the Cs-D_1 transition. We will report on the effect of vapor temperature on the achievable delay for single photons with many different linewidth. A record delay of 28 ns was observed for almost 100% of the transmitted photons (Fig.1 a). The ideal single-photon nature of the emitted photons was proven by autocorrelation measurements ($g^{(2)}(0) \approx 0$) after the interaction of the photons with the atomic vapor.

Photon indistinguishability is another fundamental property for quantum information purposes. In the present study we performed Hong-Ou-Mandel measurements under several different conditions (Fig. 1 b), using the alkali vapor as variable delay line. When both successively emitted photons are delayed, an increase of the photon indistinguishability is observed: we attribute this finding to a photon wavepacket "filtering" effect. It is worth noting that when only one photon is delayed ($\Delta t \approx 3$ ns) the HOM visibility is fully maintained. These findings prove that photons coherence properties are preserved after interacting with the atomic vapor, opening the way to the implementation of vapor-based quantum memories for single and indistinguishable QD photons.

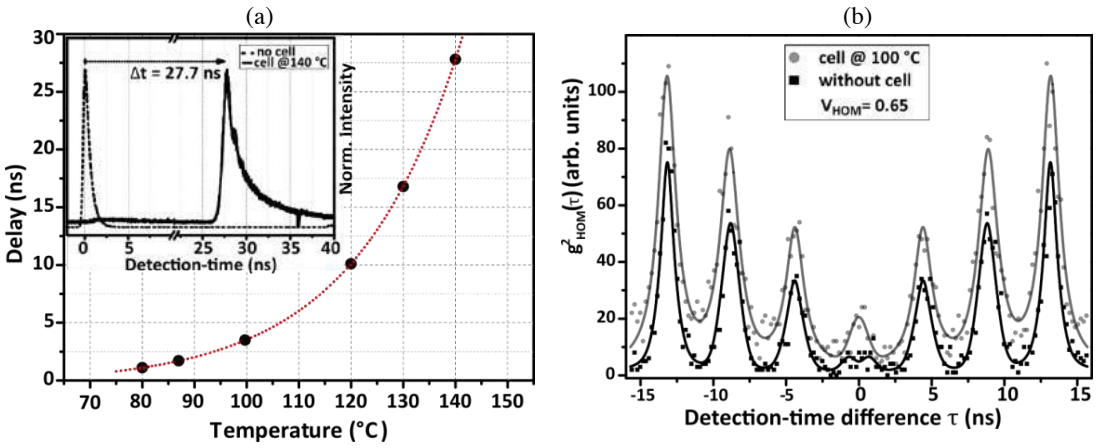

Fig.1 (a) Photon delay as a function of vapour temperature: in the inset the record delay with respect to non-delayed photons is also shown. **(b)** HOM visibility. The black curve shows the reference HOM visibility. Delaying one photon with the vapour and making it interfering with a non-delayed photon results in the HOM in grey. Both visibilities are around 0.65.

Abstract- Metasurfaces consist of flat, ultrathin optical components that can have a functionality resembling that of optical structures that are over an order of magnitude larger in size. These layers enable a significant change in the amplitude and/or phase of the electromagnetic wave within a deeply subwavelength thickness. Separately, photodetectors and other optoelectronic devices are used to detect photons through creation of charge carriers in a semiconductor. In this talk, I combine these concepts and discuss the use of lossy, ultrathin film metasurfaces for the generation of hot carriers, and their subsequent collection, enabling compact polarization and wavelength selective optoelectronic components.

Perhaps the simplest form of a metasurface is an ultrathin, lossy film, which can enable a nontrivial phase change upon reflection that differs significantly from zero or pi. With proper design, these structures can enable nearly complete absorption in an ultrathin film. In cases where the absorption leads to excited free charge carriers, so-called hot carriers, optoelectronic devices can be designed to take advantage of these carriers. When a photon is absorbed within the metallic structure, its energy is transferred to an electron, which is promoted to a higher state within the conduction band (a similar phenomenon can occur for holes depending upon the incident photon energy and the density of states of the material [1]). These excited carriers can typically travel for a few tens of nanometers before collisions cause thermallization. Some fraction of carriers will be able to make it to an interface and, for a metal-semiconductor interface, be injected into the semiconductor, causing current. We have found similar results for thin metal-insulator-TCO (transparent conducting oxide) structures [2-4].

In this talk, I will discuss our recent work on the theory, fabrication, and testing of optoelectronic devices based on metasurfaces. By tailoring the absorption properties of these ultrathin films, both broadband and wavelength selective IR detectors can be fabricated on a Si-based platform. I will also present results of various imaging detectors based on these concepts.

Abstract— We illustrate an active loss compensation scheme for a non-ideal negative index flat lens (NIFL), based on the recently developed plasmon injection or PI scheme. The scheme is applied to an image spectra where, noise similar to real imaging systems, is artificially added. An external auxiliary source is used to amplify high spatial frequency features of the object. The compensation scheme improves SNR and has the potential to be extended to higher spatial frequencies.

Theoretically, a slab of negative (refractive) index material (NIM) can be used to amplify and focus evanescent fields which contain information about the sub-wavelength features of an object [1]. This presents an unprecedented opportunity to overcome Rayleigh's diffraction limit and achieve super-resolution imaging. However, since NIMs are artificially realized with metamaterials which are inherently lossy, compensation of these losses becomes a critical limitation especially under the deep sub-wavelength regime where the Fourier components of the image spectra are suppressed under the noise. A recently developed compensation scheme dubbed plasmon injection [2], was conceptualized with surface plasmon driven NIM [3] and provides loss compensation without using a gain medium or non-linear effects. This scheme was then applied passively as a post-processing technique to reconstruct an object with sub-wavelength features [4]. However, passive compensation (PC) is inherently prone to noise amplification under the deep sub-wavelength regime.

Here, we demonstrate that an external auxiliary source can be used to overcome noise amplification and recover high spatial frequency features of the object, which are buried under the noise. We call this "active" compensation (AC) to distinguish it from passive as in [4]. We define the NIFL imaging system by it's relative permittivity and permeability, $\epsilon_r = \epsilon^{'} + i\epsilon^{''}$ and $\mu_r = \mu^{'} + i\mu^{''}$, with $\epsilon^{'} = -1$ and $\mu^{'} = -1$ and $\epsilon^{''} = -0.1$ and $\mu^{''} = -0.1$. We construct an auxiliary source whose Fourier spectra is

$$A(k_y) = 1 + P_o \cdot exp\bigg[- \frac{(\frac{k_y}{k_o} - k_c)^2}{2\sigma^2} \bigg]. \tag{1}$$

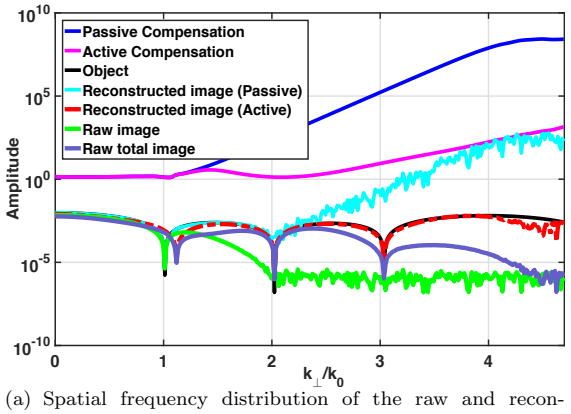
The spatial distribution of the auxiliary is $A(y) = \mathcal{F}^{-1}\{A(k_y)\}$, where $\mathcal{F}$ is the Fourier transform operator, is convolved with the object $O(y)$. The new object, denoted by $O^{'}(y)$, is called the total object and is

$$O^{'}(y) = \int_{-\infty}^{\infty} O(y) \cdot A(y - \alpha) d\alpha. \tag{2}$$

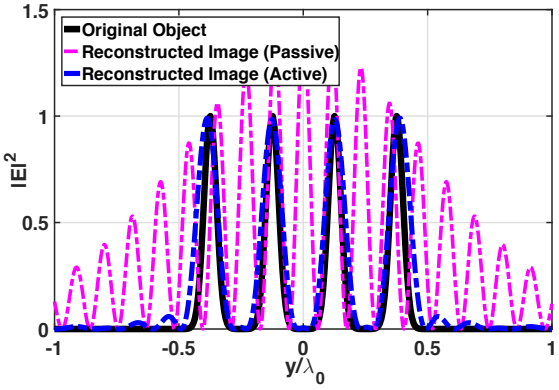
The corresponding image spectra is then determined with the finite element software package COMSOL Multiphysics. Noise is added to the spatial frequency distribution of the image. The noise process is a circular Gaussian random variable at each spatial frequency component. The noisy Fourier spectra obtained from the image plane is

$$I_N^{'}(k_y) = T_P(k_y) \cdot O(k_y) + T_P(k_y) O(k_y) \cdot P_o \cdot exp\bigg[- \frac{(\frac{k_y}{k_o} - k_c)^2}{2\sigma^2} \bigg] + N(k_y) \tag{3}$$

where $N(k_y)$ is the noise. The second term of Eq. 3 represents an amplification effect provided by the auxiliary source. This can be used to recover the spatial frequency components of the image spectra that are buried under the noise by simply controlling the characteristics of the auxiliary, such as its central frequency k_c, the amplification strength P_0 or its full width at half maximum σ.



(a) Spatial frequency distribution of the raw and reconstructed images.



(b) Electric field intensity distribution.

Figure 1: (a) Passive $[T_P]^{-1}$ and active compensation $[T_A]^{-1}$ schemes. PC results in noise amplification in the reconstructed spectra unlike AC. The reconstructed images are obtained by multiplying the raw images with the corresponding compensation filter. (b) AC allows image reconstruction in the deep sub-wavelength regime unlike PC. Note that the passive compensated image has been scaled down by 10^7.

The image spectra given by Eq. 3 is then compensated by the inverse of the active transfer function denoted by $T_A(k_y)$

$$T_A(k_y) = T_P(k_y) + T_P(k_y) \cdot P_o \cdot exp\Big[- \frac{(\frac{k_y}{k_o} - k_c)^2}{2\sigma^2} \Big] \tag{4}$$

to reconstruct the object. The inverse of $T_A(k_y)$ is the active compensation shown in 1(a). $T_P(k_y)$ is the passive compensation in the absence of an auxiliary or when $P_0 = 0$. The resulting compensated Fourier spectra and spatial intensity distribution are shown respectively in figure 1(a) and (b), which shows how AC can reconstruct deep sub-wavelength features while PC fails. Figure 1(a) also shows how AC reveals a spatial frequency feature at $\frac{k_y}{k_o} = 3$ from the noise floor which goes undetected under PC. Moreover, AC significantly reduces noise amplification when compared with its passive counterpart thereby improving the signal to noise ratio of the imaging system.

The AC scheme makes the NIFL imaging system more versatile and opens up new avenues of high resolution imaging in the deep sub-wavelength regime where noise affects the image spectra. We have also identified some potential methods to implement convolution in the spatial domain, metasurfaces being the primary candidate. A more detailed analysis on how to design such a metasurface which can be used to convolve the object with the pump will be the focus of our future research endeavors.

Chirality of topological gap solitons in bosonic dimer chains

D. D. Solnyshkov[1*], O. Bleu[1], B. Teklu[1], and G. Malpuech[1]
[1]Institut Pascal, University Clermont Auvergne, Clermont-Ferrand, France
[*]corresponding author: dmitry.solnyshkov@univ-bpclermont.fr

Abstract-We study gap solitons which appear in the topological gap of 1D bosonic dimer chains within the mean-field approximation. We find that such solitons have a non-trivial texture of the sublattice pseudospin. We reveal their chiral nature by demonstrating the anisotropy of their behavior in presence of a localized energy potential.

A 1-dimensional (1D) periodic lattice with 2 different tunneling coefficients leading to the "dimerization" of the lattice is one of the simplest configurations exhibiting topological properties [1]. The dispersion of such system shows a splitting of a single *s*-type band into two bands, corresponding to the bonding and anti-bonding states of the individual dimers. These subbands are characterized by a topological invariant (the Zak phase [2]). The topology of the gap between them is determined by the Zak phase of the band below. Combining the topology of the lattice with the topology of the excitations of a quantum fluid, such as a Bose-Einstein condensate, is a particularly interesting problem of modern physics.

The properties of nonlinear solutions existing in the internal gap of the *s*-band of the 1D dimer chain can be expected to be strongly affected by its topology. The Su-Schrieffer-Heeger (SSH) soliton is perhaps one of the most famous examples of topologically nontrivial solutions [3] for a dimer chain. However, it involves dynamical dimerization, that is, modification of the properties of the lattice itself (displacement of the lattice sites or modification of tunneling coefficients): this soliton is a domain wall between two distinct lattices, each with its own dimerization order. Such dimerization domains can be observed not only in electronic systems (polymers, as in the original SSH work), but also in artificially created in photonic chains [4]. Recently, chiral solitons of the SSH type were observed in double chains [5].

But there also exist solitonic non-linear solutions, called gap solitons, that do not require the modification of the lattice and do not close the gap, contrary to the chiral edge states and the SSH soliton. Many of them have been studied in dimerized and zigzag lattices in acoustics [6], Bose condensates [7], and photonic systems [8,9], with a particularly interesting recent experimental observation [10]. However, the crucial role played by the anisotropy of the Bloch part of the soliton wavefunction with respect to the two different atoms forming the lattice (and defining the sublattice pseudospin) has remained unnoticed.

In this work [11], we demonstrate that a gap soliton in a single dimer chain can exhibit chirality. We study a gap soliton in the topological gap of a dimer chain, first using the tight-binding variational approach, and then by direct solution of the Gross-Pitaevskii equation with a periodic potential. This solution is strongly different from the chiral SSH soliton [5], because it does not involve the modification of the lattice itself. It is also different from the dark-bright solitons [12], because it does not involve neither the polarization degree of freedom, nor an extended condensate. The topological gap soliton (TGS) is a typical localized solution, appearing from the states at the boundary of a topological gap. We demonstrate that such solitons exhibit a nontrivial pattern of sublattice pseudospin due to pseudospin-anisotropic interactions. We determine their sublattice-polarization degree and demonstrate the chiral nature of these solitons via their asymmetric behavior with respect to a localized defect

(see Figure 1), which gives a striking contrast with the isotropic behavior of non-topological gap solitons (GS). These results are confirmed by direct calculations. A closer look at recent experimental data in a photonic dimer chain [10] confirms our predictions for the chiral nature of the TGS. Our results are valid for any photonic system, such as coupled waveguides [4, 10], and also for atomic condensates out of thermal equilibrium.

We acknowledge the support of the project "Quantum Fluids of Light" (ANR-16-CE30-0021).

Surface plasmon polariton mediated light-matter interactions in monolayer molybdenum diselenide-nanoantenna hybrid structures

Geeta Sharma[1], Astha Singh[1] and Parinda Vasa[1,*]

[1]Department of Physics, Indian Institute of Technology Bombay, Mumbai 400 076, India

[*]corresponding author: parinda@iitb.ac.in

Abstract*:* We report a simple approach to growing large area monolayer molybdenum diselenide films on different substrates using chemical vapor deposition technique. We have investigated surface plasmon mediated light-matter interactions in monolayer molybdenum diselenide-gold nanoantenna hybrid nanostructures. Our results show significant changes in the lattice constant, bandgap energy, photoluminescence lifetime and Raman lines as a direct manifestation of the Purcell effect in MoS_2-nanoantenna hybrid structures. Preliminary studies also offer indications of strong coupling in optimized sample configurations.

Layered materials show remarkable properties when thinned down to monolayer limit because of their two dimensional nature and strong electron confinement [1]. Two-dimensional (2D) monolayers of transition metal dichalcogenides, such as molybdenum diselenide (MoS_2) are currently being paid increasing attention, due to their promising future in next generation electronics and photonics. Particularly, atomically thin MoS_2 films have drawn significant interest due to the remarkable transition from an indirect bandgap to direct bandgap semiconducting material [2,3]. In conventional approaches, MoS_2 layers are synthesized by various techniques such as micromechanical exfoliation assisted by scotch tape, intercalation assisted exfoliation, solution exfoliation, physical vapor deposition, hydrothermal synthesis, sulfurization of molybdenum trioxides, etc. However, the size of MoS_2 monolayers obtained using most of these methods is limited to only a few tens of micrometers, which is not suitable for large-scale integrated device applications. Recently, chemical vapor

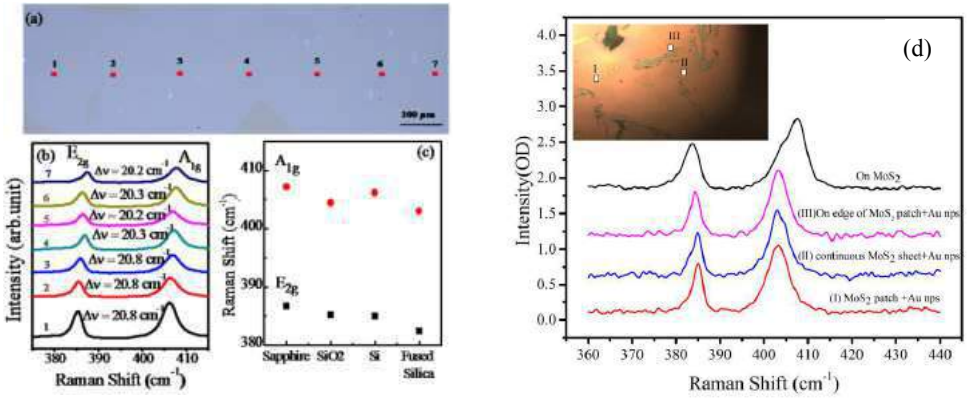

Figure: 1 (a) A large area monolayer MoS_2 film grown using chemical vapor deposition. (b,c) Characterization of the film using Raman spectroscopy, and (d) changes in Raman spectrum of a MoS_2 monolayer due to surface plasmon polariton mediated light-matter interactions.

deposition route has been extensively explored to achieve scalable synthesis of high quality MoS_2 monolayers for the development of practical devices. We have developed a simple chemical vapor deposition approach to growing large area monolayer MoS_2 films on different substrates [Fig. 1(a-c)] by sulfurization of MoO_3 in ambient pressure. Our technique involves relatively lower temperature synthesis [4], and does not require any kind of seeding or elaborate treatment of the substrate surface.

The focus of this work is to investigate nanoscale surface plasmon mediated light matter interactions in MoS_2 monolayer-gold antenna hybrid nanostructures. Elliptical and rod-shaped gold nanoparticles supporting localized surface plasmon (LSP) resonances act as efficient nano-antenna. Due to the strong plasmonic field localization offered by these nanoparticles, we have observed significant changes in the lattice constant, bandgap, photoluminescence lifetime and position as well as the width of Raman lines [Fig. 1(d)]. Our observations are a direct manifestation of the Purcell effect in these MoS_2-nanoantenna hybrid structures [5]. The changes in the bandgap energy, and thus the absorption spectra are also supported by the bandstructure calculations, which take into account the lattice distortions caused by the plasmonic fields. Preliminary studies offer indications of strong coupling in optimized sample configurations [6,7].

Dispersion of the Nonlinear Susceptibility in Single Gold Nanoantennas.

Abstract- We compare the third harmonic generation and incoherent photoluminescence contributions to the nonlinear optical response obtained in individual gold nanoantennas upon illumination with near-IR femtosecond pulses. With this procedure we could extract the dispersion of the nonlinear susceptibility.

Nanoantennas are excellent tools for accessing the nonlinear response of metals owing to the strong enhancement of light-matter interaction occurring in the near-field. For example, excitation of gold nanostructures with intense radiation triggers both coherent and incoherent phenomena such as third-harmonic generation (THG) [1] and multi-photon photoluminescence (MPPL), respectively [2,3]. In this work, we study the interplay between these frequency conversion mechanisms in order to unveil the effective $\chi^{(3)}$ nonlinear response of metals.

In our experiment, we exploit tuneable near-infrared pulses from a femtosecond Er:fiber laser system to excite individual gold nanorods. The resonant antennas are fabricated via electron beam lithography with subsequent evaporation of gold and lift-off. The inset in Fig. 1 (a) shows a typical rod structure resonant at 2000 nm. This simple geometry is chosen since its influence on the spectral shape of the MPPL is well understood [3]. The resulting nonlinear emission of the nanorods under illumination is spectrally resolved, as depicted in Fig. 1 (a), showing the prominent THG peak residing on a broad MPPL output.

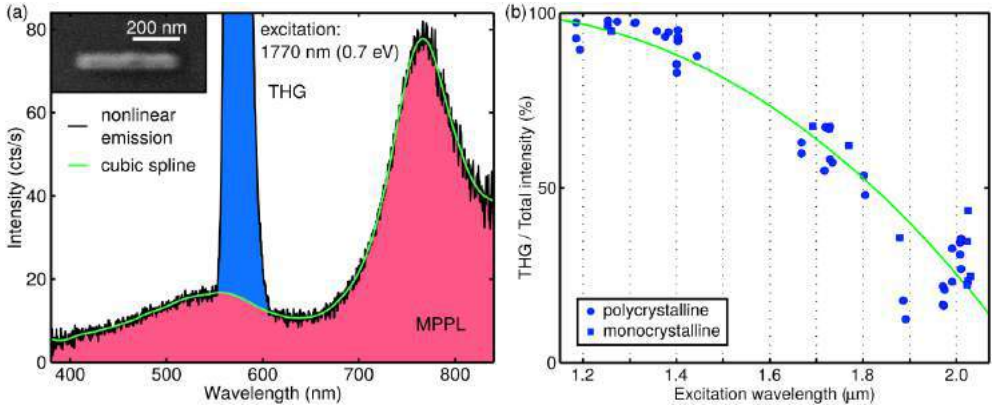

Fig. 1 (a) Typical nonlinear emission spectrum of single polycrystalline nanoantenna (black). The green line separates the coherent THG peak (blue) from the incoherent MPPL contribution (red), so that they can be integrated individually. A SEM micrograph of the corresponding nanoantenna is shown in the inset. (b) Ratio of the integrated THG output vs. the total nonlinear emission. Each data point represents the result from a single individual antenna. The green line serves as a guide to the eye.

The assessment of the nonlinear response of metallic nanostructures is complicated by the simultaneous occurrence of THG and MPPL combined to a field enhancement that cannot be determined with sufficient precision. We circumvent this problem by comparing the yield of the two nonlinear processes in individual gold nanoantennas illuminated by resonant optical pulses. This approach allows us to directly evaluate the susceptibility of gold since the field enhancement is identical for the two processes that are measured experimentally on the very same emitter. Figure 1(b) shows the ratio between the THG and the total nonlinear emission for a large set of antennas, all excited resonantly with pulses of the same temporal duration and peak intensity. This parameter is investigated as a function of the driving wavelength. The experimental results show an overwhelming contribution of the THG to the nonlinearity for short wavelength excitation.

In summary, we have investigated the nonlinear emission of single gold nanorods. By comparing the yield coherent and incoherent processes occurring on the same specimen, we overcome the dependence on the field enhancement. With this procedure we could obtain a fundamental insight in the origin of the nonlinear response by observing a strong dispersion of $\chi^{(3)}$ in THG that becomes more favourable when the fundamental excitation approaches a three photon resonance for the direct excitation of electrons from the d-band to the Fermi level.

Abstract- We use phase-change materials (PCMs) as a switchable dielectric environment for infrared antennas and surface polaritons. Specifically, we combine an ultrathin film of PCMs with a substrate hosting surface phonon polaritons and realize the all-optical, non-volatile, and reversible switching of resonators for these ultra-confined polaritons.

The strong confinement and enhancement of light when coupled to surface waves or nanoparticles is key for various applications in nanophotonics such as sensing, imaging or other devices that enable the manipulation of light fields. In the mid-infrared spectral range, metallic nanoantennas and materials supporting surface phonon polaritons (SPhPs) can be used as building blocks of such devices. In both cases, the optical functionality is usually only obtained at a fixed wavelength, determined by the geometric design and the material properties.

In the first part of this talk, I will present our latest results on active mid-infrared plasmonics, i.e. the tuning of nanoantennas resonances via variation of the refractive index *n* of an embedding medium based on phase-change materials (PCMs) [1,2]. PCMs offer a huge contrast in the refractive index *n* due to a phase transition from amorphous to crystalline state, which can be thermally, optically or electrically triggered. I will show thermal and optical large-area switching of IR antenna resonances as well as individually addressable switching of single structures. Application potential for switchable chirality [3] and switchable detectors [4] will also be presented.

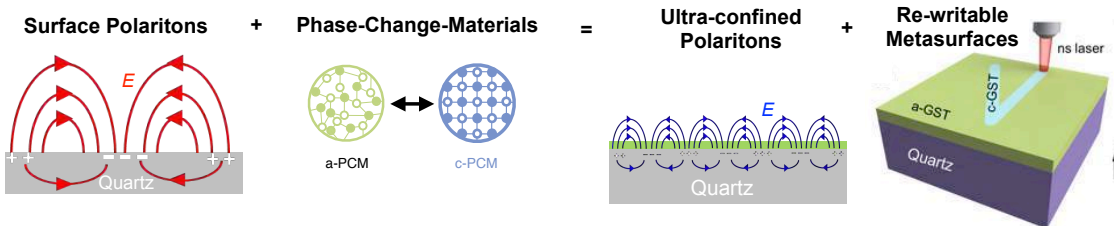

Figure 1: Sketch of our concept of combining Surface Phonon Polaritons (SPhPs) with a thin, switchable layer of Phase-Change-Materials (PCM) for achieving ultra-confined Polaritons and re-writeable metasurfaces.

In the second part, I will introduce Phonon-Polariton-based IR antennas made from polar dielectrics which

exhibit lower losses and larger Q-values compared to metallic nanoantennas. Specifically, we employ a PCM as a switchable dielectric environment for loading the SPhPs [5]. This allows us to realize all-optical, non-volatile, and reversible switching of the SPhPs by controlling the structural phase of the PCM. We experimentally demonstrate that single nanosecond (ns) laser pulses can locally switch an ultra-thin PCM (down to 7 nm, < $\lambda/1200$) for exciting ultra-confined SPhPs (polariton wavevector $k_p > 70k_0$, $k_0 = 2\pi/\lambda$) in quartz. This offers a new, elegant way to prepare all-dielectric, optically rewritable SPhP resonators without the need of complex fabrication methods.

Our approach of combining PCMs and SPhPs (Fig. 1) opens up new possibilities for non-volatile, rewritable and active nanophotonics, in particular for re-configurable, digital and memory metamaterials, flat optics and metasurfaces.

Bose-Einstein condensates show many remarkable properties, like superfluidity and excitation of quantized vortices [1]. Exciton polaritons in a semiconductor microcavity provide the opportunities to study Bose-Einstein condensation at a relatively high temperature with direct spectroscopic imaging and optical controllability. Exciton polariton is a hybrid light-matter quasiparticle, therefore the effects of the particle-particle interaction can be explored through its exciton component, while the photon component results in a relatively high decay rates and the need for a continuous pump to maintain the population. Due to the spatial and temporal coherence of the condensed exciton polaritons, their radiative decay results in a coherent photoluminescence of the microcavity, thus forming a polariton laser [2]. The driven-dissipative nature of exciton polaritons offers a platform for investigation of non-Hermitian properties [3] of Bose-Einstein condensate, which can be utilized to study both the fundamental properties of an open non-equilibrium quantum system and future novel optoelectronic or photonic micro-devices.

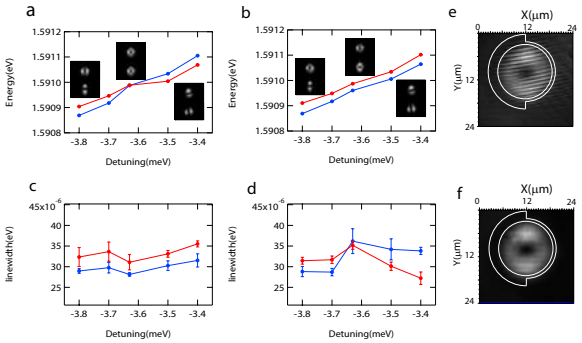

FIG. 1: Experimentally observed crossing-anticrossing transition of the real (a,b) (energy) and imaginary (c,d)(linewidths) parts of the eigenenergies with changing width of the optically-induced potential (white line), schematically shown in (e,f). A vortex mode forms in the vicinity of the exceptional point, as confirmed by the image of spatial polariton density distribution (e) and interference (f) with the reference beam.

In this work, we show the existence of a chiral mode in the form of a single charge vortex in an optically engineered ring resonator. The resonator is formed by a spatially shaped optical pump beam which induces a non-Hermitian trapping potential for exciton-polaritons. The two half rings have different widths, shown schematically in Fig.1(e,f), which affects the overlap of exciton-polariton condensate with the gain region. By adjusting the width of the half-ring and the detuning between the microcavity photon and exciton resonance, we observe the transition from crossing to anticrossing of complex eigen-energies, which signals the existence of an exceptional point. Furthermore, we confirm the formation of a chiral mode - a charge one vortex - at the exceptional point, in analogy with microwave [4] and optical [5] resonators. The fine manipulation of the relative phase between the two dipole modes (see Fig.1(a,b)) offers a new opportunity to control the vorticity and realize the mode switch in a macroscopic quantum system. Our method can be extended to generate high-order orbital angular momentum states through coalescence of multiple non-Hermitian degeneracies, which can find application in optical switching and information processing.

Abstract To investigate internal structures of chiral optical responses in nanomaterials, we developed near-field optical activity imaging systems, and observed near-field CD images of two-dimensional gold nanostructures. Local CD signals with amplitudes as large as 100 times the macroscopic CD signals of the same samples were obtained, even for achiral structures. Furthermore, local linearly polarized near-field excitation of highly symmetric circular disks (that give no local CD signals) yielded circularly polarized scattering fields.

Chirality is a broad concept that characterizes structures of systems in almost all hierarchy of materials in natural sciences. Chirality also plays a key role in nanomaterials science. It is of fundamental importance to investigate internal structures of chiral optical responses in nanomaterials, to design functionality of chiral features of the materials. We developed near-field optical activity (typically circular dichroism, CD) imaging systems, and observed near-field CD images of two-dimensional gold nanostructures fabricated with electron beam lithography technique. We found local CD signals with amplitudes as large as 100 times the macroscopic CD signals of the same samples, for two-dimensional chiral gold nanostructures.[1] Even highly symmetric achiral structures (as typified by rectangular nanostructures) gave locally very strong CD signals,[2,3] as shown in Figure 1. In this case, average of the signal over the nanostructure yielded roughly null CD intensity.

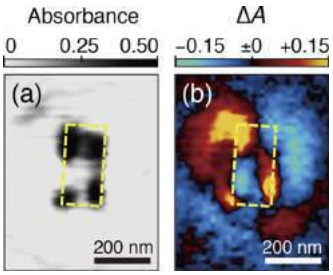

Figure 1. Near-field optical images (at 633 nm) of a gold rectangle.[2] (a) Transmission image. (b) CD image.

While even achiral nanostructures showed local CD activities, circularly symmetric two-dimensional nanostructures, such as circular disks, never give CD at any local positions. However, when the circular disk is illuminated with linearly polarized light, the circular symmetry is broken, and it potentially yields locally chiral optical fields. We extended the near-field CD microscope and conducted measurements of local optical activity for gold nanodisks. It has been found that the disk scattered circularly polarized optical fields when it was illuminated locally with linearly polarized excitation light, and that the ellipticity and the polarization azimuth angle of the scattered field depended on the incident polarization angle and relative position on the disk. The results obtained here may provide basic principle to get highly chiral optical fields, which may give us a chance to pioneer analytical applications of chiral optical fields.

Abstract- The gravitational-like interactions induced by radiation are analyzed analytically a numerically for the particular case of two electric dipoles illuminated with a fluctuating random field

The idea of gravity like interactions induced by radiation dates back to works by Spitzer in 1941 [1]. More recently, the analyses of the interaction between two dipolar particles in isotropic random electromagnetic fields have shown how regions with gravitational like potentials may show up at short distances [2,4]. The interaction between two particles illuminated by artificially generated random fields has been very recently found experimentally [4] and theoretical and numerical analyses have shown that the diffusion properties of a dipole may be tuned also by using random light illumination [5,6].

In this work, we extend the analysis of gravitational-like interactions to more complicated systems [7] and we analyze the dynamics of dipoles explicitly illuminated with a group of fluctuating plane waves with wave vectors, polarizations and phases randomly distributed. Molecular dynamics simulations are implemented, in order to look for the existence of Kepler orbits in such a system.

Abstract - Coherent perfect absorption (CPA) and coherent perfect transparency (CPT) is discussed in 2D structures for instance based on graphene or intersubband transitions of a semiconductor heterostructure. In particular, asymmetric devices are analyzed, either relying on plasmonic resonances, properly engineered in a metal-dielectric metamaterial, or, more simply, constituted by an optically conductive surface on top of a substrate.

The light absorption properties of a system are typically considered an intrinsic material feature, mostly determined by its dielectric constant, thickness, etc. It has recently been shown, however, that full interferometric control of absorption can instead be accomplished by varying the relative phase of two coherent optical fields. Depending on the phase relation, the system can become totally opaque (coherent perfect absorption – CPA) or tuned to complete transparency (coherent perfect transparency – CPT).

These phenomena are now starting to be widely investigated at a fundamental level (CPA is actually considered the time-reversed process of lasing) and in view of innovative applications in plasmonics, or even in diagnostics and imaging techniques where the high selectivity provided by the interferometric absorption control could prove highly beneficial. Here I will discuss CPA and CPT in devices relying on polaritonic resonances, properly engineered in a metal metamaterial on top of a quantum well semiconductor heterostructure. Using diffraction gratings on Gallium Arsenide suspended membranes, "two-beam absorbance" measurements in a counter-propagating Mach Zehnder geometry reveal the absorption phase modulation. Furthermore, we report on experiments of coherent absorption on turbostratic multilayer graphene grown on silicon carbide substrate. From the analysis of the experimental data, the graphene conductance G can be deduced independently of the substrate and, thus, the number of layers N_G can be directly quantified.

For a proper interpretation of the experimental results, a general theory of CPA in linear two-port systems is constructed, without any symmetry requirements except for reciprocity; it demonstrates that optical absorption describes an ellipse as function of the difference between the intensities of the incident beams. The model is interpreted in the polariton case within a standard coupled-mode theory, and allows casting the graphene results in the more general landscape of optically conductive surfaces.

Abstract— Extending nanoplasmonics to the UV-range has awaken a great interest due to the current and potential applications in biological sensing, photocatalysis or spectroscopy. Very recently, rhodium (Rh) has been proposed as a promising candidate for this purpose. Its low tendency to oxidize overcomes the main problem with metals such as aluminum or magnesium. In addition, it presents outstanding catalytic properties. As the synthesis of rhodium nanocubes has been recently reported and because of its UV-plasmonic performance interest, in this research we present an analysis of the plasmonic behaviour of Rh nanocubes aggregates.

Plasmonics in the UV range results of interest in fields such as biological sensing, photocatalysis or spectroscopy [1, 2, 3]. Sanz et al. [4] studied several metals in order to find those whose properties made them more promising for UV-plasmonics. Two of the most compelling metals for this purpose are aluminum (Al) [5] and magnesium (Mg) [6]. However, nanoparticles (NPs) made of these two metals suffer from the formation of a native oxide layer whose thicknes strongly depends on the ambient conditions. Rhodium (Rh) has been proposed as an alternative due to competitive plasmonic performance and its promising properties [7]. On the one hand, it is a non-oxidizing catalytic metal. On the other hand, it is possible through chemical means to synthesize NPs with sharp edges like cubes [8] and tripod stars[9, 7], with sizes down to 10 nm.

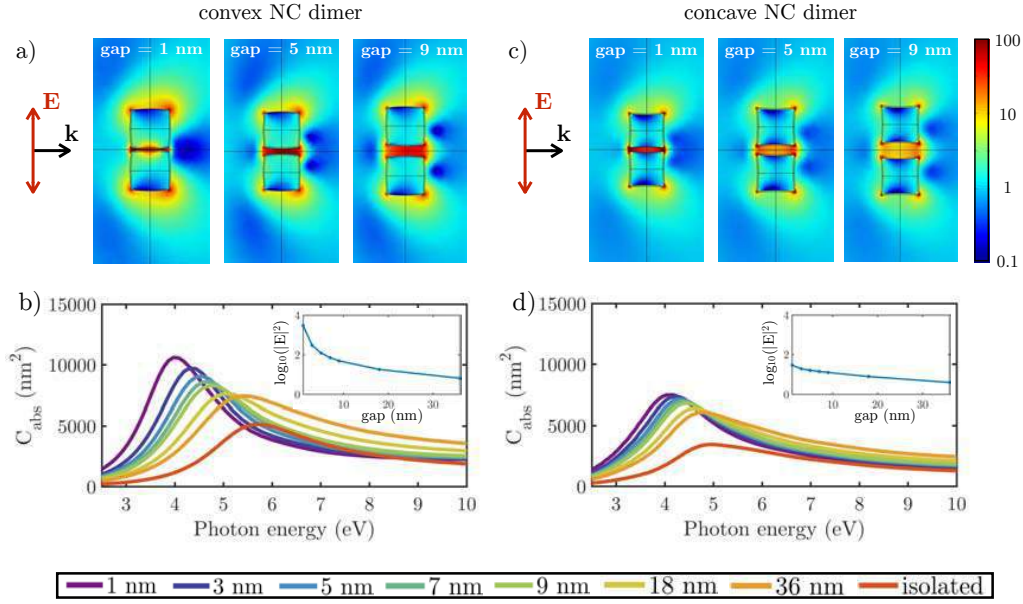

Figure 1: (a,c) Logarithmic scale $|E|^2$ images at the resonant energy and (b,d) spectral absorption cross-section C_{abs} for convex (left) and concave (right) NC dimers of several gaps, varying from 1 to 36 nm, illuminated under normal incidence with P polarization. The inset in (b,d) indicates the electric field intensity ($|E|^2$) at the center of the gap as a function of the inter-particle distance.

In this work we report a detailed numerical analysis of Rh nanocubes (NCs), paying special attention to the coupling and cooperative effects that appear when aggregates of NCs are considered. We will analyze the effect of different deviations from the perfect shape that can be seen in TEM images of synthesized Rh NCs, i.e. rounded edges and/or either concavity or convexity of their faces [8]. The hot spots created in the region between two interacting NCs (dimer) are of particular interest in SERS-like applications [10]. In this investigation we will study the dependence of UV plasmon resonances and hot spots of Rh NCs dimers on their geometry, shape, and also on electromagnetic parameters of the incident radiation like angle of incidence (AOI) and polarization when they are on substrates.

Abstract- The optomechanical response of a heterogeneously integrated two-dimensional photonic crystal defect cavities on top of silicon-on-insulator waveguides is investigated and evidences an optomechanical coupling involving both dispersive and dissipative mechanisms. By controlling the optical coupling between the constituting elements, we were able to vary and understand the relative strength of these couplings. This scalable platform allows for unprecedented control on the optomechanical coupling mechanisms, with a potential benefit in cooling experiments, and for optomechanical circuits for optomechanically-driven signal-processing applications.

Optomechanical systems, in which the vibrations of a mechanical resonator are coupled to an electromagnetic radiation, have permitted the investigation of a wealth of novel physical effects. Typically for the most of these systems, optomechanical coupling originates from a dispersive dependence of the nanocavity resonance frequency on its geometry, which is modulated by mechanical motion. Dissipative optomechanical coupling consists in the modulation of the lifetime of the cavity photons through the motion of a mechanical oscillator. Very recently, it has been demonstrated that this effect is observed in a wide variety of devices [1-2]. Dissipative couplings may significantly enhance the detection sensitivity in optomechanically-based sensing schemes [3] and open new possibilities in optomechanical control with systems featuring both types of coupling mechanisms [4], where a tailored coupling strength is highly desired.

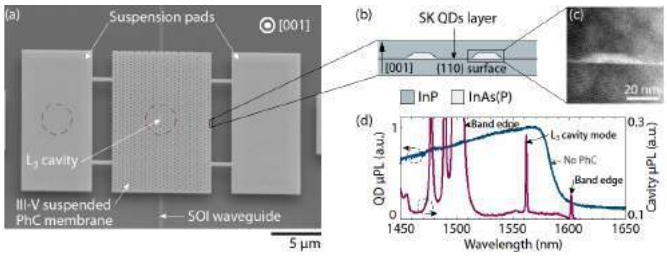

Figure 1. (a) S.E.M. picture of the photonic crystal membrane with an L3 cavity in the center above a Silicon waveguide. Inside the membrane, InAs(P) Stranski-Krastanov Quantum Dots (SK-QD) have been incorporated (b) in the InP membrane. A T.E.M. image is shown in (c). The emission spectrum of these QD is represented in blue (Fig. 1d) and the spectrum of the L3 cavity is in purple.

To fully exploit these phenomena in realistic devices or circuits, the integration of optomechanical resonators on a standard semiconductor platform is required. Here, we propose a novel approach to heterogeneously integrate arrays of two-dimensional photonic crystal defect cavities on top of silicon-on-insulator waveguides (Fig 1a). Added to that, quantum dots (QD) are incorporated in the middle of the III-V photonic crystal membrane with an emission spectrum around 1.55 μm (Fig 1b-d).

We are able to extract the dissipative and dispersive contributions of the optomechanical coupling of these devices. Tailoring of different contributions was demonstrated using external mean or integrated controls on the geometry of the optical access channel to the nanocavity

Abstract- Mie-type leaky mode resonances supported by Semiconductor nanowires (NWs) can produce an antireflective response for certain polarization and wavelengths of light. This paper presents the design and simulations of 3D silicon nano pillars as Mie resonators canceling reflection from a silicon substrate, which offers a broadband (400-600nm) near unity transmission and an average reflectivity in the visible range (400-800nm) as low as 2.2% under unpolarized illumination. The results are of interest to the solar cell community.

I. INTRODUCTION

Reflection is an essential factor limiting solar cell efficiencies. It is especially important for materials with high refractive index like silicon, which is broadly used as an absorption material in solar cells. The subwavelength scale of a metamaterial unit cell makes them a great candidate as a functional light management component for ultra-thin solar cells. Metamaterials are normally constructed from resonant metallic nanostructures and many efforts have been made in design metallic metasurfaces for light management purposes, which suffer from intrinsic loss of metal in the operating wavelength of solar cells. In recent years, researchers have proved semiconductor and dielectric nanostructures can also realize similar optical functionalities based on optical resonances [1], which naturally avoid the loss from metallic materials.

This paper presents the design and simulation of 3D silicon nano pillars as Mie resonators canceling reflection from silicon substrate, which offers a broadband (400-600nm) near unity transmission and an average reflectivity in the visible range (400-800nm) as low as 2.2% under unpolarized illumination.

II. DESIGN AND SIMULATION

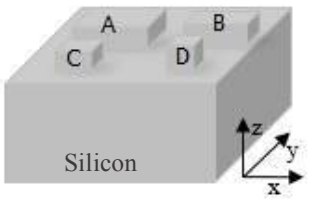

Figure 1 Unit cell of designed structure. The four pillars with different size atop the silicon substrate are marked as ABCD.

Semiconductor nanowires (NWs), especially silicon NWs, support Mie-type leaky mode resonances and have been explored and demonstrated in recent years [2,3]. These resonances can produce an antireflective response for certain polarization and wavelengths of light, depending on their size and geometrical shape. Based on the same physical mechanism, a metasurface constructed by four 3D nanopillars with different widths on top of a semi-infinite silicon substrate has been simulated and optimized to act as a broadband antireflection layer for unpolarized light, such as sunlight.

Fig. 1 shows the unit cell of the investigated structure with four differently-sized parallelepiped pillars marked as A, B, C, D. The optimized thickness of the pillars is identical and fixed at 77nm.

To better understand how the pillar size affects the reflection from the structure, a simulation was first conducted using a structure with same sized nanopillars (see inset of Fig. 2(a)). Fig. 2(a) shows the simulated reflection spectra for pillar sizes of either 52 nm or 80 nm with normal incidence of unpolarized light, and unit cell periodicity is 217 nm. Reflection of bared silicon is shown as reference. Different reflection minima can be observed for two different pillar sizes. The smaller pillar gives resonance and reflection minima at shorter wavelength and vice versa. The larger pillar size tends to affect the reflection more in the wavelength range(400-900nm) we are investigating.

Fig. 2(b) presents the reflection spectra for the nanostructure shown in Fig. 1 with different distribution of sizes (see inset and legend of Fig. 2(b)). The unit cell periodicity is 217 nm. We observe a broadband (400-600 nm) of near-zero reflectivity from the simulated reflection spectra for several different carefully designed size distribution of the silicon nanopillars. In addition, a tradeoff of reflection at shorter and longer wavelength range can be seen in Fig. 2(b) by only adjusting one of the pillar's size.

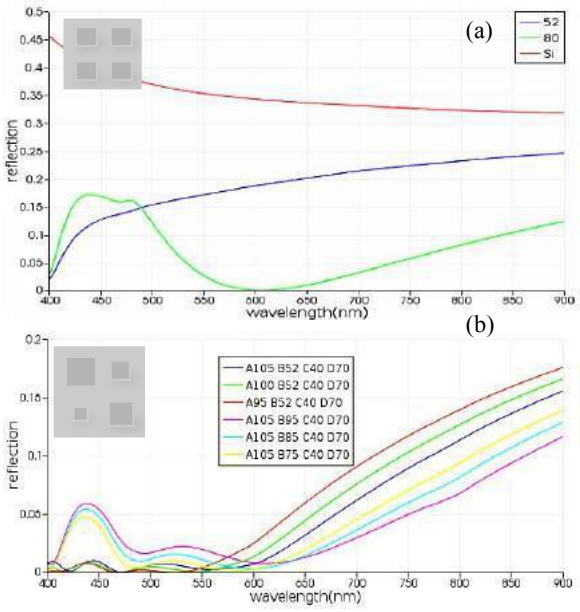

Figure 2. (a) Simulated reflection from the structure shown in the inset for two different pillar sizes 52nm(blue) and 80nm(green). Reflection of bared silicon is shown as reference(red). The unit cell periodicity is 217 nm. (b) Reflection spectra of structure in Fig.1 with four pillars with different width. Designed pillar sizes are shown in the legend with corresponded location ABCD as shown in Fig.1. The unit cell periodicity is 217nm. Insets are the view of the structure

III. CONCLUSIONS

In conclusion, we showed simulations of a broadband polarization-independent antireflection coating by carefully designed silicon nanopillars on silicon substrate (Fig. 1). The goal is to reduce the reflection of light for solar cells. The average reflection in the visible range (400-800nm) of the proposed silicon-patterned metasurfaces could reach as low as 2.2%. At the same time, from 400nm to 600nm, which is in the peak solar energy wavelength range, a near unity transmission is observed.

Hybrid Chiral Plasmonic Structures for Sensing

A. Karimullah,[1] M. Kadodwala[1]

[1]School of Chemistry, Joseph Black Building, University of Glasgow, G12 8QQ, Glasgow, UK

[*]corresponding author: Affar.Karimullah@glasgow.ac.uk

Abstract- Our work on sensing with chiral plasmonic systems has led us to develop new hybrid structures that display unique optical properties such as large optical rotation and plasmonic induced transparency. The optical properties are dependent on the strong coupling between individual components of the structures and are used to develop new sensing paradigms for biomolecular structure and surface orientation not perceivable by classical spectroscopic techniques. Here in we will describe the unique high-throughput fabrication method of these structures, their optical properties and their applications to chiral plasmonic sensing.

Chiral Plasmonic sensing utilizes superchiral near fields generated by chiral nanostructures to sense asymmetry in material.[1] Such materials are predominantly biomolecules such as proteins that have an inherent chiral structure due to the amino acid building blocks. However the chirality is further propagated in the higher order structure of the protein which are important in biochemical, pharmaceutical and medical research. In order to detect these changes, we require new forms of more sensitive plasmonic systems that are able to detect the increasingly complicated properties of biomolecules. We have developed new forms of plasmonic systems utilizing an inverse and solid structure of various patterns thus forming a hybrid structure. These effectively disposable plasmonic systems show enhanced optical properties and strong coupling effects between individual elements.[2] Tullius et al [1] have demonstrated the ability of such hybrid plasmonic systems to detect higher order structure of proteins and detect changes in the structure due to binding interactions. In this work we will describe properties of such hybrid structures and demonstrate that ability to sense biomolecular structure arises from the strong coupling effects present within the nanostructures.

Abstract- We present experimental and numerical investigation of core-shell plasmonic nanostructures composed of noble metals and refractory oxides. A variety of nanostructures of different geometries, including nanospheres, nanospheroids, and nanodisks, and a range of oxides, such as SiO_2, Al_2O_3, ZrO_2 and TiO_2, were investigated, which exhibit tunable optical properties across broad ranges of wavelengths and significantly enhanced chemical and thermal stability. The results provide important insight for developing effective optical nanodevices for applications in high-temperature environment.

Refractory plasmonic devices are highly in demand in applications in high-temperature environment, such as in data storage, solar thermophotovoltaics and nanoscale heat transfer systems [1]. Alternative plasmonic materials, such as refractory nitrides TiN and ZrN, are being under focused research due to their excellent thermal properties and competent optical properties comparable to that of gold. However, these materials have larger absorption cross-sections than those of noble metals. This generates much stronger self-heating effect which is undesirable in many applications where high degrees of thermal, optical, and morphological stabilities are crucial.

Here, we present the results of systematic investigations on core-shell nanostructures of various geometries composed of noble metals and a range of refractory oxides such as SiO_2, Al_2O_3, ZrO_2 and TiO_2. We compared the optical and thermal properties for spherical, spheroidal and disk-shape core-shell nanostructures where noble metals being either the core or the shell. All the nanostructures exhibit localized surface plasmon resonances (LSPR) that are tunable across a broad range of wavelengths by varying the geometry and materials of either the cores or shells. The results of a spherical Au nanoparticle coated with various thickness refractory oxides are shown in Fig.1(a), which demonstrate how the optical properties can be readily tuned with various coating materials and thicknesses. On the other hand, the refractory oxides coating can provide enhanced thermal stability due to their high melting points and low thermal expansion coefficients which help shielding the noble metal in the core. A thick coating layer of refractory oxides is found to increase the electric field intensity enhancement on the surface of metal core significantly (Fig.1b, c). This could cause stronger self-heating effect which is undesirable in some applications, for instance, in the heat assisted magnetic recording (HAMR) antennas. However, it can be very useful in other applications requiring high field enhancements such as in surface enhanced Raman scattering (SERS). We found that using oxides as cores and noble metals as shells can significantly reduce the optical absorption and mitigate the self-heating effect, which in addition is strongly

related to the size and the aspect ratio of the core-shell structure, thus opening multiple pathways for engineering the structures to minimize or optimize the heat generation for various applications.

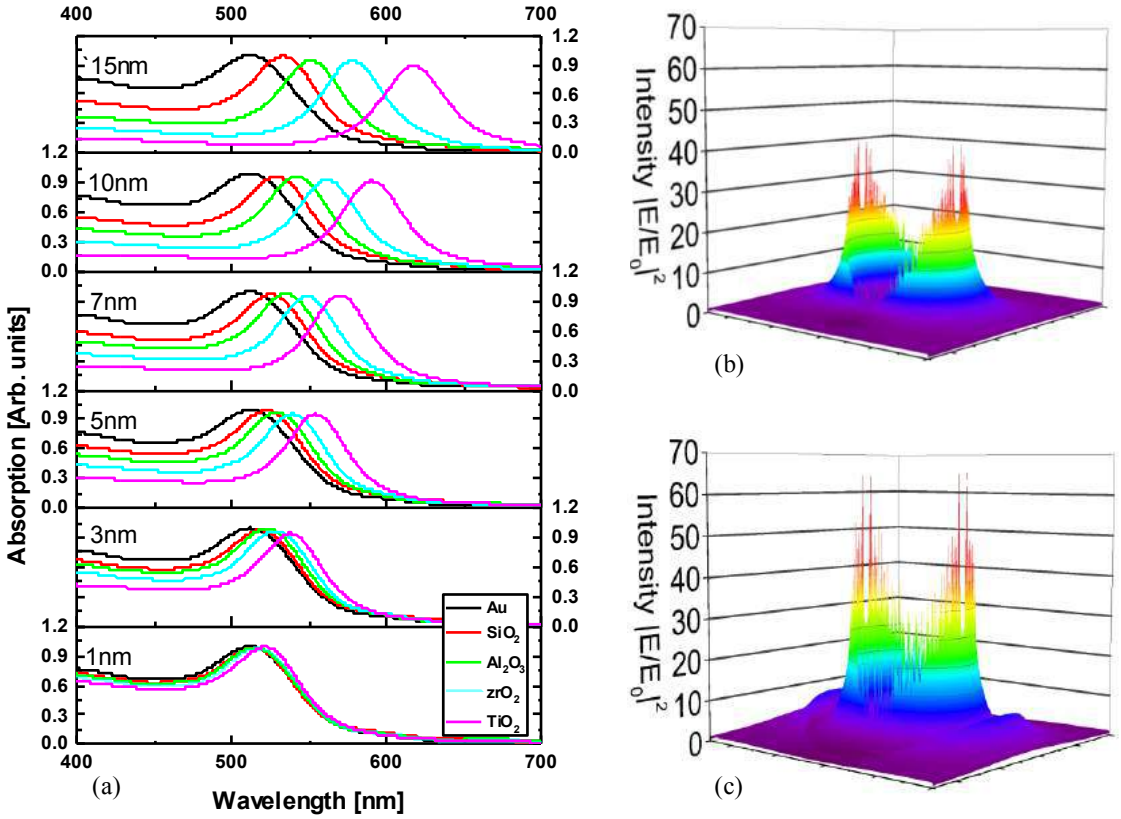

Figure 1 (a) Calculated plasmonic absorption spectra of a variety of core-shell structures (the black curves are for a bare Au sphere of 40 nm in diameter; coloured curves are for Au nanoparticles coated with various oxides), indicating the strong dependency of plasmonic resonance on the thickness and materials of shells. (b) and (c) are simulated field enhancements of (b) a bare spherical Au nanoparticle of 40 nm and (c) coated with 15 nm SiO_2 layer, respectively.

We also experimentally investigated the optical properties and thermal stability of the core-shell nanostructures, which were strongly impacted by the materials and structures. The results will provide important insight for developing effective optical nanodevices for applications in high-temperature environments.

Abstract- We generate long-tailed superthermal light on the non-lasing mode of a nanophotonic ensemble formed by two coupled nanolasers. An original and simple experimental technique is implemented in order to access the full probability distribution of output pulse energies. We interpret our results on the basis of a mean field theory and find, through an analogy with out-of-equilibrium thermodynamics, a new route for the generation of superthermal light statistics as a rapid cooling, quenching, of mode fluctuations.

In modern semiconductor optical cavities, non-trivial photon statistics may result from complex light-matter interaction at the nanoscale. As an example, superthermal fluctuations ($g^{(2)}(\tau = 0) > 2$) have been observed in single mode micropillar cavities as a result of superradiant quantum dot emission [1], as well as polarization mode switching in two-orthogonal polarization devices [2]. In the latter, mode competition has been identified as the main ingredient leading to non-gaussian (bimodal) probability distributions and hence superthermal light.

Evanescently coupled micro/nano lasers gather particular interest in the context of multimode nonlinear active cavity arrays. The possibility to engineer the coupling strength –both intercavity and intermode- has made possible the observation of nonlinear bifurcations such as spontaneous symmetry breaking between cavities [3] or asymmetric scattering from the blue (symmetric (S), in-phase) mode to the red (anti-symmetric (AS), out-of-phase) mode [4]. The following question arises: to what extent non-equilibrium dynamics and mode interaction in coupled nanolasers enables controlling the full photon statistics, i.e. beyond low order moments ? In this work we investigate a route for the generation of superthermal light with heavy-tailed distributions on the non-lasing mode of our coupled nanolasers systems.

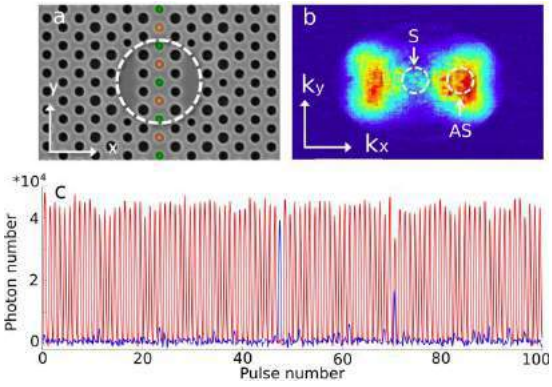

Figure 1: a) Coupled PhC nanolasers with barrier engineering (colored holes). Dashed circle: pump spot. b) Fourier plane. c) Sequence of output pulses on AS (red) and S (blue) modes.

Our experiment consists in two evanescently coupled photonic crystal (PhC) nanolasers etched in a semiconductor (InP) semiconductor free-standing membrane containing InGaAs/InGaAsP quantum wells (Fig 1a).

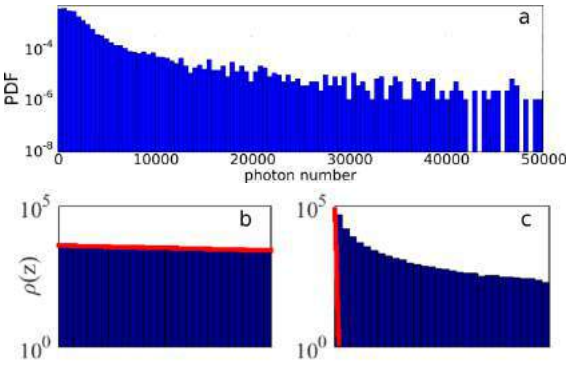

Figure 2: a) Histogram obtained from the n-time series on mode S of Fig. 2. b,c) Numerical density of photons on mode B before (b) and at the pulse maximum intensity (c). Red line: Fokker-Planck equation equilibrium distribution.

The sample is optically pumped with a pulsed laser (λ = 800 nm, 100 kHz repetition rate, 100 ps duration) leading each time to the optical emission of a single fluctuation. The AS mode, having lower optical losses, is lasing at threshold. The emission is collected with a N.A. = 0.95 microscope objective and its back focal plane is imaged through a lens to obtain the far-field pattern. In order to detect the light output, from each mode we use two single mode fibers as pinholes to simultaneously select a small region around k = 0 (mode S) and shifted along the x direction for the AS mode (Fig. 1b). Signals are sent to two Avalanche Photodiodes that deliver photocurrents proportional to the pulse energy. Typical n-time series contain 10^4 pulses. Fig. 1c shows a segment of two simultaneous n-time series showing both the AS and the S mode signals for $P = 6*P_{th}$. These n-time series allow us to obtain photon number PDFs. While the AS mode shows poissonian fluctuations, the S mode develops superthermal ($g^{(2)}(0) = 3.5$) fluctuation. This value obtained from the n-time series is confirmed by a Hanbury Brown and Twiss measurement. More importantly the superthermal statistics is associated to a heavy-tailed distribution as apparent in Fig. 2a.

We provide a complete theoretical interpretation for the appearance of the heavy tail in the photon number distributions from an analogy with out-of-equilibrium rapid cooling (quenching). In this framework each output pulse is a different stochastic realization. which can is eventually formalized by solving the associated Fokker-Planck equation [5]. We show that passing through the lasing threshold corresponds to an abrupt decrease of the contribution of spontaneous emission –that plays the role of an effective temperature- during which the statistics of the trajectories in phase space are dominated by nonlinear transport. Tuning the duration of this out-of-equilibrium quenching phase allows to obtain long-tailed distributions (Fig 2b,c).

Besides a surprising analogy with our experiment, we show that this out-of-equilibrium transformation, in which nonlinear transport dominates over diffusion fully explains the occurrence of heavy-tailed superthermal distributions on the non-lasing mode of our coupled nanolasers. We then open the road to an intuitive way to generate photon extra-bunching and, more generally, to mold the statistics of emitted photons in a nanolaser device.

Extreme nonlinear optics from graphene plasmons

J. D. Cox[1]* and F. J. García de Abajo[1,2]

Abstract-The large incident electric field intensities required to achieve extreme nonlinear optical phenomena can be realized through plasmonic near-field enhancement in doped graphene nanostructures. Here we show that the combination of strong local fields and a pronounced intrinsic nonlinearity can result in efficient broadband high-harmonic generation and a dramatic modulation in the optical absorption associated with plasmon resonances in graphene, paving the way for compact ultraviolet and ultrafast light sources and all-optical switching in nanophotonic devices.

The remarkably high intrinsic optical nonlinearity of graphene can be pushed even further when the frequency of impinging light matches that of its long-lived and electrically-tunable plasmon resonances [1,2]. Through their enhanced absorption cross-sections, plasmons in doped graphene provide the means to concentrate electromagnetic energy on extreme subwavelength scales, thereby generating enormous local electric fields. Here we explore extreme nonlinear optical phenomena that are enabled by plasmonic enhancement in graphene. In particular, we investigate (1) high-harmonic generation (HHG) and (2) transient absorption arising from the elevated electronic temperature in the carbon layer upon ultrafast optical pumping. Our studies of these plasmon-assisted nonlinear effects are based on rigorous time-domain simulations, wherein graphene nanoribbons and nanoislands are described atomistically, adopting a tight-binding description of their electronic states combined with the random-phase approximation [3].

HHG usually necessitates cumbersome laser amplification schemes to reach the enormous incident electric field intensities it requires. In the case of doped, nanostructured graphene, our results indicate that high harmonics can be emitted with unprecedentedly large intensity by tuning the incident light to localized plasmon resonances of ribbons and finite islands, which in turn can be modulated via electrical gating. In contrast to HHG in atomic systems, we observe no cutoff in harmonic order, while a comparison of graphene plasmon-assisted HHG to recent measurements in solid-state systems suggests that the HHG yields from bulk semiconductors can be produced by graphene plasmons using 3-4 orders of magnitude lower pulse fluence [4]. Our findings support the strong potential of nanostructured graphene as a robust, electrically-tunable platform for HHG.

In contrast to the instantaneous nonlinear response that is commonly explored in the graphene optics community, where input and output fields maintain relative coherences, a delayed nonlinearity also takes place as a consequence of the strong dependence of the graphene response on the temperature of its conduction electrons [1,5]. We demonstrate that strong transient modulation of the optical absorption associated with plasmonic excitations in graphene nanostructures can occur when electrons are optically pumped to an elevated temperature. We systematically investigate the effect of the transient chemical

potential and electron temperature on the absorption of (1) cw illumination, (2) individual ultrafast pulses, and in (3) pump-probe schemes, where a pump pulse is used to modulate the absorption of a delayed probe pulse. Our results indicate that plasmons in doped graphene nanostructures hold great promise for all-optical switching applications in nonlinear nanophotonic devices.

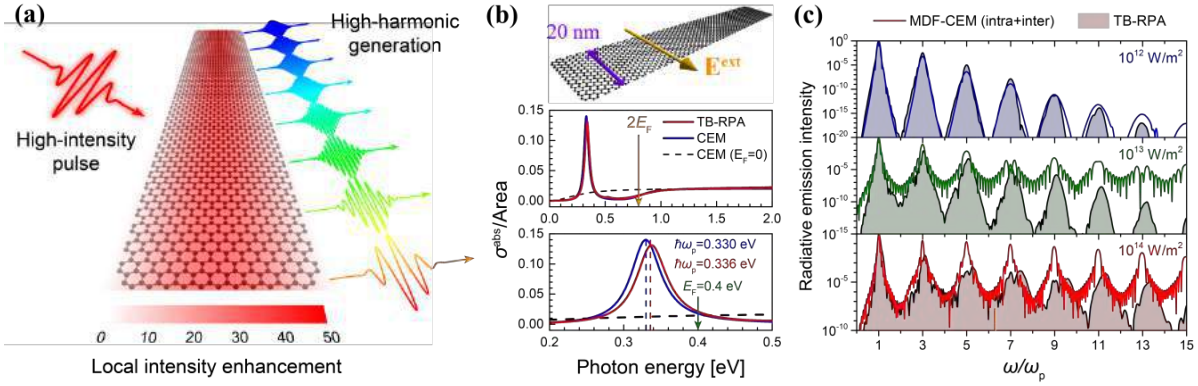

Figure 1. High-harmonic generation (HHG) assisted by graphene plasmons. (a) Schematic illustration of a doped graphene nanoribbon illuminated by an intense optical pulse that is resonant with the ribbon transverse dipole plasmon. The latter produces strong in-plane electric field intensity enhancement (see color scale) that boosts the generation of high-harmonics. (b) Absorption cross-section of a 20-nm wide armchair edge-terminated graphene nanoribbon doped to a Fermi energy E_F=0.4 eV, as predicted by atomistic tight-binding/random phase approximation (TB-RPA, red curves) and classical electrodynamic (CEM, local-RPA conductivity at 300 K, blue curves) simulations for transverse light polarization (see upper graphic). The prominent resonance feature corresponds to the transverse dipolar plasmon within the $2E_F$ optical gap. The dashed curve shows the classical simulation for the undoped ribbon. (c) Spectral decomposition of the light emission energy under illumination by a normally-incident pulse (100 fs FWHM duration, centered at the frequency ω_p of the ribbon plasmon), as calculated in the time-domain for three different pulse peak intensities (see legend) within the atomistic (TB-RPA, filled curves, $\hbar\omega_p$=0.336 eV) and massless Dirac fermion/classical electromagnetic (MDF-CEM, unfilled curves, $\hbar\omega_p$=0.330 eV) descriptions. Each curve is normalized to its own maximum value around the fundamental frequency.

Abstract- In recent years, nanotechnology and nanoscience have been expanding their toolbox dramatically. Metallic nanoantennas – also known as plasmonic resonators – can be considered as one of these novel tools providing an effective route to couple photons in and out of nanoscale volumes. Emerging as a promising alternative are all-dielectric resonant nanoantennas which demonstrate similar light concentration and manipulation capabilities yet benefiting from negligible Ohmic losses. The higher the level of control over the way an optical antenna interacts with light, the more effective this tool becomes and the further its applications will reach. Essential to this end is a detailed knowledge of such an antenna's supported modes and scattering characteristics. Especially in nanophotonics applications where every photon counts, one immediately benefits from directed photon routing for efficient photon collection.

We present a study of the modal field distribution in both plasmonic (i.e metallic) and all-dielectric rod-shaped nanoantennas. Using experimental near-field mapping in combination with finite-difference-time domain simulations, standing-wave TE and TM modes are revealed in these antennas operating at visible and near-infrared frequencies. [1-3]

Symmetry-breaking of these resonators allows the coupling of dipolar resonance modes with higher order (odd or even parity) modes. Interestingly, this effect gives rise to far field radiation patterns that can strongly deviate from the omni-directional dipole radiation. Reducing the rod-shaped antenna's symmetry into a V-shape allows the standing-wave modes observed in the near-field to generate highly directional radiation patterns. Additionally, the dielectric antenna even allows bi-directional color routing. We reveal the basic mechanisms behind this phenomena for both plasmonic [5-6] and dielectric V-antennas. [7]

The obtained insight in how directional emission and scattering are generated and how different modes come together to form far-field properties of a nanoantenna is indispensable to create new nanoscale optical devices for, e.g., sub-wavelength color routing, self-referenced directional sensing, metamaterials and flat optics.

Abstract- Strontium molybdate thin films have been studied by means of ellipsometry, XRD, and DC resistivity measurements in order to evaluate their potential use in the advancing field of plasmonics and nanophotonics. $SrMoO_3$ (SMO) thin films were grown by pulsed laser deposition on three types of substrate: $LaAlO_3$, MgO, and $SrTiO_3$. It is shown that $SrMoO_3$ exhibits tunable plasmonic behaviour at wavelengths above 600 nm with losses comparable to those of gold.

Plasmonic phenomena are expected to have a significant impact in applications such as nanoscale imaging, biological sensing, energy harvesting, and communication systems in the coming years. Traditionally, the research into plasmonics has been focused on the noble metals Au and Ag as a result of their high carrier concentrations in the near infrared[1]. However both materials are subject to excessive losses at optical frequencies[2], are incompatible with silicon-based electronics[1], and are unsuitable for high temperature applications[3], hence there arises a need for research into alternative plasmonic materials.

$SrMoO_3$ (SMO) is a compound with a perovskite-type crystal structure which has been shown previously to exhibit both metallic and Pauli paramagnetic properties. Furthermore, the bulk material shows temperature stability up to approximately 1000 K while thin films of SMO have been studied with a view to electrode applications as a result of their low room temperature resistivity. With a cubic lattice constant of 3.975 Å SMO is theoretically well-suited to growth on substrates such as $SrTiO_3$ (STO), MgO and $LaAlO_3$ (LAO), though its potential for plasmonic and nanophotonics applications has never previously been reported.

With such electronic properties in mind this article considers the potential for plasmonic and nanophotonics applications of $SrMoO_3$. We consider the optical, structural, and electrical properties of SMO thin films grown on substrates of STO, LAO and MgO with film thicknesses ranging from 50 - 200 nm. Having studied the effects of changes to the substrate temperature, laser energy, film thickness and deposition rate we observe that the ENZ crossover can be lowered to 600 nm, though this is should not be considered a lower limit. In particular, the optical properties of samples are shown to have strong dependency on the residual strain in the samples, controlled by both film thickness and deposition rate (Fig. 1). It was found that a higher ENZ frequency could be achieved by reducing the residual strain e.g. depositing thicker films at a lower deposition rate. In addition, it is noted that, as the ENZ frequency is increased, the optical losses present in SMO decrease (Fig. 2) and so compare favourably to those of gold and TiN.

Thus, SMO is a promising alternative material for plasmonics and nanophotonics applications operating in the visible to near infrared spectral regions.

Abstract- Hot charge carrier extraction from metallic nanostructures is a very promising approach for applications in photocatalysis, photovoltaics, and photo-detection. Here we demonstrate that a monolayer of Au nanoparticles can be assembled on a multi-stack layered configuration to achieve broadband, near-unity light absorption. We show that this enhanced light absorption leads to a 40-fold increase in the photon-to-electron conversion efficiency in photo-electrochemical cells. The measured data is interpreted with a model that enables us to establish that efficient hot carrier extraction is limited to spectral regions where (i) the photons have energies higher than the Schottky barrier at the gold-semiconductor junction and (ii) the absorption of light is localized on the metal nanoparticles.

It is expected that the rate of plasmonic hot charge carrier relaxation can be substantially increased under conditions where the metal nanostructures absorb nearly all incident photons across a broad spectral bandwidth [1,2]. Figure 1A shows the metal−semiconductor−nanoparticle structures, which consist of an optically thick metal film (200 nm) and a single layer of Au nanoparticles, separated by a thin 50 nm TiO_2 layer. These samples were made by means of sequential physical vapour deposition of materials.

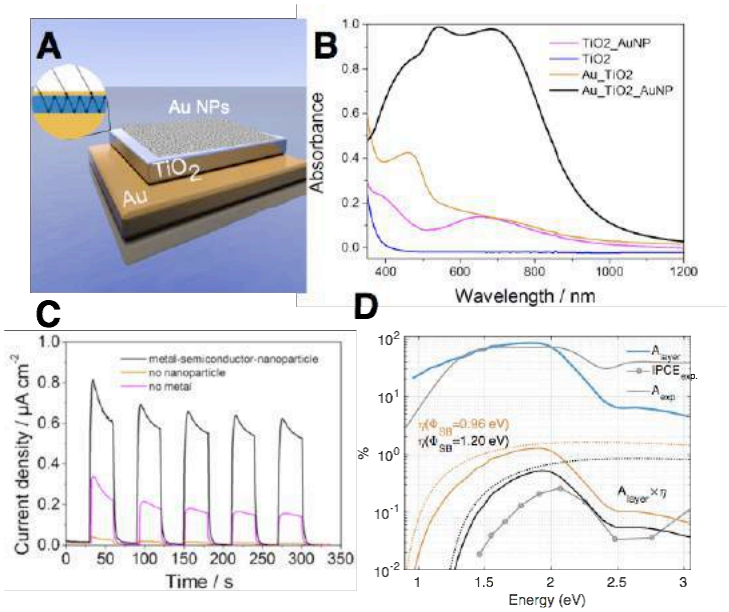

Figure 1: Plasmonic Perfect Absorber. A Diagram and SEM of the multi-stack structure. B Absorption spectra. C Photo-current vs time for different stacks. D Comparison of the measured IPCE (dots) to the derived model (black lines).

Figure 1B shows that for the multilayer stack (black line), the absorbance (measured *via* specular and diffuse transmission and reflectance) approaches 100% for some wavelengths and has a wide bandwidth. Figure 1C shows that the increased absorbance leads to increase photocurrent in photoelectrochemical cells made with these samples as photo-anodes. The efficiency (IPCE) also increases some 40x (when compared to non super-absorbing samples) and the IPCE spectrum can be well described by a model that we have developed [1].

Volume plasmon polariton modes in semiconductor hyperbolic metamaterials

D. Wei[1], C. Harris[2], and S. Law[1*]
[1]University of Delaware, USA
[2]Lincoln University, USA

Abstract- This paper describes the first observation of volume plasmon polariton (VPP) modes in semiconductor hyperbolic metamaterials (HMMs). The metamaterials are grown using molecular beam epitaxy, after which gold gratings are fabricated on top. These gratings allow light to couple to the high-wavevector VPP modes in the HMM. Experimental data is compared to simulations, and a good agreement is found; the experimental VPP dispersion curve matches predictions. Potential applications of VPPs include subdiffraction focusing and waveguiding.

Hyperbolic metamaterials (HMMs) can be created using a superlattice of alternating subwavelength metal and dielectric layers. We have previously demonstrated HMMs grown with molecular beam epitaxy (MBE) using heavily doped InAs as the metallic component and undoped InAs as the dielectric component [1]. HMMs have a variety of unique properties, including the ability to support high-wavevector modes, sometimes called volume plasmon polaritons (VPPs). VPPs arise from the coupling of surface plasmon polaritons at every metal/dielectric interface. As more interfaces are added, more VPP modes are available. The high-wavevector of the VPP modes means that they can be harnessed for a variety of applications, including subdiffraction focusing and waveguiding. In this paper, we present data showing the successful excitation of VPP modes in semiconductor HMMs.

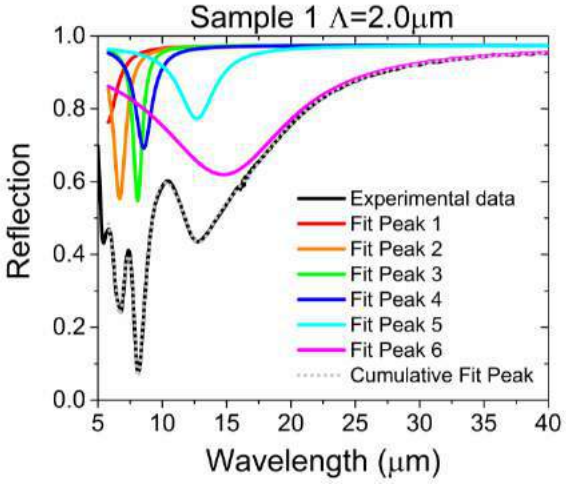

Figure 1. TM-polarized reflection as a function of wavelength for Sample 1 with grating period Λ=2.0μm. Black is experimental data, which is fit from the plasma wavelength (5.8μm) to 40μm using six Lorentzians (colored curves). The cumulative fit is shown as a gray dotted line.

HMMs were grown using MBE and standard photolithography and liftoff techniques used to fabricate gold gratings on Samples 1 and 3, as discussed previously in [1]. These samples had HMM onset wavelengths of 5.8μm and 9.5μm, respectively. The grating periods varied from Λ=1.8–4.6μm and the fill factor was held constant at 0.5. The gratings are necessary in order to match the wavevector of the incident light to the large wavevector of the VPP modes. A variety of gratings were fabricated to trace the dispersion of the VPPs. The samples were then placed in a Fourier transform infrared spectrometer and polarized reflection data was taken at a 10˚ incident angle. The data exhibited a variety of absorption features, an example of which is shown in Fig. 1. The data was then fitted using multiple Lorentzians to extract the positions of the resonances. COMSOL, a finite element modeling program, was used to simulate the optical properties of the samples, taking into account the precise shape of the band structure in the superlattice. In Fig. 2, the simulated TM reflectivity is shown in grayscale, while the extracted positions of the resonances are shown as colored dots. Different colors and shapes indicate different grating periods. Some resonances exhibit a constant wavelength, regardless of grating period; these are structural Fabry-Perot type resonances. However, for both samples, high-wavevector VPP modes can be observed. Sample 1 shows three distinct modes, while Sample 3 shows two. The resonant wavelength of these modes is strongly dependent on the wavevector in the material, as expected for VPP modes.

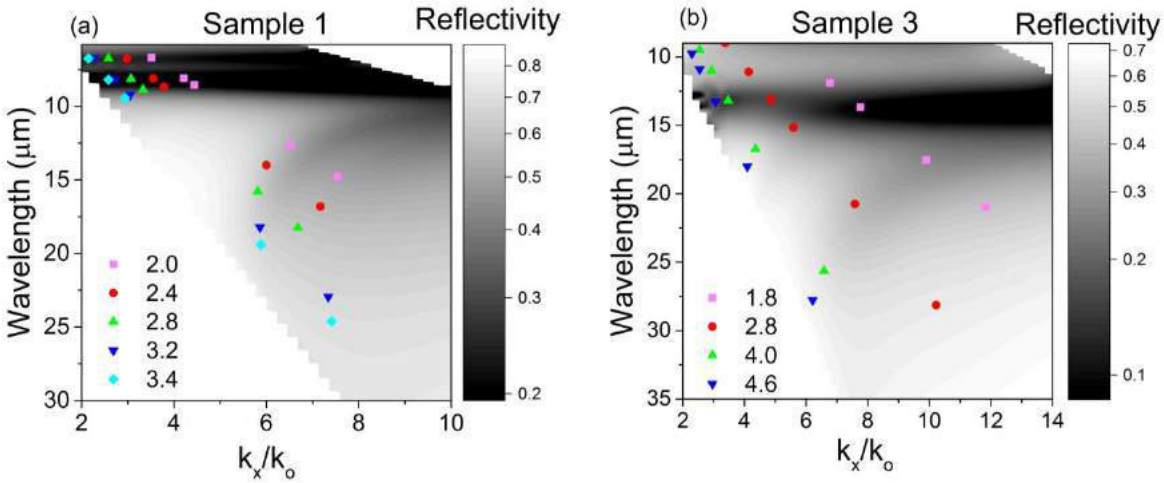

Figure 2. Simulation (grayscale) of reflection as a function of wavelength and wavevector in the HMM normalized to air for Sample 1 (a) and Sample 3 (b). Colored points indicate experimental position of VPP resonances for gratings with periods as indicated in the legend.

To our knowledge, this is the first successful excitation of VPP modes in a semiconductor HMM, and the first such experiment to be performed using a grating coupler. Now that the dispersion of these modes is understood, they can be leveraged for applications in infrared waveguiding, focusing, and imaging.

Four-wave mixing of dispersive and solitary waves in polariton waveguiding systems.

A. Yulin [1*]

[1]ITMO University, 197101, Kronverksky pr. 49, St. Petersburg, Russian Federation

[*]corresponding author: alex.v.yulin@gmail.com

Abstract-Different regimes of resonant scattering of quasi-linear excitations on solitary waves in polariton systems are considered. One and two dimensional waveguides are studied by numerical simulations. It is shown that the efficient new frequencies generation can take place in these systems at low intensities of the pump. The resonance condition for the scattering is derived and compared against the results of the numerical modeling. The recoil of the scattering on dynamics of the solitary waves is also addressed.

Recently it was shown that solitary optical waves can form in exciton-polarton systems in weak coupling regime [1]. The advantage of these systems is that strong nonlinear effects can be observed at very low intensity of the pump. Apart from pure fundamental interest the systems under consideration can also find practical application for example for new frequency generation.

In this work we theoretically study the interactions between strong and weak waves in polariton systems described by the coupled equations for the optical E and exciton φ fields. In the dimensionless variables they have the form

$$\partial_t E - \partial_t E + \gamma_1 E + \sigma\varphi = f(x,t), \quad (1)$$

$$\partial_t \varphi + \gamma_2 \varphi + \alpha i|\varphi|^2\varphi + \sigma E = 0, \quad (2)$$

where γ_1 and γ_2 account for the losses in the photon and the exciton subsystems, σ is the coupling strength, α is the nonlinearity coefficient and $f(x,t)$ is the complex amplitude of the exciting optical field.

Choosing the appropriate shape and the intensity of the spatially localized driving force $f(x,t)$ it is possible to excite propagating solitary waves very much similar to the nonlinear pulses studied in [1]. In experiments the shape of the driving force is controlled by the shape of the optical pump and by the structure of the coupler. To study the interaction between the solitary and the dispersive wave we need the second low intensity component of the pump having a different frequency. The mixing between the solitary waves and the quasi-linear excitations results in the generation of new frequencies.

We would like to notice that the second source can be either resonant or non-resonant. In the latter case the excitation efficiency is very low and practically no propagating waves are excited. However the induces non-resonant field can interact with the solitary wave and this mixing couple a wave with detuned frequency into the wavegude. This process is illustrated in Fig. 1 showing the interaction of such a kind. In panel (a) the temporal evolution of the field is shown. The narrow intense line is the solitary wave which at $t \approx 200$ hits the area excited by the non-resonant part of the pump. At this moment generation of the propagating scattered wave starts. Panel (b) shows this process in spectral representation. The patterns corresponding to the soliton, to the non-resonant excitations and to the scattered wave are clearly visible. It is seen that the frequency and the wavenumber of the scattered wave are connected by the dispersion relation for the linear waves. We would like

to remark here that as it is seen in panel (a) of Fig.1 the trajectory of the solitary wave is changed because of the interaction with the non-resonant field. This means that the weak excitations can be used to control the parameters of the solitons in polariton systems.

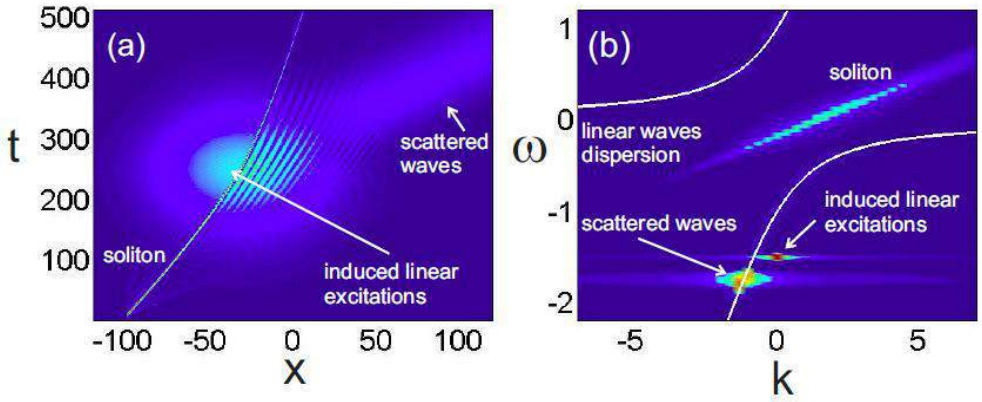

Figure 1. Panel (a) shows temporal evolution of the photon field in the system excited by a weak non-resonant pump and by a strong resonant pump leading to the formation of a solitary wave. The non-resonant pump is delayed by $t \approx 130$. The spectral representation of the field is shown in panel (b).

In one-dimensional case it is difficult to provide efficient scattering of the propagating dispersive waves on the solitons because either the scattering or the scattered wave experiences high losses. However in two-dimensional case this kind of scattering can be obtained.

Abstract-The key point in constructing biosensors based on metallic nanostructures concerns proper modification of their surfaces with defined (bio)receptors. This important tasks involves not only reproducible synthesis of homogenous nanostructures, but also establishing reliable methods for functionalization of the nanostructures that would enable efficient exploitation of plasmonic interactions in such a hybrid system. In the presentation we describe several architectures where successful control of biosensor activity of metallic nanostructures has been demonstrated.

In this work we present several ways of modification of metallic nanostructures for applying them as optical biosensors. One example concerns immobilization of an antibody for the bacteriophage T7 on gold nanospheres. The nanospheres were chosen to have the localised surface plasmon resonance in the visible range, i.e. at 520 nm, while the T7 bacteriophage was used as a model system of mammalian viruses belonging to the family of adenoviruses. In the presence of the target virus, which forms an immunocomplex with the antibody, the nanospheres tend to agglomerate. The resulting shift of the plasmon absorption band can be easily be detected by eye as the sample suspension changes its colour. The efficiency of this effect scales with the virus concentrations. An alternative approach employs a biopolymer with selected functional groups instead of antibodies as the biorecognition element. These relatively simple modifications of the metal nanoparticle surfaces resulted in fast and sensitive immunotests with detection limits in the range of pM [1] or fM [2]. We also showed that properly modified metal particles can have reasonable selectivity against non-specific viruses, in this case the M13 bacteriophage.

Metallic nanowires, due to their ability to efficiently transport excitations, are also very suitable nanostructures to construct biosensors. Moreover, diameters of such nanowires, which are in the range of 100 nm, are small enough to exhibit plasmonic effects in the visible spectral range, while their lengths exceeding tens of micrometers make them visible with a standard optical microscope. We intend to discuss selected properties of silver nanowires synthesized using a wet-chemistry approach [3]. The surface of the nanowires is amenable to a large array of surface functionalisation techniques, for example using thiol reactions. In the experiment focused on attaching photosynthetic pigment-protein complexes to the nanowires we demonstrate strong enhancement of fluorescence of these complexes due to plasmonic interactions by combining advanced fluorescence microscopy techniques. This is the first observation of metal-enhanced fluorescence in such a bioconjugated hybrid nanostructure.

In the presentation, I will show our results on lasing in plasmonic nanoparticle arrays at visible wavelengths [1]. The most startling result is that the lasing action occurs simultaneously in two modes at different energies, namely the bright and dark modes of the plasmonic lattice. We have found an intriguing out-coupling mechanism through which the dark mode can radiate to the far field. The out-coupling mechanism is based on the finite size of the array and is explained with gradual built-up of dipole moments in nanoparticles towards the array edges.

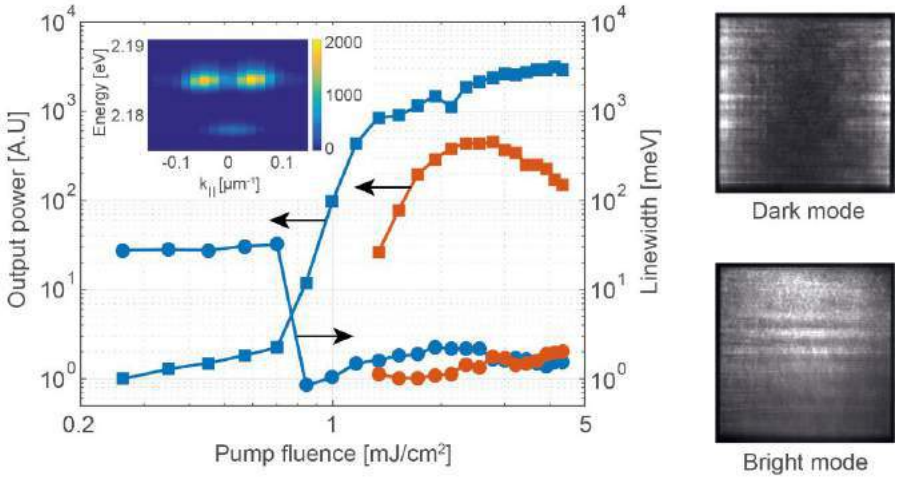

Figure 1. Left: Measured output power and linewidth of the dark mode (blue) and the bright mode (red) as a function of pump fluence. Inset: the momentum-energy distribution of the emission above threshold. Here, k_{II} refers to the in-plane momentum along one of the principal directions of the square lattice. Right: Real space distribution of the laser emission of the dark and bright mode, respectively.

We use an organic dye, Rhodamine 6G, as the gain material. The arrays consist of cylindrical silver nanoparticles with a diameter of 60 nm and a height of 30 nm, arranged in a square lattice. The periodicity is varied between 370 – 390 nm and the samples exhibit lasing in the wavelength range of 560 – 595 nm. We achieve a remarkably narrow linewidths of < 0.2 nm, beam divergence of 0.3° and a spatial coherence across the whole 100 x 100 μm^2 sized array. The results demonstrate a novel access to the dark mode and pave the way for studies of strong light-matter interaction and condensation phenomena in plasmonic lattices. In the presentation, I will also discuss recent advances related to this work.

Abstract— In this work, we theoretically analyze Dyaknov surface plasmons (DPs) and bulk plasmon waves in CMOS compatible hyperbolic metamaterial slab. The slab consists of alternate layers of Si and aluminium-doped ZnO (AZO). We have shown that the dispersion and directivity of the analyzed waves can be efficiently tailored in the mid-IR by change of geometrical parameters of the structure and doping level of AZO layers.

Research on surface waves has intensified in the last decade due to their unique properties of surface sensitivity and field localization, which lead to improved nanophotonic devices for sensing, light-trapping, and imaging based on near-field techniques. Conventional Dyakonov surface waves supported by the interface between anisotropic and isotropic dielectrics could propagate in a very narrow range of directions because of weak optical anisotropy of natural materials [1, 2]. Using of artificial media it is possible to achieve strong anisotropy and, therefore, substantially increase the range of allowed propagation directions for Dyakonov waves [3]. In the extreme anisotropic cases, when the hyperbolic regime manifests [4], the Dyaknov surface waves transform into Dyakonov plasmons [5, 6, 7, 8]. Here, theoretically analyzed the spectrum of CMOS compatible photonic structure exhibiting properties of hyperbolic media in the mid-IR and supporting Dyaknov plasmons (DPs).

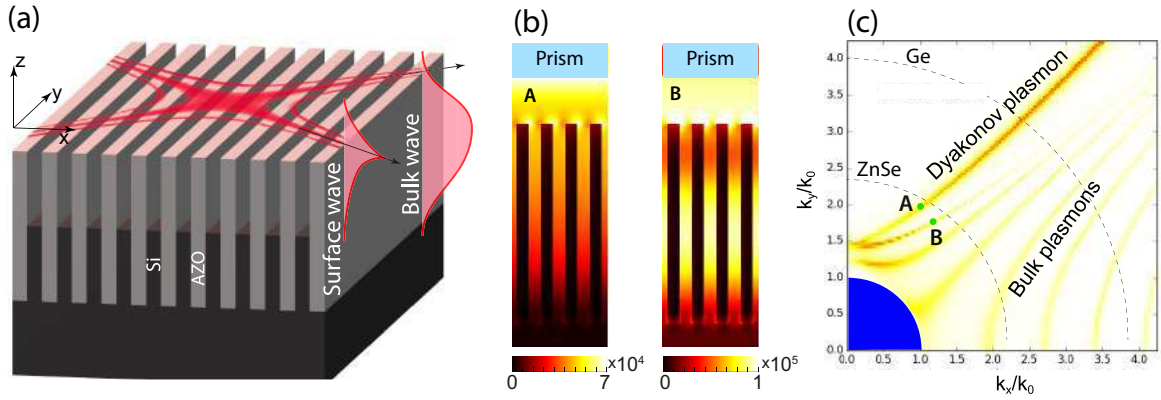

Figure 1: (a) Sketch of Si/AZO trench structure. (b) Electric field distribution ($|\mathbf{E}|$) for Dyaknov surface plasmon and fundamental bulk plasmon modes. (c) Simulation of the equal-frequency contours for Dyakonov and bulk plasmons at wavelength 3 μm.

The structure shown in Fig. 1(a) represents a high-aspect ratio (1:20) aluminium-doped ZnO (AZO) trenches partially filled by silicon. The thicknesses of AZO and silicon layers are the same and equal to 200 nm, the thickness of the slab is 4 μm.

The equal-frequency contours were found numerically by simulations of the reflectance spectra in the Otto geometry with high-index ZnSe prism. The reflectance map [Fig. 1(c)] plotted in the Fourier plane shows presence of several waveguide modes with hyperbolic dispersion. The analysis of the field profiles [see Fig. 1(b)] makes clear that these are surface (Dyakonov plasmons) and bulk plasmon modes. Dispersion and directivity of the Dyakonov plasmons and bulk plasmon modes can be effectively tailored by change of doping level of AZO, thickness of the layers and Si amount in the trenches.

In conclusion, we have proposed the CMOS compatible photonics structure supporting Dyakonov and bulk plasmon modes. Flexibility of the optical properties of the analyzed structures makes them very prospective for a plethora applications in photonics and biosensing. The obtained results provide useful guidelines for practical implementations of structures supporting Dyaknov plasmons in the mid-IR.

Abstract--We demonstrate that the photonic Peierls chain, in which couplings alternate between electric and magnetic, has different topological phases with different boundaries. Furthermore, we measure the density of states, the symmetry type of the band-edge states and the topological winding number with the aid of experimentally measured dispersion and mode characteristics. These results are powerful evidences to demonstrate the topological phases trivial or not. This is the first time to measure the winding number since the proposal of topological metamaterials.

One-dimensional finite models with topological band structures represent a simple and versatile platform to demonstrate novel topological concepts. Here we present a periodic photonic system made of split ring resonator elements to study topological phenomena. The photonic Peierls chain, in which couplings alternate between electric and magnetic, has different topological phases with different boundaries. Furthermore, we measure the density of states, the symmetry type of the band-edge states and the topological winding number with the aid of experimentally measured dispersion and mode characteristics. These results, in turn, are powerful evidences to demonstrate the topological phases of states trivial or not. It is worth mentioning that, this is the first time to measure the winding number since the proposal of topological metamaterials.

Figures: .

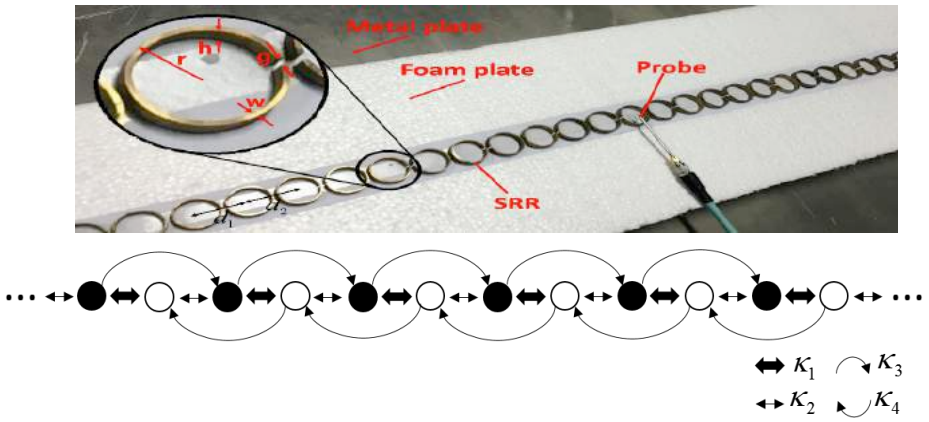

Fig. 1 The schematic illustration of the photonic Peierls chain. In this photonic Peierls chain, the couplings between the split ring resonators alternate between electric and magnetic (negative and positive). The appearance of the non-mutual next-nearest coupling causes the non-Hermitian nature with Parity-Time symmetry.

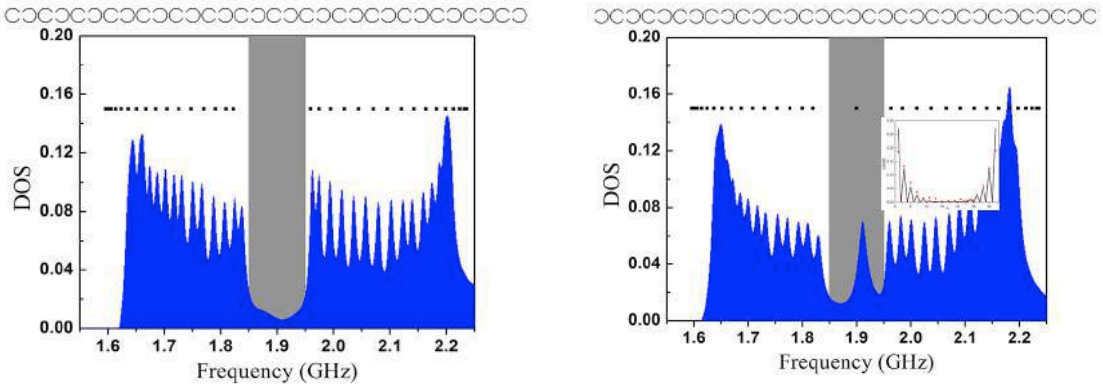

Fig. 2: The experimentally measured densities of states for different split ring reasonators with different boundaries, so as with different topologies. The topological non-trivial phase shows clearly a "zero-energy" state within the gap that corresponds to the topolgoical edge state.

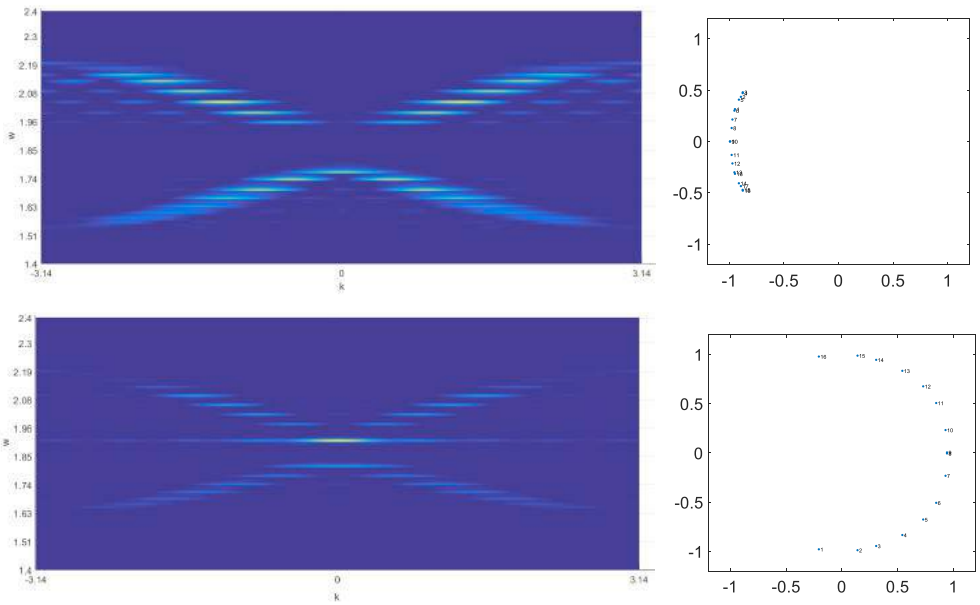

Fig. 3: The experimentally measured band dispersion and winding number for the photonic Peierls chains with two different boundaries. The lower two sub-figurs show clearly the "zero-energy" mode and the nonzero (unit 1) winding number for the topological non-trivial phase.

Abstract-We present our recent advances in the development of high-efficiency fiber-chip surface grating couplers engineered by sub-wavelength grating nano-structuration. The intriguing technological concept of sub-wavelength grating refractive index engineering affords an additional design freedom in the development of high-quality optical coupling interfaces for sub-micrometric silicon-on-insulator technology. We present an overview of various demonstrations of high-efficiency surface grating couplers, particularly develop for applications in silicon photonics across the near-infrared wavelengths.

We have demonstrated by both designs and experiments a set of different fiber-chip surface grating couplers engineered by sub-wavelength grating metamaterials, requiring only a one step of lithography patterning and reactive ion etching, while providing the state-of-the-art fiber-chip coupling performance [1-7]. In particular, we have reported on apodized single-etch grating couplers with optimized thin film interference pattern. Those grating couplers are implemented in a conventional 220-nm-thick silicon photonics platform, with a coupling efficiency of up to -2.2 dB and -2.5 dB for wavelengths near 1.55 and 1.3 μm, respectively [3-5]. In addition, a sub-decibel fiber-chip coupling efficiency of -0.70 dB has been experimentally realized by utilizing the CMOS-compatible manufacturing via backside metallization [5].

We have also developed a flexible grating coupler concept with an ultra-high intrinsic directionality. The grating couplers can be fabricated by using only two, deep and shallow, etching levels, typically used in silicon photonic foundries [6, 7]. This coupling structure obviates the need of using typically complex fabrication processes such as high-index overlays, customized etch depths, and bottom mirrors. In particular, we have shown that the blazing effect can directly be implemented in any conventionally used silicon-on-insulator substrates, with a negligible dependence on the thickness of the BOX layer. We reported an experimental coupling efficiency of -1.3 dB near 1.55 μm in a standard 220-nm-thick silicon platform [7].

Electromechanically Tunable Metal-Air-Metal Nanocavity

J. Takahara[1,2*]

[*]corresponding author: takahara@ap.eng.osaka-u.ac.jp

Abstract- We demonstrate an electromechanically tunable metal-air-metal structure based on a gold nanowire suspended on a gold substrate in visible range. By applying voltage to the nanowire, the suspended nanowire can be pull down by the electrostatic force, resulting in scattering spectral change due to Fabry-Perot resonance of a plasmonic nanocavity. Such nanocavity provides a promising route for achieving dynamical control of the interaction between surface plasmon and inserted objects such as fluorescent molecules or quantum dots in the gap.

Metal-Insulator-Metal (MIM) structure is a fundamental structure for plasmonics. In recent years, MIM structures have been applied to an efficient light absorber as a component for plasmonic metasurfaces. In such applications, a finite-length MIM structure, i.e. an MIM resonator plays a crucial role to control the efficient interaction between surface plasmon to light. Recently, electromechanically reconfigurable plasmonic metamaterials have been proposed for achieving tunable plasmonic characteristics [1]. More recently, we have reported static gap plasmon resonance in various gap sizes of a plasmonic nanowire (NW) suspended on a metal substrate [2]. Such structure, so called Metal-Air-Metal (MAM) structure, has a great potential for the dynamic control of gap plasmon resonance. Achieving electrical tuning of plasmon resonances in visible range remains a challenge, in contrast to the great success of tunable plasmonic nanostructures in the other spectral regimes.

In this paper, we demonstrate electromechanically tunable MAM structure in visible range, which is capable of dynamically tuning the resonant properties of the nanocavity [3]. In addition, we report our recent results about the modulation of light emission from colloidal quantum dots placed inside the MAM resonator.

Figure 1 shows a SEM image of a 500-nm-wide and 150-nm-thick gold NW suspended over Al_2O_3 coated (20 nm thick) Au film (80 nm thick) with a suspended length of 13.4 μm and an initial air gap of ~250 nm [3]. The suspended NW was fabricated using a probe-based pick-and-place method capable of arranging NWs on a substrate.

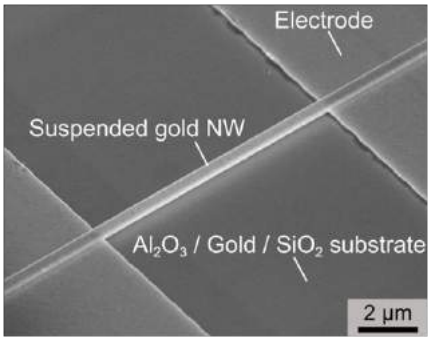

Fig. 1 SEM image of the suspended gold NW. The scale bar is 2μm.

We measured dark field image of the NW under applying voltage to the NW and performed spectroscopy. We observed the scattering color of the NW was changed with decreasing of the gap distance between the NW and the substrate from 250nm (initial) to 100nm. Hence, the gap distance can be tuned by applying voltage, resulting in controlling Fabry-Perot resonance of MAM nanocavity.

In conventional MIM nanocavity, the spacing insulating layer prevents access to the enhanced filed spot in the gap, making them limit to use in static applications. Such dynamic MAM nanocavity provides a promising route for achieving dynamical control of the interaction between surface plasmon and inserted objects such as

fluorescent molecules or quantum dots in the gap. We have placed colloidal quantum dots (CQDs) inside the MAM resonator and observed the light emission from CQDs. We report our recent results about the modulation of light emission.

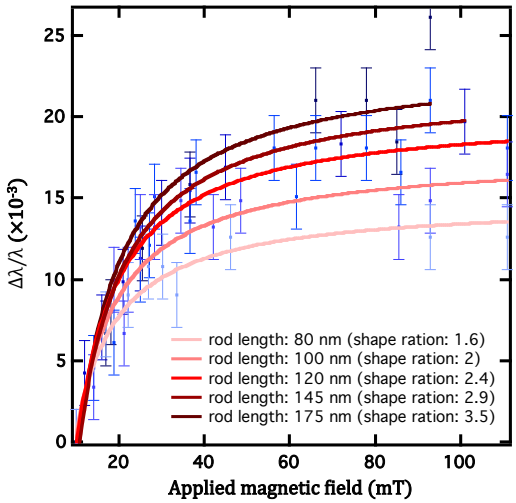
Abstract- We report on the fabrication of plasmonic hybrid Ni-Au nanoantennas. The optical properties of such nanostructure depend on the applied magnetic field and/or the temperature. Thus, we tune under control the plasmon resonance using external stimuli.

Over the past two decades, metallic nanoparticles have attracted increasing interest because of their varied and complex optical properties. These properties are mainly governed by the collective oscillations of conduction electrons called "plasmons". In particular, the excitation of the latter by optical fields leads to a local exaltation of the electromagnetic field on the surface of the nanoparticle. This very intense nanosource makes it possible to envisage nanometric optical concepts by controlling, manipulating and amplifying light at this scale. In recent years, a new challenge is the control and manipulation of optical properties using an external stimulus [1].



In this context, we developed Ni-Au plasmonic nanoantennas which exhibit an optical response that can be modulated either by the application of an external magnetic field or by a change in temperature. Thus, we are able to control the plasmon resonance of such individual nanoobjects over several tens of nanometers as shown in figure 1.

Abstract: Photonics structures are currently the leading platform for on-chip nonlinear optical application. However, limitations in compactness, interfacing with electronics and broadband operations have open the path to complementing and competing platforms such as the base based on plasmonic structures. These are promising for nonlinear optics because they strongly confine light at the nanoscale, enhancing in this way the light-matter interactions. Although Ohmic losses are an impediment to the full success of plasmonic-base structures, we showed here how plasmonic structures perform better than any other platform by harnessing efficiently the material nonlinearities manly thanks to a slow-light effect, exhibiting a different behavior than the one in dielectrics.

The Kerr effect leads, amongst other things, to a variation Δn of the refractive index with light intensity I. In turn, this leads to an intensity-dependent nonlinear phase shift $\Delta\phi_{NL}$. The key challenge that needs to be overcome in nonlinear optics is that these effects are weak and so it is crucial to use materials with the strongest possible nonlinearity and geometries which maximize these effects in small volumes, compatible with modern chip-based devices. For many years, metal-based (i.e., plasmonic) devices have promised to meet this challenge[1-3], but though the metal can compress the light very strongly, leading to huge intensities, they are also lossy, quickly dissipating these high intensities upon propagation.

Here we report which characteristics make plasmonic metal-dielectric-metal (MDM) structures the most promising nanoscale platform for nonlinear optical signal generation. After reviewing our previous work where we introduced a simple figure of merit, $F = \gamma P_{th} L_{ATT}$,[4] where $L_{ATT} = 1/\alpha$ with α the absorption coefficient, we then show that for MDM structures $F \propto 1/n^{\beta}$ with $1 \leq \beta \leq 3$, where β depends on the detailed properties of the device and n is the refractive index of the nonlinear medium. It is thus very advantageous to use nonlinear materials with low refractive index in this geometry.

We then introduce the concept of nonlinear effectiveness EFF_{NL}, in order to quantify the ability of a waveguide mode to make use of the material nonlinearity, i.e., to convert a material's nonlinear index change into a nonlinear phase shift. The EFFNL is defined as $EFF_{NL} = \Delta\varphi_{NL,mode} \Big/ \Delta\varphi_{NL,pw} = f_l \cdot S \cdot \rho_{NL}$, where the numerator and the denominator represent respectively the nonlinear phase shifts for the mode and for a plane wave in bulk, and therefore for a plane wave in bulk material, $EFF_{NL} = 1$. The nonlinear effectiveness is also proportional to a factor f_l, which represents the loss of the waveguide structure; $f_l = 1$ for a lossless mode and $f_l \equiv 2/(3\ln(3))$ for a lossy mode. The second factor S represent the slow-light effect, and the third, ρ_{NL}, is the field overlap with the nonlinear medium, which quantifies the fraction of energy in the mode that contributes to the nonlinear effects and the degree to which it does so ($0 \leq \rho_{NL} \leq 1$). Figure 1a shows the EFF_{NL} comparison between the best plasmonic structure for nonlinear optics, the MDM, and the one for all-dielectric waveguide, the Si-slot waveguide. Here the nonlinear effectiveness is plotted versus the thickness of the central layer for the MDM structure (dark blue) and an all-dielectric silicon slot waveguide (pink), Si-slot waveguide.

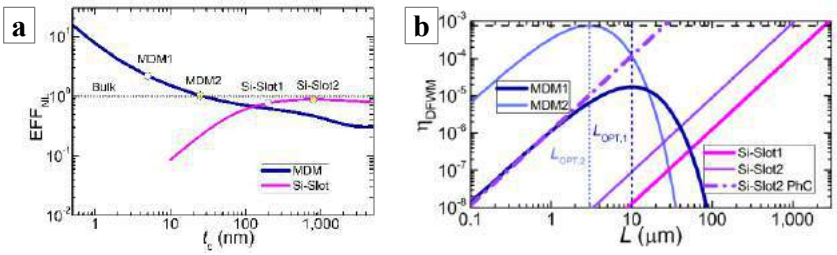

Figure 1. (a) Nonlinear effectiveness versus t_c for MDM structures (dark blue), the MDH structures (red) and an all-dielectric silicon slot waveguide (pink). (b) Four-wave mixing efficiency versus propagation length for five devices.

The nonlinear effectiveness of the MDM structure is superior to that of the Si-slot waveguide as $t_c \rightarrow 0$. This is because the field remains confined in this limit while the presence of slow-light effects contributes to the efficient use of the nonlinear refractive index change. In contrast, Si-slot waveguides exhibit modest slow light effects and cannot confine the light when the low-index layer becomes too thin.

In Figure 2b we compare the nonlinear performance for five structures, showing η_{max} versus propagation length. We consider two MDM structures with t_c=25 nm (dark blue) and t_c=5 nm (light blue); two silicon slot waveguides, with t_c=800 nm (purple) and t_c=200 nm (pink), and a silicon slot waveguide with a slow-down factor of S=6 (dashed), which mimics typical photonic crystal waveguides. The silicon slot waveguides consist of a nonlinear central layer with thickness t_c, surrounded by two 100 nm thick silicon layers (n=3.47), surrounded by air. Each of these is driven at the maximum power level of the thin MDM structure. Note that the thin MDM structure reaches $\eta_{max} \approx 10^{-3}$ after only 2.5 μm of propagation length, while all other devices require at least an order of magnitude more propagation lengths to reach the same efficiency.

Furthermore, we show that the slow-light effect mechanism is substantially different between an MDM and an all-dielectric waveguide such as a photonic crystal structure. The slow-light effect in MDMs arise because the energy in the metal propagates backwards due to its negative permittivity. This mechanism differs from that for slow-light effects in photonic crystals which rely on a narrow band structural resonance. Since the metal and dielectric permittivity have opposite signs over a large wavelength range, the slow-light effects and thus the MDM's nonlinear effectiveness are intrinsically broadband.

We have investigated the merits of plasmonic structures for degenerate four-wave mixing. We find that the MDM structure has the highest performance thanks to a combination of strong field confinement and slow light effects, but is limited by the damage threshold of the nonlinear material. Such structures beat all-dielectric structures if the required efficiency is low. The performance scales linearly with the damage threshold, and can thus be improved by using better nonlinear materials.

Abstract— Chirality, an exciting property of objects lacking in mirror symmetry, provides the ability to sense the handedness of light's polarization. Instead of following the conventional apporach based on purely geometrical aspects, we now introduce a novel and versatile concept realized by a heteromaterial composition of nanostructures. Here, we report on our experimental and numerical observation of optical activity of geometrically symmetric nanoassemblies enabled by heteromaterial selection.

According to the definition introduced by Lord Kelvin [1], chirality refers to a lack of mirror symmetry of a *geometrical figure, or group of points*. Such objects can be found in nature and, when inetracting with light, are capable of distinguishing between right- and left-handed circular polarization [2]. Recently, optical activity of a variety of different artificial chiral 3D and planar nanostructures has been reported [3, 4]. However, so far a chiral optical behavior has been induced by a non-mirror-symmetric geometry of the studied structures.
Here, we present a novel concept of chiral optical response induced by heteromaterial composition of a single nanoassembly. To this end, we investigate a geometrically mirror-symmetric particle-arrangement, composed of equally sized and shaped achiral building-blocks [5] (see also Fig. 1a). In such assemblies, the choice of different materials and a proper arrangement break the symmetry of the system and enable its optical activity. The chiral behavior originates from the interaction of the multipolar responses of the individual constituents. Depending on the input polairzation state (right- or left-handed circularly polarized light) and, therefore, the phase between the linear polarization components of the illumination, indiviudal particles interact differently with their respective neighbor in the assembly due to the heteromaterial composition. The mutual interference of the multipolar modes will, therefore, result in different interaction schemes and, eventually, in a chiral response.

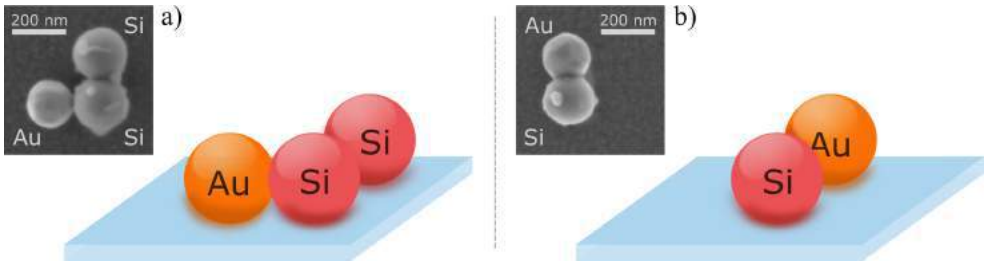

Figure 1: Sketches and SEM images of optically chiral three- (a) and two-particle (b) assemblies built from gold and silicon nanospheres.

For a proof-of-principle experimental demonstration, we recently measured the optical activity of a geometrically symmetric trimer [5] (see Fig. 1a). The trimer was assembled from gold and

silicon nanospheres on a glass substrate, utilizing a pick-and-place technique developed in-house [6]. For normal incidence, circular dichroism, i.e., the differential absorption of right- and left-handed circularly polarized light is observed. The experimental results are in excellent agreement with the numerically calculated optical response of the nanotrimer.

The heteromaterial-driven chiroptical effects can be further tailored by involving particles made of many different materials, changing the number of particles or changing their arrangement. We envision that heteromaterial selection will allow for the development of many different geometries of nanostructures exhibitng a chiral optical response. Even simpler geometries than the one described above may feature optical activity. Indeed, our recent studies confirm that optical activity can be induced also in a heterogeneous two-particle-assembly (Fig. 1b). Details will be discussed in the presentation.

In summary, we propose and investigate experimentally and numerically a new concept of chiral optical activity of a single nanostructure. In contrast to the studies reported so far, the chiral behavior originates from heterogeneous material selection of the individual constituents of the geometrically symmetric nanoassembly. Our concept of the heteromaterial-driven chiroptical response provides a new degree of freedom for precisely designing the chiral properties of individual structures at the nanoscale.

Abstract— A negative Kerr nonlinearity of quasiundoped graphene at telecom wavelengths is demonstrated experimentally based on our novel chirped-pulse-pumped self-phase modulation approach. Since a positive Kerr nonlinear index had been assumed for graphene so far, our result will modify considerably strategies for exploiting waveguide nonlinearity enhancement induced by graphene layer deposition.

Graphene became a topic of intense research since its isolation [1] due to the panoply of applications relying on the unusual band structure of this 2D honey comb lattice of carbon atoms [2]. Particularly, graphene is a promising material for nonlinear optical applications due to the extremely large magnitude of its Kerr nonlinear index, n_2 (five orders of magnitude larger than n_2 of silicon, which is one of the largest available in integrated photonics), as was demonstrated earlier using four-wave mixing (FWM) experiments [3]. Although the sign of n_2 does not affect the (optimum) conversion efficiency of FWM, a positive n_2 had been tacitly assumed for graphene [4].

In this work, we carry out self-phase modulation (SPM) experiments where graphene-covered silicon-on-insulator (SOI) waveguides are pumped with positively and negatively chirped pulses in order to determine both magnitude and sign of the waveguide nonlinear coefficient, γ_K. Moreover, n_2 of graphene can be extracted since the nonlinear coefficient of bare SOI waveguides is also measured. A new analytical model that accounts for SPM and linear losses but also the interplay between SPM and the input chirp is used to fit the experimental spectral broadening induced by SPM and as such extract γ_K. Based on this analysis, we conclude that quasiundoped graphene possesses a negative n_2 at $1.55\,\mu$m, while its magnitude is in accordance with previous reports [3].

Our chirped-pulse-pumped SPM method relies on the following equation that governs the evolution of the root-mean-square (RMS) spectral width, μ_2, of the pulse along the waveguide (in the $z-$direction):

$$\frac{\mu_2(z)}{\mu_2(0)} = 1 + \frac{2\gamma_K P_0 \Delta z_{\text{eff}} C_0 \sigma_{31} + (\gamma_K P_0 \Delta z_{\text{eff}})^2 \sigma_{41}}{1 + 4\,C_0^2 \sigma_{21}}, \tag{1}$$

where P_0 refers to the input pulse peak power, Δz_{eff} is the effective length, C_0 accounts for the input pulse chirp and σ-coefficients are positive-valued dimensionless shape-factors [5]. This equation shows how the spectrum can broaden or get narrower depending on the sign of $\gamma_K C_0$ in the low-power regime, namely, when the term that depends linearly on P_0 becomes important compared to the term that depends quadratically on P_0. This model allows determining γ_K, including its sign, by means of measurements of μ_2 for different $z-$lengths, provided C_0 is known.

The most important features of the graphene-covered SOI waveguides and the laser sources employed in our experiments are described in Fig. 1. Further information about the laser sources, graphene deposition and patterning to vary the length of the graphene sections can be found in [5] and references therein. The relative spectral broadening is measured for six SOI waveguides covered by a graphene section with a length varying from 0 (*i.e.*, no graphene coverage) to $250\,\mu$m. When Source (1) is used [see Fig. 1(b)], 1.2 ps, 1.8 W pulses at $1.55\,\mu$m with $C_0 = 0.8$ are injected into the on-chip waveguides. In this case, the laser source provides directly positively chirped pulses. In contrast, to provide negatively chirped pulses at the waveguide input, the (slightly positively chirped) pulses emitted by an optical parametric oscillator (OPO) are sent through a negative-dispersion fiber with properly chosen length. As a result, 3 ps, 1.7 W pulses with $C_0 = -0.25$ excite the waveguides when Source (2) is considered.

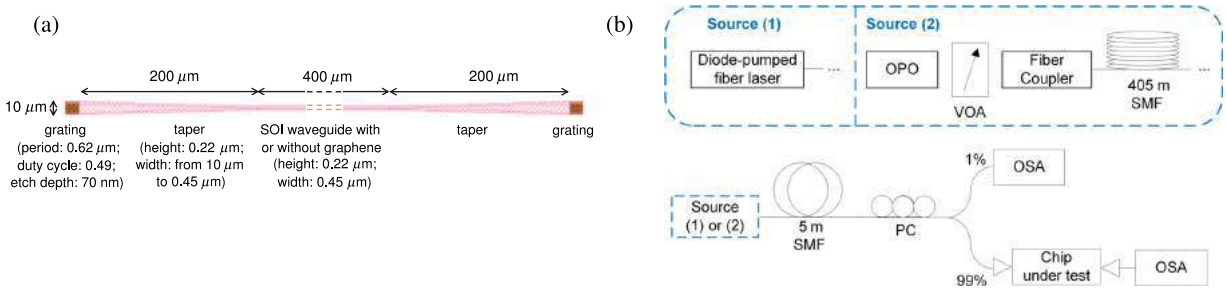

Figure 1: (a) Outline of the waveguides used in our experiments. (b) Experimental setup for the SPM measurements. The acronyms refer to variable optical attenuator (VOA), single-mode fiber (SMF), polarization controller (PC), and optical spectrum analyzer (OSA). Note that the input and output spectra are measured simultaneously using two OSAs.

Our experimental results are shown in Fig. 2. The experimental broadening factors for both positive and negative input-chirp cases can be fitted on the basis of Eq. (1) with γ_K as only fitting parameter. This fit provides $\gamma_K = -1.4\,\mathrm{W}^{-1}\,\mathrm{mm}^{-1}$ in the graphene-covered sections, which yields $n_2 = -10^{-13}\,\mathrm{m}^2\,\mathrm{W}^{-1}$ for graphene. In Fig. 2, the red lines are the theoretical curves for the case where the graphene-covered sections would have the same (positive) nonlinearity as that of bare SOI waveguides. The poor correspondence between these hypothetical curves and the experimental data showcases the strong impact of graphene on γ_K. Although the magnitude of the n_2 that we find agrees with previous works [3], this previously unreported negative n_2 of graphene changes drastically present approaches that pursue larger γ_K through graphene layer deposition.

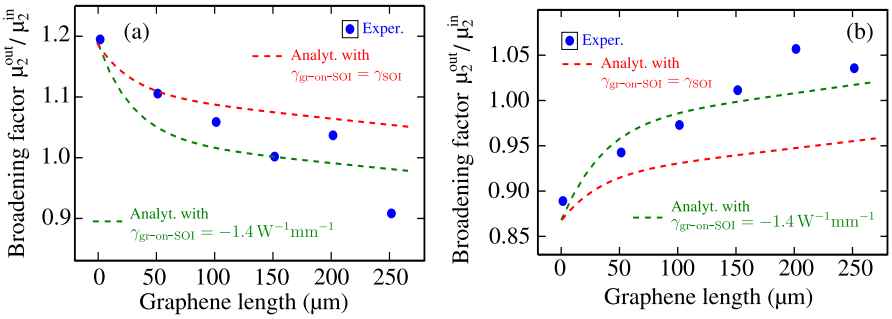

Figure 2: (a) Experimental measurement of γ_K for a positively chirped input pulse. (b) Experimental measurement of γ_K for a negatively chirped input pulse.

Light on Wheels –
Transverse Angular Momentum as a Tool for Nanophotonics.

P. Banzer

*corresponding author: peter.banzer@mpl.mpg.de

Abstract-We discuss the concept of *photonic wheels*, i.e., light carrying an angular momentum (density) perpendicular to the propagation direction, as a versatile and very flexible tool for nanophotonics. We review recent studies involving transverse angular momenta.

Evanescent fields, waveguide modes, propagating surface plasmons and focused light beams share an intriguing feature. As a direct consequence of the spatial confinement they are resulting from, components of the field oscillating along the propagation direction are formed, which are usually dephased by $\pm\pi/2$ with respect to their transverse counterparts [1]. Hence, the electric or magnetic field (or both) are elliptically polarized with the polarization ellipse coinciding with a plane of propagation. Richards and Wolf first recognized this subtle detail for tightly focused light beams [2] and Huard and Vigoureux for evanescent waves [3]. In the notation of the angular momenta of light, such confined fields therefore exhibit components of the spin, which are orthogonal to the propagation direction [1] in contrast to the conventional case of circularly polarized light. This research area of transverse angular momenta was initiated in 2009 [4] and, since then, received considerable attention (see for instance [1] for a review). In some cases, the angular momentum (spin) density or the net angular momentum might be even purely transverse [4-7].

The most flexible scheme for which this phenomenon of transverse angular momentum in general and transversely spinning fields in particular can be observed and even, more importantly, also spatially tailored is the framework of nonparaxial propagation in free-space. By properly choosing the input beams to be tightly focused, tailored landscapes of locally varying transverse and longitudinal angular momenta can be created at the nanoscale [1,5-7,12]. The resulting field distributions can be used, e.g., to selectively excite individual nanoparticles or other nanoscopic systems and to control their emission. In this context it was shown that an electric field spinning around an axis parallel to a nearby interface results in highly directional emission across a dielectric interface or directional coupling to plasmons [1,6-11], with the emission direction depending on the spinning sense. The latter one can be controlled easily by placing the nanoparticle in the focal field of a tightly focused light beam where the local spin (density) depends on the relative particle position [6,7].

This effect of transverse angular momentum components in focused light beams in combination with the aforementioned directional emission of a spinning dipole across an interface paves the way for a wide range of different applications and effects [1,5-11], some of which will be discussed in this presentation.

Microgels are cross-linked polymeric chains with dimensions ranging from several hundreds of nano- to a few tens of micro-meters. Microgels are highly sensitive to the environmental changes. Their shape and volume can experience a dramatic change in response to external stimuli such as temperature, pressure and ionic strength. This ability has attracted a lot of attention due to potential applications as micro-sensors, micro-actuators, micro-valves and drug delivery devices. In particular, temperature-responsive microgels can exhibit extremely large deformation in response to a variation of temperature of the environment. Combining photo-thermal materials (plasmonic nano-particles) with microgels opens a unique opportunity to design micro-dynamical systems, which can be controlled all-optically. In this presentation, we discuss our recent advances in the development of physical models capable to describe optically controlled, gold nanoparticle loaded microgel systems. Appropriate consideration involves self-consistent coupling of diffusion, elasticity, heat transfer and electrodynamic models. Using simple examples, we discuss how shape and volume of microgels can be controlled using light.

Plasmonic Enhancement of Light-matter Interaction in Planar Materials

Hossein Taghinejad, Syed Hamed Shams Mousavi, Tianren Fan, Mohammad Taghinejad, Ali A. Eftekhar, and Ali Adibi

School of Electrical and Computer Engineering

Georgia Institute of Technology

Two-dimensional metal dichalcogenides (2D TMDCs) have been of great interest lately due to their unique potentials for forming new optoelectronic devices. This talk is focused on the integration of 2D TMDC nanostructures with plasmonic nanostructures to considerably enhance their optical properties for enabling new devices for light emission and detection. It is shown that by using a carefully engineered plasmonic nanocavity, orders of magnitude improvement in light-matter interaction in these hybrid materials can be achieved. Supported by theoretical calculations, this technique will be experimentally presented for a variety of hybrid nanostructures, and its prospects for forming practical nanophotonic devices will be discussed.

Nonlinear plasmonics at anisotropic metal-dielectric interfaces.

Abstract— We show sensitivity of second harmonic generation to the surface plasmon propagation direction at anisotropic Au/dielectric interfaces. The symmetry of the iron garnet enables interplay between even and odd components of the nonlinear susceptibility leading to a 95% asymmetry of the second harmonic output. Illustrating this interplay with a simple two-component model, we discuss its applicability to nonlinear magneto-plasmonics and nanophononics.

Featuring strong electromagnetic field localization, surface plasmon-polariton (SPP) excitations are key building blocks of modern nanophotonics. Recently, nonlinear plasmonics [1] benefited from numerous observations of SPP-enhanced second harmonic generation (SHG). Often isotropic interfaces between air and polycrystalline noble metal films are considered, where the optical properties are independent of the SPP propagation direction. Prominent SHG sensitivity to the symmetry breaking suggests its applicability for probing excitations at anisotropic interfaces where new intriguing phenomena can be expected. SHG non-reciprocity with respect to the SPP propagation also holds promise for nonlinear magneto-plasmonics [2].

In this work, we probe SPP-assisted SHG from an anisotropic interface in Bi,Tm-doped iron garnet/Au hybrid plasmonic crystals. We observe strong variations of the SHG response when the SPPs are propagating in the opposite directions, in a striking contrast to the negligible variations of the linear transmittivity. In the vicinity of the SPP resonance at the anisotropic Au/garnet interface, the modulation of the SHG intensity reaches 95%. We consider a two-source model where SHG is generated at the Au/air and Au/garnet interfaces [3]. When the SPP is excited, the relative SHG efficiency at the two interfaces changes, and the interference results in a complex shape of the SHG response. The results of the SHG phase measurements allowed us to consider SPP-induced resonant enhancement of the fundamental field as $E_\perp = E_\perp^{NR} + E_\perp^{R}$. The crystalline anisotropy of the garnet film enables both even and odd $\chi^{(2)}$ components with respect to the angle of incidence θ. Within this approach, the outgoing SHG field takes the following form:

$$P_\parallel^{2\omega}(\theta) = \chi^{(2)}_{1,\perp\parallel\parallel} E^2_{1,\parallel} \sin(\pm\theta) + \chi^{(2)}_{2,\parallel\perp\perp} (E^{\mathrm{NR}}_{2,\perp} + E^{\mathrm{R}}_{2,\perp})^2 \cos\theta, \quad (1)$$

where the lower indices 1,2 stand for the Au/air and Au/garnet interfaces, respectively.

This interference of the SHG contributions with different parity with respect to θ holds high potential for rapidly growing fields of nonlinear magneto-plasmonics and nanophononics. Firstly, interface anisotropy can be utilized to enhance variations of the SPP-driven SHG output upon the magnetization reversal in garnet. Furthermore, anisotropic interfaces constitute a popular playground in nanophononics where surface phonon-polaritons (SPhPs) in polar dielectrics are excited instead of SPPs in metals. In particular, interplay of anisotropy-driven phonon modes with SPhPs was shown to strongly enhance the SHG output in the mid-infrared [4].

Enhancement of Electrocataytic Activity of Octahedoral Au-Core/Pt-Shell Nanoparticles by Visible Light Irradiation

T. Kameyama, K. Sato, and T. Torimoto
Graduate School of Engineering, Nagoya University, Japan
kameyama@apchem.nagoya-u.ac.jp

Abstract Octahedral Au-core/Pt-shell (Au@Pt) nanoparticles were successfully prepared via a galvanic replacement of Cu monolayer underpotentially deposited on Au core with a Pt monolayer. The visible-light irradiation to Au@Pt nanoparticles-immobilized electrodes enlarged a cathodic current of oxygen reduction reaction (ORR), suggesting that the electrocatalytic activity of Pt shell layer was enhanced by the photoexcitation of localized surface plasmon resonance peak of octahedral Au-core particles.

Noble metal nanoparticles (NPs), exhibiting localized surface plasmon resonance (LSPR) in visible-light region, have attracted much attention because their optical properties can be tuned by precise control of their shape and size.[1,2] Recently, the enhancement of catalytic properties by the plasmonic properties of metal NPs has been intensively investigated, because hot carriers could be created in plasmonic metal NPs by the photoexitation of LSPR.[3] In this study, we try to improve the catalytic activity of Pt with LSPR of octahedral Au NPs. An electrochemical technique is used for preparing Pt shell layer on octahedral Au NPs, resulting in the formation of Au@Pt core-shell NPs. The photoexcitation of LSPR peaks of octahedral Au core in Au@Pt NPs can modify the catalytic activity of Pt shell layer for oxygen reduction reaction (ORR) as a model reaction.

Octahedral Au NPs were prepared by reduction of $HAuCl_4$ in diethylene glycol containing poly(diallyldimethylammonium chloride) at 230 °C for 1 h. The underpotential deposition (UPD) of Cu monolayer onto octahedral Au NPs immobilized on an HOPG electrode was carried out with constant potential application at 0.26 V vs. RHE in an aqueous solution containing 1.0 mmol dm^{-3} $CuSO_4$ and 0.1 mol dm^{-3} H_2SO_4. Thus-obtained Cu-deposited Au NPs on HOPG substrate immersed in aqueous solution containing 0.5 mmol dm^{-3} K_2PtCl_4 for 10 min to replace Cu monolayer by Pt, resulting in the core-shell structure of octahedral Au@Pt NPs.

The Pt shell deposition on Au surface increased the average edge length of octahedral NPs from 65 nm to 66.5 nm without significant change in shape as observed in the SEM image of Fig. 1a and b. To elucidate the surface Pt coverage on the particles, we obtained the electrochemical active surface area (ECSA) of octahedral Au@Pt NPs by measuring cyclic voltammograms. The deposition of Pt layer on Au NPs

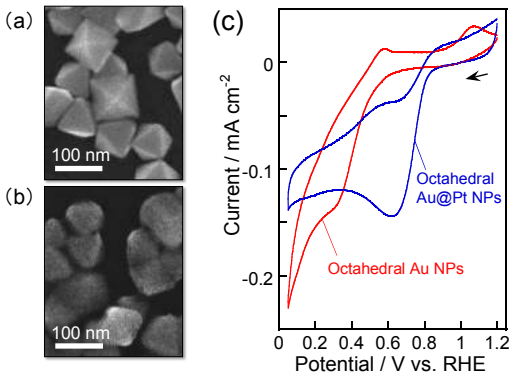

Figure 1. SEM images of octahedral (a) Au NPs and (b) Au@Pt NPs. (c) Cyclic voltammograms of octahedral Au and Au@Pt NPs in O_2 saturated 0.1 mol dm^{-3} $HClO_4$ aqueous solution.

decreased the peak current assignable to the reduction of Au oxide layer (ca. 1.15 V vs. RHE). In contrast, the peaks originating from the reduction of Pt oxide layer and the H_2 desorption on Pt surface were newly observed for Au@Pt NPs at 0.65 and 0.05V vs. RHE, respectively. These results indicated the surface of octahedral Au NPs was partially coated by the Pt shell layer. The Pt surface coverage was determined to be 85 % on octahedral Au@Pt NPs from ECSA.

Figure 1c shows the cyclic voltammograms of the octahedral Au and Au@Pt NPs for ORR in a dark condition. The cathodic current for ORR on octahedral Au@Pt NPs was observed at more negative potential than ca. 0.85 V vs. RHE, the onset potential of which was more positive than that of bare octahedral Au NPs, indicating that the electrocatalytic activity for ORR was much larger on the surface of Pt shell layer than on the bare Au surface. Furthermore the visible-light irradiation to octahedral Au@Pt NPs twice enlarged the cathodic current density of ORR at 0.7 V vs. RHE from -0.12 to -0.21 mA cm^{-2}. These results suggested that the LSPR excitation of the Au core in Au@Pt NPs greatly modified the electrocatalytic activity of the Pt shell layer for ORR.

Abstract- We report on developments in fabricating nanoplasmonic volumetric isotropic and anisotropic materials with plasmonic resonances at visible and infrared wavelength ranges. We push the melt-based crystal growth techniques for developing novel methods as the NanoParticle Direct Doping method enabling doping dielectric matrices simultaneously with plasmonic nanoparticles and quantum dots or rare earth ions. We also push the methods utilizing the self-organization mechanism as in directional solidification of eutectic composites.

Two types of materials will be discussed: (i) based on directional solidification of eutectic composites [1, 2], and (ii) directional solidification of dielectrics directly doped with functional nanoparticles of various sizes, shapes and chemical composition (metallic-plasmonic, quantum dots) as well as various additional elements as rare earths, obtained by the NanoParticles Direct Doping, NPDD [3, 4].

It has been shown previously that with self-organization mechanism during the eutectic crystallization various shapes pertinent to metamaterials can be obtained as the 'split-ring resonator' geometry [1], rodlike [5] or lamellar structures which can be used as hyperbolic metamaterials [6], or for subwavelength transmission of electromagnetic waves [7, 8]. It has been also shown that porous three-dimensional structures can be obtained [9] as well as curved multilayer structure obtained by rotation during the eutectic growth - resembling necessary structure for metamaterial hyperlens [10]. Recently we demonstrated eutectic-based tunable nanoplasmonic materials for the first time in visible [11, 12, 13], and we have demonstrated a composite with plasmonic resonances at infrared wavelengths [to be published].

The Talbot Effect in a Metamaterial

H. Nikkhah*, T. J. Hall
University of Ottawa, Canada
*hnikk057@uottawa.ca

Abstract- The effect of anisotropy and spatial dispersion of a metamaterial on the Talbot effect may be engineered in principle. This has profound implications for applications of the Talbot Effect such as the design of multimode interference coupler (MMI). The presentation reports findings on the design of a metamaterial, and its approximation by a Kronig-Penney material that is designed to suppress the modal phase error, which limits the scaling of MMI port dimension.

The (fractional) Talbot effect describes the longitudinally spatially periodic (multiple) self-imaging of transversely spatially periodic in free-space. The theory of the Talbot effect assumes Fresnel diffraction, equivalently of a spectrum of plane wave modes concentrated on-axis, and the phase relation between the self-images predicted evinces an intimate relationship with number theory [1]. The free-space Talbot effect may be mapped to a description of the self-imaging properties of a planar multimode waveguide. The theory of the waveguide Talbot effect follows that of the free-space Talbot effect once account is taken of the (near) zero of the field introduced by the waveguide sidewalls. This somewhat complicates the phase relations. The free-space Talbot effect extends naturally to a homogenous medium and, consequently, to metamaterials.

There have been significant improvements in MMI design to improve performance (uniformity, efficiency, bandwidth) and to reduce the size of its foot-print. However, the performance of MMI on a high index contrast platform decreases significantly as the number of ports is increased. The modal phase error scales with the number of ports. This can be ameliorated by the use of a low index contrast platform [2] but this expedient conflicts with the requirement for high quality fractional self-imaging that the modal expansion is close to a Fourier series. It is modal phase errors caused by the failure of the paraxial approximation that impair performance, whether introduced by coupling of the access-waveguides or by failure of the paraxial approximation in a multimode section.

Additional degrees of freedom are needed to tune the individual phases of the intermediate modes, which might be introduced by appropriate patterning of the geometrical or optical properties of the multimode section. The perturbation of the lateral refractive index profile in the multimode section to reduce the modal phase errors has been considered theoretically [3]. Shallow etching of the multimode region can also reduce the effective index contrast [4], but these solutions have the demerit of requiring a multiple etch steps in the fabrication process. MMIs formed using a subwavelength grating waveguides (SWG) structure offer a solution requiring only a single etch step. In this way, the lateral refractive index contrast may be reduced by using SWG in the lateral cladding regions of the multimode section while the high index contrast on the access waveguides remains to be able to place them closely to reduce the size of MMIs when the number of ports increases [5]. Moreover, the modal birefringence of the waveguide can be controlled by depositing low and high index layers with the subwavelength pitch on the top of the waveguide [6]. MMIs that make use of the anisotropy of SWG structure to achieve ultra-compact footprints have been reported recently [7] and an MMI with ultra-broad bandwidth of 450 nm and phase deviation below 3 degrees has been achieved [8] by engineering the dispersion

properties of the multimode region using SWG to mitigate the wavelength dependence of the Talbot distance.

Homogenised bulk SWG behave as strongly anisotropic materials with a c-axis normal to the layers of a 1D multi-layer (Kronig-Penney) or for a 2D photonic crystal in 3D along the axis of uniformity. A Kronig-Penney structure is uniaxial as is a 2D square or hexagonal lattice of circular cylindrical holes in 3D. Anisotropy can help reduce the Talbot length but temporal and spatial dispersion is necessary to control the modal phase error and the wavelength dependence of the Talbot length. Anisotropy and, even more so, spatial dispersion complicate the theoretical description of waveguide structures. The metamaterial can result in a Talbot length substantially independent of vacuum wavelength – thereby permitting broadband operation [7]. In principle, the paraxial approximation may be made exact in the metaxial regime and therefore modal phase error eliminated – thereby permitting the scaling of MMI port dimensions.

The presentation reports findings on the design of a metamaterial, and its approximation by a Kronig-Penney material that is designed to suppress the modal phase error, which limits the scaling of MMI port dimension. The findings may enable the realisation of photonic integrated circuits components of unprecedented performance. For example, a compact broadband MMI with large port counts would constitute a breakthrough in integrated passive coupler / splitter components enabling, for example, single component discrete space passive DFT functions and large cross-overs with accurate port phase relations.

Abstract-We present theoretical and numerical investigations on the locally resonant nanophononic metamaterials with ultralow thermal conductivity. The anomalous dynamics and thermal transport properties induced by various hybridizations between the local resonances of the branched nanopillars and the bulk modes of the host nanowires are verified by finite element analysis. A cantilever-in-mass model is proposed to theoretically analyze and control the resonance hybridization band. Particularly we report on near-zero thermal coefficients at local resonances with flat dispersion curves.

Analogous to locally resonant acoustic/elastic metamaterials, an emerging concept of nanophononic metamaterials (NPM) has been proposed recently for thermoelectric energy conversion [1]. Based on the local resonances of the nanopillars built on the surface of a host membrane, NPM can reduce the thermal conductivity without causing undesirable obstruction to the electron transport and thermoelectric conversion efficiency. Various numerical investigations on NPM have been conducted by using lattice dynamics (LD) calculations and molecular dynamics (MD) simulations [2, 3]. Little work has been reported about the analytical model of this emerging nanostructure. In this work, to theoretically investigate the dynamics and thermal transport properties of a side branched NPM (see Figure 1(a)), we propose a cantilever-in-mass model to describe the one-side branched nanowire. As shown in Figure 1(b), the host nanowire can be represented by an outer mass of m_1, and the side branched nanopillar can be enacted by a mass-less cantilever beam with an effective length of L_{eff} and an inner mass of m_2. This cantilever-in-mass model can be further transformed into a classical spring mass-in-mass model [4]. On basis of Euler–Bernoulli beam theory, we can calculate the equivalent spring stiffness of the nanopillar as $k = 3EI_z / L_{eff}^3$, where I_z is the moment of inertia about the bending z-axis or y-axis. Using the spring mass-in-mass model, we obtain the effective mass of the one-side branched nanowire as

$$m_{eff1} = m_1 + \frac{\omega_2^2 m_2}{\omega_2^2 - \omega^2} \tag{1}$$

where ω_2 is the locally resonant frequency of the internal resonator and can be written as

$$\omega_2 = \sqrt{\frac{Ea^2}{4L_{eff}^3 \rho L_h}} \tag{2}$$

The phonon dispersion relation of a one-side branched nanowire is illustrated in Figure 1(c). The mode

shapes at three representative frequencies (I, II and III) around different flat bands are visualized. It is observed that within the flat bands, the branched nanopillars exhibit distinct resonant profiles whereas the host wire does not confine any vibrations. Strong resonance coupling and hybridization between host structure and nanopillars induce the flat bands, which further result in a distinct reduction in group velocity. Using the Equations (1) and (2), we can theoretically analyze and control the first resonance hybridization bands. By modifying the resonator size, the thermal conductivity of the NPM can be further theoretically manipulated and tailored, which could be potentially significant in thermoelectric conversion.

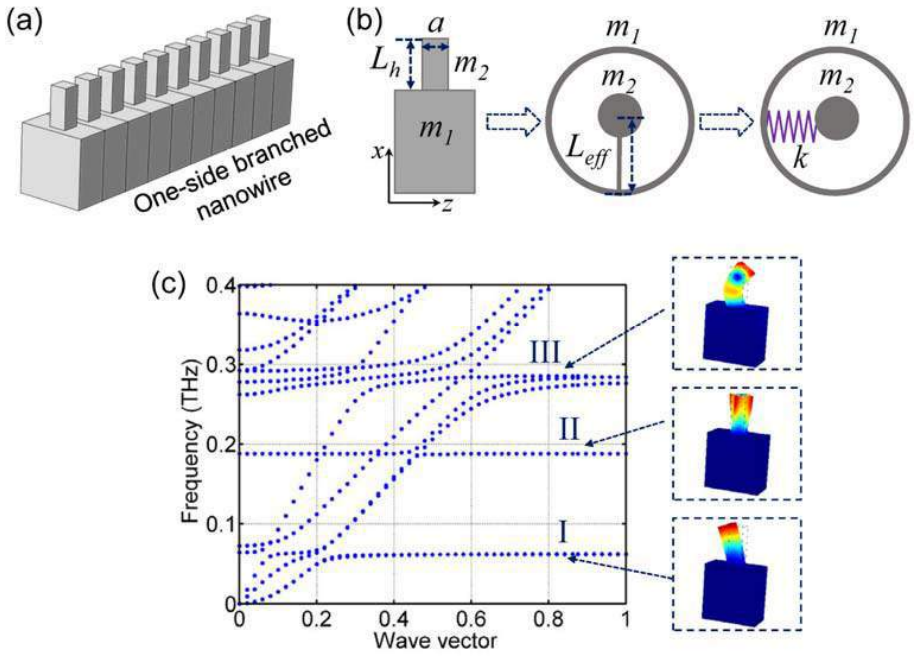

Figure 1. (a) Schematic diagram, (b) equivalent cantilever-in-mass model and (c) phonon dispersion relation for a one-side branched nanowire.

Abstract-We perform spatiotemporal imaging of acoustic waves in a metamaterial based on silica microspheres arranged in different patterns on a glass substrate, including waveguides. An ultrafast optical pump-probe system is used to obtain time-resolved two-dimensional images of both surface and bulk acoustic wave interactions with the microspheres. We also identify the metamaterial frequency band-gap regions through a detailed examination of the experimentally and theoretically obtained acoustic dispersion relations.

Materials consisting of two-dimensional arrays of particles demonstrate interesting effects on macro- and micro-scales [1,2]. Such materials exhibit a number of vibrational resonances corresponding to different types of particle motion and their mutual interactions. In particular, metamaterial structures consisting of microspheres on a glass substrate have lately been investigated by examining their interaction with propagating surface acoustic waves (SAWs), allowing the elucidation of the nature of the particle contacts and the demonstration of metamaterial band gaps corresponding to different resonances [2–4].

Arranging acoustic metamaterials in different patterns to form structures such as waveguides and cavities, in a similar way to analogous phononic-crystal and photonic-crystal structures, allows the construction of devices to control acoustic wave propagation. Such structures are ideally suited to spatiotemporal imaging studies. However, such real-time imaging has not been performed in acoustic metamaterials. In the case of particle arrays, the interaction of the particles with surface and bulk modes is expected to exhibit metamaterial band gaps.

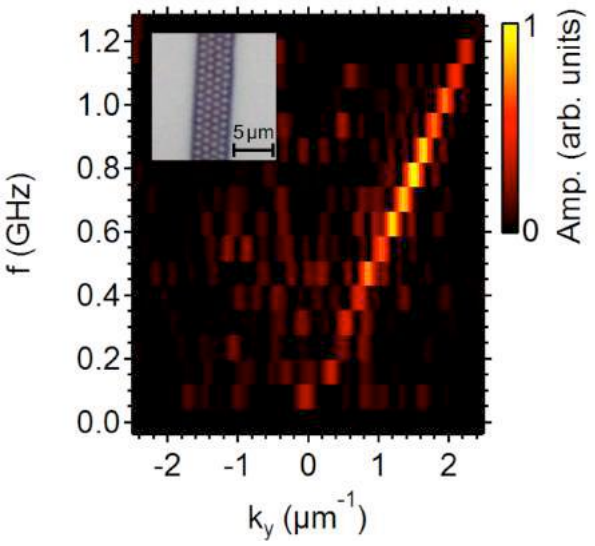

Fig. 1 Dispersion relation (frequency f vs wave number k_y along the propagation direction) of SAW propagation in a metamaterial arranged in the form of a linear waveguide. Inset: optical micrograph of a section of the sample.

However, gaps formed by bulk modes have not been experimentally studied in detail.

Here we experimentally investigate the interaction of propagating acoustic waves in a float-glass substrate with a surface structure consisting of a monolayer of 1.08 μm diameter silica spheres, demonstrating interactions with both SAWs and surface-skimming longitudinal bulk waves (SSLWs). These are excited and detected using an optical pump-probe set-up with a Ti:sapphire femtosecond laser operating at 75.6 MHz [5]. The glass substrate is coated with a 0.1 μm aluminum film for coupling with the laser pulses. The probe pulses, of wavelength 830 nm and duration ~200 fs, detect the out-of-plane surface particle velocity of the propagating waves. The beams are focused to spots of about 1 μm in diameter, and images are generated over areas up to ~200×200 μm^2, allowing animations of the surface motion to be obtained at acoustic frequencies up to ~1 GHz. Time-resolved images show acoustic waves—in particular SAWs and SSLWs—propagating along the sample surface.

Fourier analysis allows the propagation to be visualized at different frequencies, and allows the acoustic dispersion relation to be determined. In this connection, **k**-space images of the wave propagation on homogeneous samples show the presence of two acoustic modes, representing the SAWs and the faster SSLWs. Figure 1 shows the dispersion relation of SAW propagation for an arrangement of particles in the shape of a linear waveguide, in which case only the SAW mode appears. The inset of the figure shows an optical micrograph of the metamaterial waveguide sample, which consists of a column about 4 μm wide of closely packed microspheres. There is a pronounced dip in amplitude around ~300 MHz, corresponding to a wavelength of ~12 μm—considerably larger than the particle diameter—as expected for metamaterial-related resonances for this type of structure. This dip corresponds to the metamaterial band gap, a region in which the wave vector is a complex quantity.

The dispersion relation of a uniform array of microspheres is investigated by means of an analytical theory based on the interaction of the acoustic waves in the substrate with the particle vibrational resonances. We find good agreement with this theory and the experimentally determined dispersion relation of such a uniform array.

This work demonstrates the application of ultrafast laser imaging to microscale metamaterials. Future perspectives include the investigation of anisotropic effects in ordered structures and crystalline substrates, as well as the investigation of wave propagation in more complex 2D heterogeneous structures.

Magneto-plasmonic nanostructures with broken symmetry for effective magneto-optical response

Abstract-The work is devoted to the development of the novel design of magnetoplasmonic nanostructures for improvement of magneto-optical properties. Namely, we propose (1) magneto-plasmonic crystals with broken symmetry for obtaining the Kerr effects at normal incidence, and (2) magneto-plasmonic quasicrystals with the broadband magneto-optical response.

Resent research has demonstrated the enhancement of magneto-optical effects in structured media. In particular, the attention has been paid to plasmonic crystals which are periodic structures supporting surface plasmon polaritons. It was demonstrated that the transverse Kerr effect and the Faraday effect are resonantly enhanced in magnetoplasmonic crystals, and also novel promising effects arise, namely the longitudinal intensity effect. As a rule, these effects are of resonant nature, due to their relation to the excitation of eigenmodes, which leads to narrow spectral range of magneto-optical response.

A specific kind of nanostructures that attracts attention is plasmonic quasicrystals [1], that demonstrate broadband optical response and, moreover, it is polarization-independent for 2D structures. We investigate magneto-optical effects in plasmonic quasicrystals formed by a uniform magnetic dielectric and a quasiperiodic 1D or 2D metallic lattice. Theoretical approach is developed and experimental results are presented. The experiments were performed with two types of structures: (i) the 1D quasi-periodic grating specially designed for obtaining plasmonic resonances at certain range of frequencies, and (ii) the 2D structure with 10-fold rotational symmetry. The Faraday effect as well as the transverse Kerr effect demonstrate broadband enhancement. We also find the conditions for the enhancement of the longitudinal magneto-photonic intensity effect.

Due to symmetry reasons linear effects associated with in-plane magnetization (such as the transverse Kerr effect) are prohibited at normal incidence. However, for practical reasons it would be useful to observe the transverse Kerr effect at normal incidence. For that reason, the spatial symmetry of the structure should be broken. To achieve that we investigate a plasmonic crystal formed by a uniform magnetic dielectric and a non-symmetrical metallic lattice. The obtained results for the transverse Kerr effect measurements at normal incidence are consistent with the theoretical considerations.

There is steady increasing demand for a reliable and sensitive detection of a broad range of biomolecules. Among various different approaches for detection, our group is interested in the use of localized surface plasmon resonances (LSPR) as a transducing principle for the biomolecular binding. The LSPR occurs in metallic nanostructures, where the spectral position and shape of the resonance can be engineered by the shape of the structure. We have used several approaches with a different degree of complexity for the customized formation of the nanostructures such as microfluidic synthesis of anisotropic particles [1,2], double concentric structures by colloidal lithography [3], pyramidal structures by template stripping and colloidal lithography [4] or by thermal annealing of thin continuous metal layers [5]. The reliable readout of the spectral position of the LSPR with very low noise is one of the key challenges in the biosensing process. The relatively simple detection can be realized on nanoparticles ensembles, but the step to the spectroscopy of a single particle is challenging [6]. Often only single or a small number of nanostructures can be measured at once and therefore a parallelization of these measurements is very time consuming. In our approach we have established hyper-spectral imaging combined with microscopy imaging system, which allows to record spectral properties of many particles simultaneously [7]. We were able to map spatial variation of the protein adsorption and to demonstrate the limitation of the ensemble LSPR measurement caused by the shape variation of the metallic nanostructures.

Abstract- We introduce a new technique to resonantly post-tune ensembles of nanophotonic resonators with light. The method is scalable, highly precise, and compliant with on-chip structures. Building on the method, we develop medium-scale nano-optomechanical architectures where first collective phenomena do emerge. We report as first example the light-mediated frequency locking of multiple nanomechanical oscillators.

The interaction between light and mechanical motion, at the core of optomechanics, is boosted in lightweight nano-optomechanical resonators. After landmark experiments realized on single resonators, the investigation of collective phenomena now requires controlling vast ensembles of coupled resonators, with the coupling mediated by light or vibrations. This evolution towards collective nano-optomechanics bears potential for a variety of sensing applications of course, but for quantum or topological photonics as well. It is however impeded by the residual disorder imposed by nanofabrication techniques, which naturally detunes high-Q resonators and precludes resonant interactions between them.

Here we present a new technique to tune ensembles of nanophotonic/mechanical resonators. Light resonantly injected into the optical mode of a first resonator immersed in a fluid (gas or liquid) triggers an etching process, leading to a fine-tuning of the resonator's dimensions. The evolution of dimensions is monitored continuously by tracking the resonator's optical resonance with a laser. This tuning process, dubbed resonant photo-electrochemical etching, is naturally scalable to multiple resonators and allows us to tune small ensembles (2 to 5 resonators). We demonstrate the versatility of the process and discuss its implementations in various contexts.

Second, we present a first application of this tuning technique, by exploring the resonant optical interaction of multiple nano-optomechanical systems. We observe a first form of collective behavior involving several distant resonators, where a unidirectional flow of light frequency-locks a chain of nano-optomechanical oscillators.

CONNECTION BETWEEN NEGATIVE INDUCED ABSORPTION AND NEGATIVE INDEX OF REFRACTION FOR IRON DOPED POTASH-ALUMINA-BORATE GLASSES SUBJECTED TO THERMAL-RADIATION TREATMENT

A.N. Salakhitdinov[1], E.M. Ibragimova[2], M.K. Salakhitdinova[3]

E-mail: smaysara@gmail.com

Abstract. This work experimentally revealed, that ^{60}Co-gamma-irradiation of potash-alumina-borate glasses doped with 2 mass.% of iron oxide to the dose of 1.7 MR in the temperature range of 150-300 ^{o}C induced differential optical density changes within $-5.7 \le \Delta D_{\lambda} \le -3$ in the wave length range of 300÷350 nm, which is characteristic for meta-material. Calculations have shown that variation of optical refraction index within $-0.66 \le \partial n / n_0 \le 0.1$ due to microstructure transformation causes changes in the differential absorption coefficient of the glass $-7.86 < \Delta\alpha_{\sim} < 0.11$.

Introduction. Besides synthesis of metamaterials [1], alternative possible way is the dynamic nonlinear effect – self-organization of multielement disordered matrix under simultaneous influence of heating and ionizing irradiation radiative effects.

Levy P.W. [2] showed that it is possible to present the radiation induced absorption formed by superposition of several individual absorption bands, in the form of Gaussian for each color center α (E) in the glasses as coefficient of absorption of photons with energy E:

$$\alpha(E)=\alpha_m \exp[- (4\ln 2/\Delta E_{1/2})(E - E_0)^2], \qquad (1)$$

where α_m – absorption coefficient at the maximum of Gaussian curve; $\Delta E_{1/2}$ – width on half-height maximum. Dexter D.L. [3] studied absorption of light by atoms in ionic crystals and improved Smakula's formula for the concentration of color centers, but this one can be use for oxide glasses

$$N_i \cdot f = 0.87 \cdot 10^{17} \cdot [n/(n^2+2)^2] \cdot \Delta E_{1/2} \cdot \alpha_m, \quad \alpha_m = (2{,}303/d) \cdot D \qquad (2)$$

where f–oscillator force, n- optical refraction index, D-optical density, d–sample thickness in cm.

The purpose of this work is to study "meta" – like optical properties related with structural transformations at thermal radiation treatment of multi-component oxide glasses.

Theoretical background. Earlier we showed that for borosilicate glasses [4] proceeding from doses dependences of optical density (D) it is possible to estimate the number of color centers N_i

Considering dispersive curves and their relation through (1) and (2): $\alpha_m=\alpha_m$ (E), n = n(E), for changes of α_m and n we can write

$$[d\alpha_m(E)/dn(E)] = [d\alpha_m(E)/dE] / [dn(E)/dE]. \qquad (3)$$

Let's assume that $$n(E)=n_0 + \delta n_E = n_0(1+(\delta n_E/n_0)), \qquad (4)$$

where n_0 - constant index of refraction, $\delta n_E/n_0$– the relative index of refraction taking into account dispersion. Replacing, for simplicity $\alpha_m(E) = \alpha_\sim$; $n_E = n_\sim$ and considering (2) and (3) for derivative $[d\alpha_\sim / dn_\sim]$ we find:

$$\left[d\alpha_\sim / dn_\sim\right] = C \cdot \left[N / \Delta E_{1/2}\right] \cdot \left\{(d / dn_\sim)\left[\left(n_0^2 + 2\right)/\left(n_0 + n_\sim\right)\right) + \left((2n_0 + n_\sim)/(n_0 + n_\sim)\right)\right\} \quad (5)$$

For simplicity we will designate $\left(n_\sim / n_0\right) = n_\sim^{'}$ and finally obtain

$$\left[d\alpha_\sim / dn_\sim^{'}\right] = \Delta\alpha_\sim = \left[2/\left(1 + n_\sim^{'}\right)\right] - \left[\left(1 + \left(2/n_0^2\right)\right)/\left(1 + n_\sim^{'}\right)^2\right] - \left[\left(2n_\sim^{'}\right)/\left(n_0\left(1 + n_\sim^{'}\right)^2\right)\right] \quad (6)$$

For meta-material [5] it is possible to accept limits of change $-0{,}66 \leq \partial n / n_0 \leq 0{,}1$ and calculate according to (6) $-7.86 < \Delta\alpha_\sim < 0.11$. Thus, due to the thermal-radiation effect, the negative value of absorption coefficient caused by results in a negative value of optical refraction index of the oxide glass. It means physically self-transparency under certain experiment conditions.

Objects of research and experimental results. We studied experimentally KAB-50 glass matrix with the composition ($50B_2O_3 25Al_2O_3 25K_2O$) mol. % doped with 2 mass.% Fe_2O_3. The samples were irradiated in ^{60}Co gamma-source at the dose rate of 236 R/s to the dose of 1.7 MR in the temperature range of 150-300 ^oC. Figure 1 shows the differential absorption spectra of the glass samples irradiated at various temperatures. The particular feature occurs in the wavelength range of 300÷350 nm, where the differential optical density becomes negative and changes in the range of $-5.7 \leq \Delta D_\lambda \leq -3$. In other words the glass sample after the treatment and additional irradiation becomes the similar of metamaterial, the same time the thermo-radiative processes can be considered as a non-linear self-transparency of glasses.

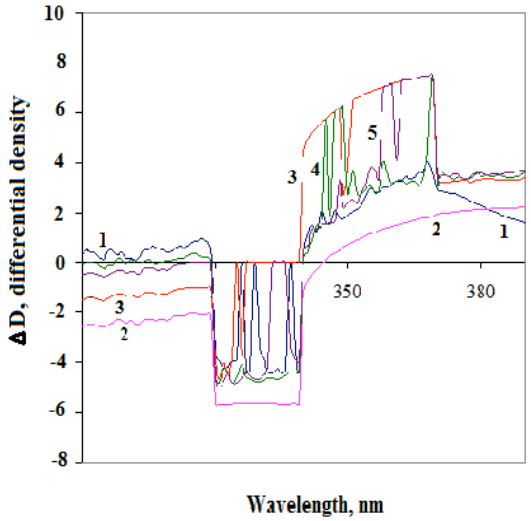

Fig. 1. Differential absorption spectra of the iron doped glasses ^{60}Co γ-irradiated at: 1-150 ^0C; 2 –200 ^0C; 3 - 250 ^0C; 4 - 300 ^0C

Abstract- Self-assembled metamaterials constitute a promising platform towards bulk optical materials with unusual effective properties. Reporting on several experimental systems, we show that they can reach unprecedented values of bulkiness and homogeneity figures of merit. This is achieved by assembling plasmonic nanoparticles into dense 3D structures, in which the localized surface plasmon resonances of the particles provide specific optical responses. We produce self-assembled hyperbolic metamaterials and self-assembled bulk nanocomposites presenting optical magnetism at visible wavelengths.

Among the exciting emerging functional nanomaterials, metamaterials are artificial composites presenting unusual properties of light propagation thanks to a specific structure at a length scale smaller than wavelength. The search for meta-properties in the visible domain has been mostly focused on nanostructured plasmonic systems. This has led to the search for new and versatile fabrication methodologies, among which nanochemistry and self-assembly have become promising routes. Two experimental systems will be discussed here, using self-assembly of metallic nanoparticles into dense organized structures, in which tailored localized surface plasmon resonances (LSPR) of the nanoparticles provide large amplitude and specific properties of the optical responses.

We produce anisotropic nanocomposites by the assembly of gold nanoparticles templated with spontaneously ordered matrices of diblock copolymers. In particular, we study periodic lamellar stacks of alternating layers of pure polymer (dielectric) and layers of composite of polymer loaded with a high density of gold nanoparticles (see Figure 1). The spectral variation of their anisotropic effective dielectric permittivity is determined by variable-angle spectroscopic ellipsometry using appropriate effective medium models.

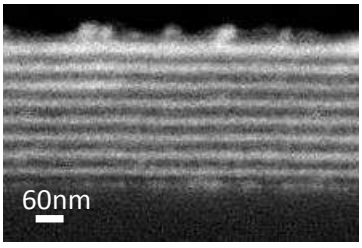

Figure 1. Side view (SEM) of a lamellar metal-dielectric

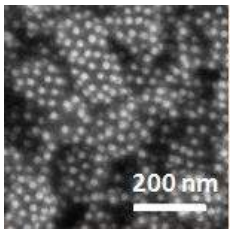

Figure 2. Top view (SEM) of assembled plasmonic raspberries

For large gold loading, the lamellar stack presents a frequency domain, in which the ordinary and extraordinary components of the dielectric function are of opposite signs. This peculiar property, called "hyperbolic", allows for the propagation of large magnitude wavevectors, carrying details finer than half the wavelength, otherwise corresponding to evanescent non-propagative waves in a usual dielectric. We therefore demonstrate for the first time the possibility of using a self-assembly methodology for the fabrication of bulk hyperbolic metamaterial[1].

We obtain plasmonic nanoclusters made of metallic satellites surrounding a dielectric core (so-called "plasmonic raspberries") by colloidal engineering. We measure both the electric dipolar and the magnetic dipolar scattering cross-section of these plasmonic raspberries vs. wavelength with a polarization resolved spectroscopic light scattering experiment. The raspberry-like nanoclusters are subsequently assembled to form a bulk metamaterial (see Figure 2), with an effective permeability parameter probed by spectroscopic ellipsometry at variable incidence, found to take values between 0.8 and 1.4, over the visible light wavelength range[2]. We thus created the first nanostructured metamaterial exhibiting a strong isotropic artificial optical magnetism in visible light.

We will discuss these results and how they can open new routes for metamaterial fabrication.

Abstract-We introduce a new class of photonic band gap materials based on amorphous gyroid networks. The amorphous gyroid networks are created using the concept of local-self uniformity that controls spatial correlations of on a wide range of length scales.

The fundamental correlations between the geometrical/topological characteristics of photonic materials and the advanced optical functionalities they provide is a fundamental problem in the field of structured photonic materials. To this end we introduce a new metric, local self-uniformity (LSU) [1] as a measure of the structural order of photonic network architectures of predefined valency.

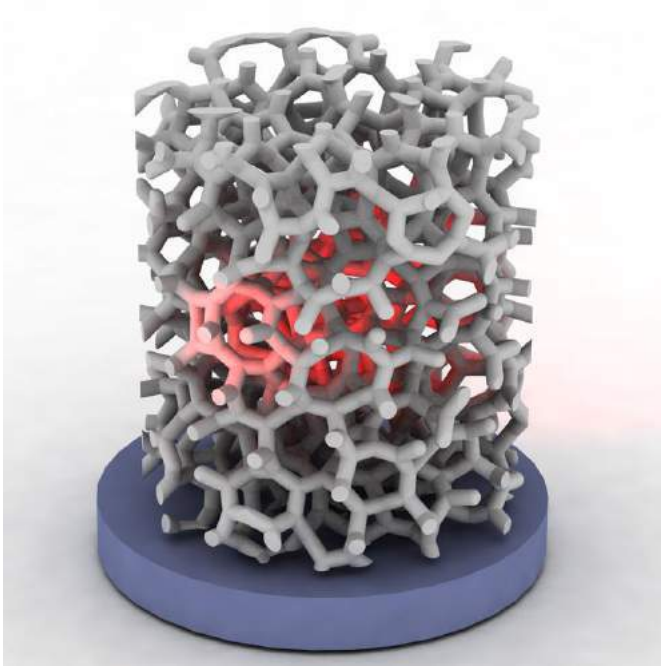

Figure 1: Schematic design of an amorphous gyroid photonic network.

The LSU metric can quantify the correlation between uniformity of the local environments and the overall photonic band gap properties and provides a new paradigm in the design of aperiodic media. LSU can be employed to uniquely classify photonic networks with a precisely defined upper limit reached for the only known strongly isotropic structures, the trivalent (SRS-gyroid) and tetravalent (diamond) networks. The lower reaches of the scale describe an interesting minimal local self-uniformity, or maximal self-dissimilarity. The LSU concept enables us to explore photonic band gap formation in a completely new architecture, the

amorphous gyroid network and to show that very distinct photonic architectures presenting large photonic band gaps, be they periodic or aperiodic, all are characterized by high values levels of local self-uniformity. The LSU metric renders the exact nature of their underlying seed patterns, whether crystalline, quasicrystalline, or hyperuniform, irrelevant.

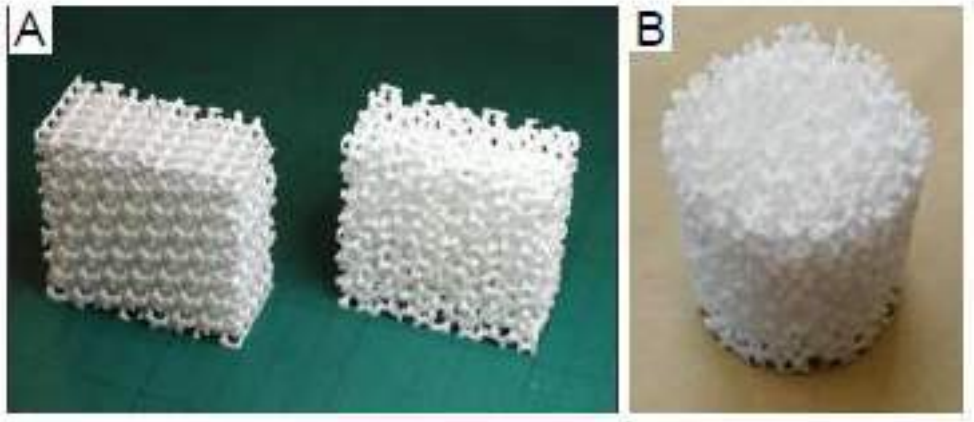

Figure 2 Alumina 3D-printed networks. The single network gyroid and amorphous gyroid blocks (A). Completed cylinder (B) assembled from the two semi-cylindrical pieces.

The new amorphous gyroid network is of significant interest for photonic applications. Amorphous gyroid is a three-dimensional continuous random network (CRN) characterized by 3-fold connected vertices and short range structural correlations whose strength decays with distance. By analogy with the well-known glassy disordered honeycomb and amorphous diamond networks, the network structure about a given vertex in amorphous gyroid should be a low symmetry realization of its structure in crystalline single network gyroid. We can expect that an amorphous gyroid structure possessing these properties should, like other glassy networks, exhibit substantial local self-uniformity. The realization and study of amorphous gyroid thus presents an opportunity to investigate the possible connection between local self-uniformity and the formation of sizeable photonic band gaps (PBGs) in high refractive index disordered structures.

The physical concept behind amorphous gyroid networks, local self-uniformity directly links a network's physical structure to its optical properties. It describes a fundamental mechanism of photonic band gap formation. Local self-uniformity, however, has significant relevance beyond this. It illuminates a subtlety in structural coloring architectures that has so far escaped detection. Further, an appreciation of a material's local electromagnetic resonances, and the control that local self-uniformity allows over the way they couple, represents a new paradigm in complex optical material design.

Abstract- We report our advances in the development of subwavelength engineered structures for on-chip photonics circuits, including Si membrane waveguides for sensing applications in the near- and mid-infrared, and high pump-rejection filters for quantum photonics.

The large transparency window of silicon (1.1 - 8 μm wavelength range) makes it a promising material for the implementation of a wide range of applications, including datacom, sensing, nonlinear and quantum optics. Patterning silicon with features smaller than half of the wavelength (well within the capabilities of standard silicon fabrication processes) has proven to be a powerful tool to tailor material properties, allowing the realization of Si devices with unprecedented performances [1].

Here, we exploit the new degrees of freedom leveraged by subwavelength engineering to implement two types of high-performance Si filters for nonlinear optics, quantum and sensing applications in the near- and mid-infrared. First, we will present subwavelength engineered Bragg filters based on a novel differential corrugation width configuration allowing narrow-band rejection with a single etch step and relaxed fabrication constraints [2]. These filters feature a rejection bandwidth of 1.1 nm and an extinction ratio exceeding 40 dB. Then, we will show an integrated Bragg grating waveguide filter for single-mode operation in near- and mid-IR. A 500-nm-thick and 1100-nm-wide silicon waveguide allows single-mode propagation in the mid-IR, while a specific waveguide corrugation is used to radiate out the higher order modes in the near-IR. This results in an effectively single-mode operation in near-IR. Building upon this concept, we demonstrated efficient waveguide Bragg grating filters for several applications. Our achievements pave the way towards the development of new types of on-chip functionalities in silicon based on the principle of subwavelength waveguide engineering.

Abstract We report on deterministic quantum light sources for applications in quantum communication systems. The sources are based on single quantum dot - microlenses fabricated by by in-situ electron-beam lithography. These quantum devices show close to ideal single photon purity with $g^{(2)}(0)<0.01$, high photon indistinguishability with V>90%, and high potential for quantum repeater networks based on entanglement distribution. Moreover, quantum dot – microlenses can be used for efficient twin-photon emission and allow for the development of stand-alone fiber-coupled single-photon sources.

The realization of building blocks for quantum networks has become one of the driving forces for the development of advanced nanophotonic device concepts and nanofabrication technologies. Within this field, significant progress has been achieved regarding for instance the fabrication of efficient quantum dot (QD) based single-photon sources. This work has almost elusively been performed on self-assembled QDs, which is explained by their superb optical and quantum optical properties. However, due to the self-assembled growth, both the position and the emission energy of individual QDs are controlled, which leads to a very low yield of usable optical devices when standard nano-processing schemes are used. This issue strongly limits the applicability upscaling of single QD based photon sources in practical systems such as multi-partite quantum networks.

In this contribution we will present a nanotechnology platform for the deterministic fabrication of high quality quantum light sources based on self-assembled QDs. Our technique is based on in-situ electron-beam lithography which allows us to integrate pre-selected quantum dots into photonic devices with nm-accuracy and flexible device design [1, 2]. In this way we realize deterministic QD microlenses (see Fig. on the right) which can act as non-classical light sources with superb optical and quantum-optical properties in terms of the photon extraction efficiency, the single photon purity and the degree of photon indistinguishability [3]. I will also discuss effects limiting the photon indistinguishability and show how they can be explored by delay-time and temperature dependent Hong-Ou-Mandel experiments [4]. The talk will conclude with recent work

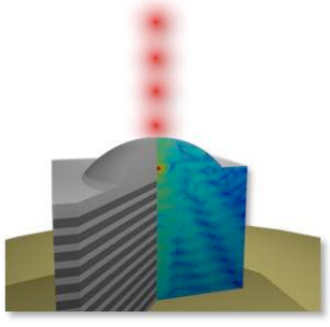

Fig. 1: Schematic view of a single-QD microlens.

and an outlook towards entanglement swapping using QD based quantum light sources [5], twin-photon emission [6] and direct fiber coupling of a QD-microlens the realize a stand-alone and user-friendly single photon source [7].

Engineering stimulated light-sound scattering in silicon

Peter T. Rakich[1]
[1]Yale University, Department of Applied Physics, New Haven CT, USA
[*]corresponding author: peter.rakich@yale.edu

Abstract- Brillouin nonlinearities permit stimulated light-sound scattering through optomechanical three-wave interactions. In conventional silicon waveguides, material response and poor acoustic confinement effectively stifle Brillouin nonlinearities. However, new optomechanical waveguides—that control both light and sound—have recently transformed Brillouin interactions into the strongest and most tailorable nonlinearities in silicon. In this paper, we use theory and experiment to demonstrate a variety of stimulated light-scattering processes. We also harness these interactions to realize light-amplification, signal filtering, and laser technologies.

Optical confinement and wave-guidance within optical fibers has allowed us to harness and enhance silica's intrinsic Kerr, Raman, and Brillouin nonlinearities. As a result, the silica fiber-optic is perhaps one of the most versatile nonlinear devices in existence [1]. These same principles have been applied in silicon photonics to yield a new class of highly nonlinear devices on a chip. For example, tight modal confinement has been used to radically enhance intrinsic Kerr and Raman nonlinearities in nanoscale silicon waveguides[2], [3].

Counterintuitively, Brillouin nonlinearities—which far surpass both Kerr and Raman nonlinearities in optical fibers—are exceedingly weak within these highly nonlinear silicon waveguides[4]. Within conventional silicon waveguides, material response and poor acoustic confinement effectively stifle Brillouin nonlinearities [4]. However, new optomechanical waveguides—that control both light and sound—have recently transformed Brillouin interactions into the strongest and most tailorable nonlinearities in silicon [5]–[8].

In this paper, we demonstrate a range of highly engineerable new stimulated Brillouin interactions in silicon waveguides by controlling both light and sound within a growing ecosystem of Brillouin-active optomechanical waveguides. In particular, we describe the recent realization of high performance Brillouin amplifiers in silicon [8] using forward intra-modal Brillouin interactions. We show how the unusual properties of forward-Brillouin interactions can be used to create microwave-photonic filtering technologies that have no analogue in all-optical signal processing [9], [10].

Building on these concepts, we introduce a new type of multi-mode optomechanical waveguide that creates phonon-mediated coupling between optical modes with distinct spatial profiles[11]. This process, termed stimulated inter-modal scattering, produces unusual new nonlinear dynamics[12], [13]. From a technology perspective, this process is intriguing because the incident and scattered fields propagate in distinct spatial modes, permitting unique forms of mode-multiplexing and dynamical mode conversion [11]. We show that this interaction opens the door to a range of Brillouin processes that enable everything from slow-light, to Brillouin-induced transparency, to new laser technologies in silicon.

Time-variant metasurfaces as a frequency converting platform

Bumki Min

[1]Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Republic of Korea

[*]corresponding author: bmin@kaist.ac.kr

Abstract- Rapidly time-varying metasurfaces are proposed as a frequency converting platform. The proposed metasurface is designed for sudden merging of two distinct resonances into a single resonance upon ultrafast optical excitation. From this dispersion-engineered temporal boundary onward, the merged resonance frequency component can be radiated.

A few years before the experimental demonstration of coherent nonlinear optical effect, Morgenthaler contemplated an alternate route towards the conversion of light frequency via velocity modulation of the wave, i.e. temporal variations of permittivity and/or permeability of the media [1]. Afterwards, continual theoretical efforts have been made to understand this linear frequency conversion. Experimental verifications followed then in the field of plasma physics; notable examples were the observation of frequency shift in rapidly growing plasma from laser ionization of gases and semiconductors. However, it was not until a group of researchers proposed chip-scale dynamic photonic structures, such as photonic crystals [2-5], micro-ring resonators [6], and waveguides [7] for the observation of wavelength conversion that the phenomena became the subject of engineering.

Active resonant metamaterials, in which the resonating meta-atoms are hybridized with electrically or optically reconfigurable natural materials, can be thought of as an optimal platform that can be spatiotemporally rearranged. Here, we propose rapidly time-varying metasurfaces as a frequency converting platform and demonstrate their efficacy experimentally at terahertz frequencies. Since our proposed conversion scheme does not rely on a nonlinearity of comprising materials, the conversion efficiency is invariant with respect to the intensity of an input wave. Therefore, this method would be beneficial especially for the frequency conversion of waves with weak intensities. Furthermore, the frequency of a converted wave and its efficiency is tailorable to a large degree as the conversion process does not require energy conservation between participating waves.

Nanowires offer new opportunities for nanoscale quantum optics; the quantum dot geometry in semiconducting nanowires as well as the material composition and environment can be engineered with unprecedented freedom to improve the light extraction efficiency.

Quantum dots in nanowires are shown to be efficient single photon sources, in addition because of the very small fine structure splitting, we demonstrate the generation of entangled pairs of photons from a nanowire.

Another type of nanowire under study in our group is superconducting nanowires for single photon detection, reaching efficiencies, time resolution and dark counts beyond currently available detectors. We will discuss our first attempts at combining semiconducting nanowire based single photon emitters and superconducting nanowire single photon detectors on a chip to realize integrated quantum circuits.

Tuning directional scattering through external magnetic fields in magneto-optical disordered media

Abstract

We analytically study light scattering of normally irradiated magneto-optical coated cylinders [1]. We show that the application of an external magnetic field along the cylinder axis, consisting of silica core and InSb shell, induces a drastic decrease in absorption and negative values of scattering anisotropy. This preferential backscattering response results in an anomalous regime of multiple light scattering from a collection of magneto-optical microcylinders, in which the scattering mean free path is larger than the transport mean free path.

1. Introduction

Preferential backscattering, which hardly occurs in natural media, is characterized by negative values of the asymmetry parameter, the average of the cosine of the scattering angle, $\langle \cos\theta \rangle$ [2]. Negative $\langle \cos\theta \rangle$ has been reported in ferromagnetic particles [3] and lossless dielectric nanospheres made of moderate permittivity materials, such as silicon or germanium nanospheres in the infrared region [4]. In these cases, negative asymmetry parameters have been show to lead to an unusual regime in multiple light scattering, in which the scattering mean free path is larger than the transport mean free path [4]. This peculiar transport regime has also been demonstrated for multiple scattering systems with correlated disorder under certain conditions [5].

Here, we propose an alternative, versatile strategy to achieve not only preferential backscattering (negative $\langle \cos\theta \rangle$) but also to control the scattering direction with an external parameter [6], which can be either an applied magnetic field or the temperature [1, 7]. We consider an infinitely long core-shell magneto-optical cylinder, normally irradiated by p waves, i.e., the magnetic field is parallel to the cylinder axis. The cylinder is embedded in vacuum (ε_0, μ_0) and consists of a dielectric core made of silica (SiO_2) ($\varepsilon_1 = 2.25\varepsilon_0$ and $\mu_1 = \mu_0$ in the far-infrared) of radius a coated with a cylindrical shell of indium antimonide (InSb) of radius b, which is a magneto-optical material strongly dependent of the external magnetic field and the temperature [9]. The complete analytical and numerical study of this system can be found in Ref. [1].

2. Results and discussion

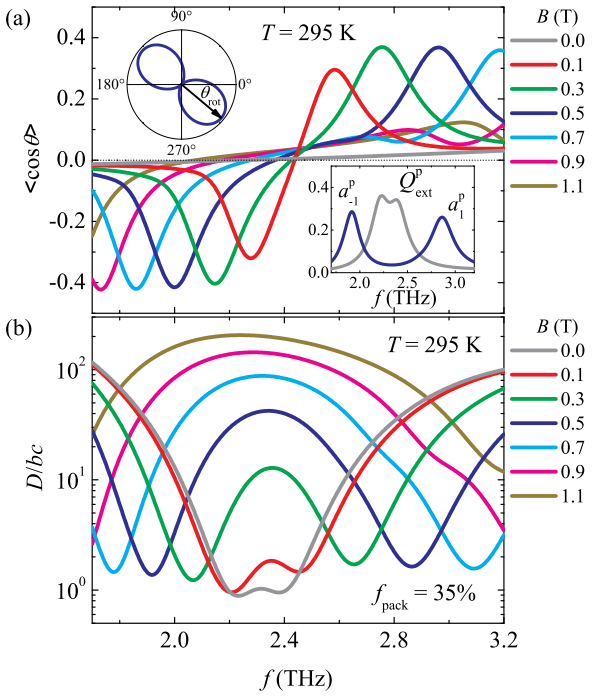

Figure 1: Light scattering by a SiO_2 microcylinder ($\varepsilon_1 = 2.25\varepsilon_0$) coated with InSb shell. The system is normally irradiated by p waves and is subjected to an external magnetic field $\mathbf{B} = B\hat{\mathbf{z}}$. (a) $\langle \cos\theta \rangle$ as a function of the frequency f, for various magnetic field amplitudes B, with the scatterer radius being $b = 2.5$ μm ($kb \ll 1$), and aspect ratio $S = a/b = 0.35$ at room temperature ($T = 295$ K). The insets show the extinction efficiency Q_{ext} for $B = 0.0$ T ($a_1^{\text{p}} = a_{-1}^{\text{p}}$) and $B = 0.5$ T ($a_1^{\text{p}} \neq a_{-1}^{\text{p}}$) and the corresponding scattering pattern for $B = 0.5$ T and $f = 2.0$ THz, where $a_{\pm 1}^{\text{p}}$ is the Lorenz-Mie coefficient for p waves. (b) The diffusion coefficient D for a collection of parallel and identical magneto-optical cylinders with packing fraction $f_{\text{pack}} = 35\%$, where c is the speed of light.

Figure 1(a) shows that the application of an external magnetic field $\mathbf{B}$ strongly affects the scattering directionality [8]. Indeed, the presence of $\mathbf{B}$ breaks the scattering isotropy of dipolar scattering, in contrast to what occurs for non-Faraday-active materials in the Rayleigh regime ($kb \ll 1$). For magneto-optical materials the Lorenz-Mie coefficient are not degenerate ($a_1^{\rm p} \neq a_{-1}^{\rm p}$) for $B \neq 0$, leading to a strongly asymmetric, magnetic field-dependent scattering pattern, as it can be seen in Fig. 1(a). In Fig. 1(b), we investigate the impact of tunable scattering anisotropy in light transport in planes composed of identical, infinitely-long magneto-optical core-shell cylinders. The parameters are the same as the Fig. 1(a): $b = 2.5$ μm, $S = a/b = 0.35$, and $T = 295$ K. Figure 1(b) reveals that the application of an external magnetic field up to $B \approx 1.0$ T leads to an increase in the diffusion coefficient $\mathcal{D}$.

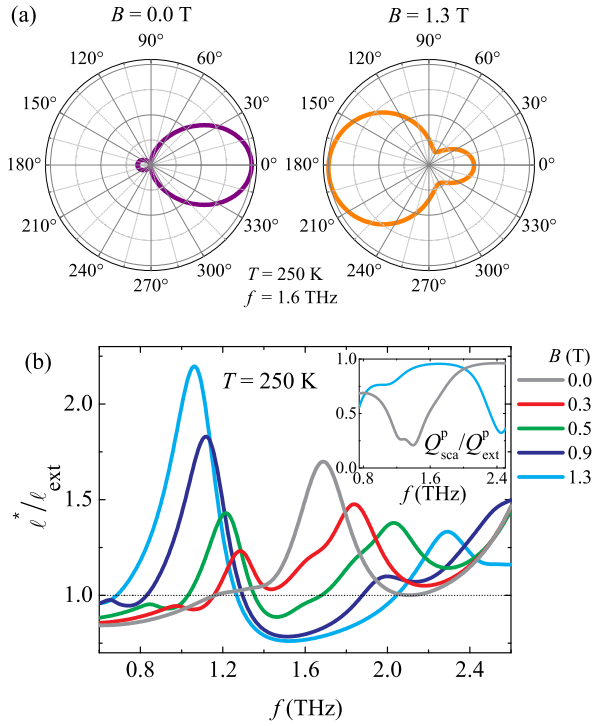

Figure 2: Light scattering by (SiO_2) core-shell (InSb) cylinders with outer radius $b = 25$ μm and aspect ratio $S = a/b = 0.5$. (a) Normalized differential scattering efficiency $\partial Q(\phi)/\partial\phi$ for a fixed frequency $f = 1.6$ THz ($kb \approx 0.84$) at temperature $T = 250$ K, for $B = 0.0$ T and $B = 1.3$ T. (b) The ratio between the transport mean free path and the extinction mean free path for a collection of cylinders.

Figures 2(a) and 2(b) demonstrate that it is possible to achieve directional scattering, which can be tuned by applying an external magnetic field, beyond the Rayleigh limit. The interference between electric and magnetic dipole contributions leads to a minimum in the internal energy around $f \approx 1.6$ THz as $\mathbf{B}$ increases. As it can be seen from Fig. 2(b), this interference induces a band (1.3 THz to 2.0 THz) of anomalous scattering in which $\ell^\star < \ell_{\rm ext}$. Moreover, for $B = 1.3$ T, $\ell^\star \approx \ell_{\rm sca}/(1 - \langle\cos\theta\rangle)$ since absorption becomes very small in this frequency range, as it can be verified in the inset of Fig. 2(b). This implies that there exists a transport regime in which $\ell^\star < \ell_{\rm sca}$, with $\ell^\star \approx 0.8\ell_{\rm sca}$.

It is worth mentioning that the application of the external magnetic field can suppress absorption in this frequency range, resulting in $Q_{\rm sca}/Q_{\rm ext} \approx 1$, as it can be seen in the inset of Fig. 2(b). In addition, for a fixed frequency and material parameters, Fig. 2(a) shows we can effectively tune the directional scattering pattern by applying $\mathbf{B}$. More details of this study can be found in Ref. [1].

3. Conclusion

Using the Lorenz-Mie theory, we have investigated the electromagnetic scattering by magneto-optical core-shell microcylinders. We have shown that the application of an external magnetic field induces a drastic decrease in electromagnetic absorption in a frequency window in the THz, where absorption is maximal in the absence of the magnetic field. We have demonstrated not only that the scattering anisotropy can be externally tuned by applying a magnetic field, but also that it can reach negative values in the THz even in the dipolar regime. This leads to an anomalous regime of multiple light scattering in a collection of magneto-optical core-shell cylinders, in which the scattering mean free path is larger than the transport mean free path in specific ranges in the THz. In our approach, we have demonstrated an unprecedented degree of external control of multiple light scattering, which can be tuned by either applying an external magnetic field or varying the temperature.

Bound states in the continuum with high orbital angular momentum in dielectric rod with periodically modulated permittivity.

E. N. Bulgakov and A. F. Sadreev
Kirensky Institute of Physics, 660036 Krasnoyarsk, Russia

Abstract— We consider bound states in the radiation continuum (BSC) in single dielectric rod with with periodically modulated permittivity. Because of rotational and translational symmetries the BSCs are classified by orbital angular momentum m, Bloch wave vector β directed along the rod and the polarization. The BSCs with high orbital angular momentum $m \neq 0$ and mixed polarizations constitutes the most interesting class of the BSCs because of high localization of EM fields near surface of the rod.

Recently confined electromagnetic modes above the light line were shown to exist in various periodical arrays of long dielectric cylindrical rods, photonic crystal slabs and two-dimensional periodical structures on the surface of material (see reviews [1, 2]). Among these different systems the one-dimensional array of spheres possesses by rotational symmetry that gives rise to the bound states in the continuum (BSCs) with orbital angular momentum [3] as shown in Fig. 1 (a). That reflects in unique properties of the scattering of plane waves by the array for the frequency nearby the BSC frequency [2, 3]. However fabrication of infinite array or at least more than hundred identical spheres [3] and arranged into a periodical array is a challenge because of technological fluctuations of shape of the spheres. Here we consider the single dielectric rod with with periodically stepwise modulated permittivity along the rod's axis z as shown in Fig. 1 (b). We consider that the permittivity takes two values $\epsilon > 1$ and $\epsilon_0 = 1$. Then the rod is equivalent to the one-dimensional array of dielectric discs with the permittivity ϵ. This system preserves the main feature of the array of dielectric spheres which is rotational and translational symmetry, however the single rod with modulated permittivity is much easier to fabricate. Each dielectric disk has two geometrical parameters, the radius R and thickness d that essentially expands the domain of existence of the BSCs for substantially lower permittivity compared to the case of dielectric spheres.

Figure 1: Infinite periodic arrays of (a) dielectric spheres and (b) discs.

In what follows we refer all length quantities in terms of the period h of the array. Because of rotational symmetry the total system splits onto the independent sectors classified by integer $m = 0, \pm 1, \pm 2, \ldots$, orbital angular momentum (OAM) which defines the BSCs which are degenerate relative to the sign of m. All components of the σ-th BSC can be expressed through auxiliary function

$$\left[\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} - \frac{m^2}{r^2} + \frac{\partial^2}{\partial z^2} + U_\sigma(z)\right]\psi_\sigma(z, r) = 0, \tag{1}$$

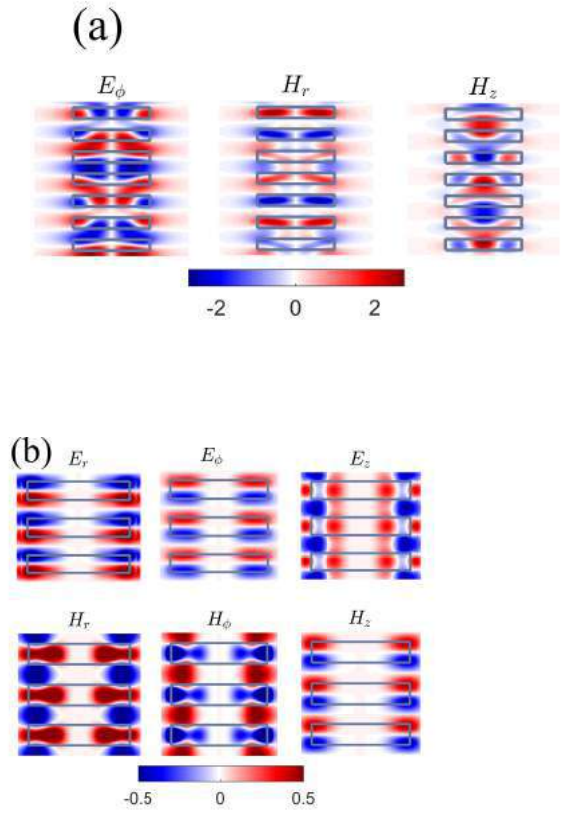

Figure 2: Patterns of the Bloch TE BSC with $m = 0, \beta = 1.08676$ at $R = 1$ and frequency $k_{0c} = 3.88423$ (a) and the BSC with high OAM $m = 5, \beta = 0$ at tuned radius of rod $R = 1.875$ and frequency $k_{0c} = 5.143873$ (b). Other parameters: $\epsilon_2 = 3, \epsilon_2 = 1, d = 0.5$.

where $\sigma = TE, TM$, $m = 0, 1, 2, \ldots$ is the orbital angular momentum and

$$U_{TE}(z) = \epsilon(z)k_0^2,$$
$$U_{TM}(z) = \epsilon(z)k_0^2 - \frac{3}{4}\left(\frac{\epsilon'(z)}{\epsilon(z)}\right)^2 + \frac{1}{2}\frac{\epsilon''(z)}{\epsilon(z)}.$$

That consideration for $m = 0$ and $\sigma = TM$ is completely equivalent to that performed by Li and Engheta in a plasmonic nanowire with periodic permittivity variation [4].

Toroidal Electrodynamics and Toroidal Metamaterials

Engineering anapole mode for the generation of toroidal dipole moment

Abstract- A novel three-dimensional plasmonic metamaterial which is able to generate a transverse toroidal dipole moment under normal illumination is presented in the optical region. In addition to the toroidal dipolar response, a non-radiating anapole mode resulting from the destructive interference between toroidal and electric dipoles is also observed. Different from the previous works, it is a specifically designed and fabricated plasmonic metamaterials for the generation of both transverse toroidal dipole moments and associated anapole mode, and readily available for feasible applications.

Natural toroidal molecules, such as biomolecules and proteins, possess toroidal dipole moments that are hard to be detected [1], which leads to extensive studies of artificial toroidal materials. Recently, toroidal metamaterials [2] have been widely investigated to enhance toroidal dipole moments while the other multipoles are eliminated due to the spacial symmetry. However, most of generated toroidal dipole moments are either aligned vertically to the substrate surface or embedded in a dielectric, which is a critical constraint for further applications of toroidal metamaterials.

In this talk, we will show several cases on the plasmonic toroidal excitation by engineering the near-field coupling between metamaterials. The gain-assistant toroidal resonance is subsequently studied for realizing toroidal lasing spaser. In addition, a novel design for a toroidal metamaterial with multi-layered structures is also studied. Because the induced toroidal dipole moment is oscillating at the interface between metallic structure and free space, this design overcomes the challenge in detecting the scattering of the induced toroidal dipole and provides a possibility of coupling with other dipolar moments. Besides, the non-radiating anapole mode [3, 4] results from the destructive interference between toroidal and electric dipoles are realized through such proposed toroidal metamaterials. To our best knowledge, this is the first proof-of-concept demonstration of anapole mode though coupled plasmonic metamaterials which offers a promising way for the investigation of optical properties with complicated electromagnetic fields.

Abstract-To perform a multipole expansion of a charge-current distribution is a key procedure when doing research on light-matter-interaction. Usually, expressions valid only for small particles are considered. Here, we derive exact expressions for electric and magnetic multipole moments, which are valid irrespective of the particle size. We show that the usually called toroidal multipole moments emerge in higher order terms of a Taylor expansion of these exact expressions. The physical implications of this Taylor expansion are discussed.

Quantifying the optical properties of artificial meta-atoms in terms of multipole moments is a key quantity to understand their optical action and to consider them in a broad range of applications in the slip-stream of nanoplasmonics, optical antennas, and metamaterials. The multipole moments, in general, represent elementary excitations into which the response of the meta-atom upon stimulus by an external illumination can be expanded. Usually, two approaches are used for this purpose. In a first one, the scattered field is taken and projected onto the vector spherical harmonics, being eigenmodes to the wave equation in spherical coordinates. Alternatively, the currents (either conductive or displacement current) induced in the meta-atom can be expanded in an orthonormal base. Since the radiated fields are completely determined by the current sources, the expansion of the currents must contain all the information that can be obtained by the expansion of the fields. However, this is usually obscured by an additional small argument approximation, valid only for scatterers having a size much smaller than the wavelength that is done to simplify the expressions for multipole moments on the base of the current distributions. The emerging approximate expression, e.g. for the electric dipole moment, read as

$$p_\alpha \approx -\frac{1}{i\omega}\left\{\int d^3\mathbf{r} J_\alpha^\omega + \frac{k^2}{10}\int d^3\mathbf{r}\left[(\mathbf{r}\cdot\mathbf{J}_\omega)\, r_\alpha - 2r^2 J_\alpha^\omega\right]\right\} \qquad (1)$$

where we have included the two lowest order terms of the Taylor expansion. Here, α is any of the three coordinates x, y, and z and the current distribution for a time-harmonic excitation is given in real space. This small argument approximation, however, ceases to be applicable for most meta-atoms of interest [1,2,3]. The second order term in the Taylor expansion of the exact electric dipole moment is often called the toroidal dipole moment. We shall emphasize that the expression is only approximate and an infinite number of terms in the Taylor expansion exists that have to be considered to restore the exact electric dipole moment.

However, the separation and the individual consideration of these terms in this Taylor expansion have some implications. Based on the pioneering work of Devaney and Wolf [4], it can be shown that the current distribution as a whole does not contribute to the radiated field. Instead, only an infinitely thin shell of the

current distribution if transformed into momentum space, for which $|\mathbf{p}|=\omega/c$ holds, contributes. ω is here the considered frequency and c being the speed of light [2]. The truncation of the Taylor series in Eq. 1 in real space causes out-of-shell components of the current distribution in momentum space to contribute to the approximate multipole moment. These approximate multipole moments are hence unsuitable for a quantitative analysis, as current contributions are considered for their evaluation that do not radiate and that do not interact with radiation. The contribution of these out-of-shell components is suppressed if the infinite number of terms in the Taylor expansion is added up. Therefore, all terms have always been taken into account to obtain physically meaningful results.

However, this Taylor expansion does not need to be considered. Instead, exact expressions for the multipole moments can be used that do not rely on the small argument approximation. We emphasize that exact expressions are readily found in literature [Eq. (7.20) in 5 or Eq. (9.165) without the magnetization current therein in 6]. Our contribution was to bring them in a form where they resemble their approximate counterparts of Eq. 1 [1,3]. This makes the approximations done in Eq. 1 much more evident.

In our contribution, we outline the derivation of these new expressions for the multipole moments on the base of the current distributions from first principles. Our expressions are exact and simple, i.e. comparable in complexity to those approximate expressions valid only for small objects and identical to those multipole moments extracted from the scattered field. For the electric dipole moment they read, e.g., as

$$p_\alpha = -\frac{1}{i\omega}\left\{\int d^3\mathbf{r} J_\alpha^\omega j_0(kr) + \frac{k^2}{2}\int d^3\mathbf{r}\left[3(\mathbf{r}\cdot\mathbf{J}_\omega) r_\alpha - r^2 J_\alpha^\omega\right]\frac{j_2(kr)}{(kr)^2}\right\} \qquad (2)$$

More general expressions will be presented at the conference, even though most important will be expressions for the dipolar and quadrupolar contributions. We show how these new expressions provide more accurate predictions to analyze meta-atoms. This has implications, and we will discuss this, on the ability to predict effective properties of metamaterials, to study the optical force acting on meta-atoms, and to study the response from meta-surfaces. Our results can be applied in the many areas where the multipole moments of current sources are used.

Abstract-Dynamic anapole is separated type of excitation. One of the most promising cases of anapole excitation has been observed in metamaterials and nanophotonics, which we discuss in this work. We show the peculiar properties of planar metamaterials, like extremely high Q-factor and strong electric and magnetic field localization, tunable toroidal metamaterials. Moreover, we discuss anapole excitation in dielectric metamaterials. Especially we discuss the role of losses in toroidal and anapole metamaterials: radiating and non-radiating nature and show that the playing between them can be crucial for effects of high Q-factor applications. We demonstrate our experimental and theoretical results in microwave, THz and optics.

Optical force on toroidal nanostructures: source representation versus field representation

Xu-Lin Zhang[1], **C. T. Chan**[1*]

[1] Department of Physics and Institute for Advanced Study, The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China

[*]corresponding author: phchan@ust.hk

Abstract- In the electrodynamic multipole expansion, all the charge and current distributions can be expanded into a complete set of contributions from electric, magnetic, as well as toroidal multipoles. However, the radiated far field from all these three types of source can be completely described in terms of electric and magnetic multipoles only, excluding the toroidal ones. We employ optical forces to address this confusion by studying the force acting on toroidal nanostructures in both source representation and field representation.

The notion of toroidal moments has always been confusing or even controversial in electromagnetics. The standard treatment of electromagnetics requires only two families of moments, namely electric and magnetic moments, to describe radiation fields for the reason that two sets of functions are complete because the fields are divergenceless in the source free homogeneous region. However, some authors showed that in addition to electric and magnetic moments, there is a third set of toroidal moments [1,2]. This issue was usually brushed aside as most electromagnetic structures do not have observable toroidal moments and so the argument of their existence is just "academic". However, due to recent advances in material fabrication, the toroidal metamaterials were theoretically predicted [1] and experimentally demonstrated at microwave frequencies [2], followed by various studies on their intriguing properties [3,4].

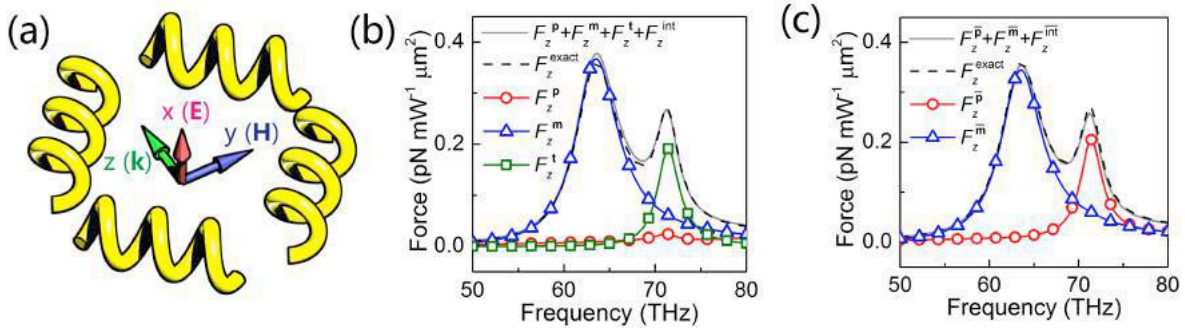

Figure 1 (a) Schematic diagram of the designed nanostructure that supports a toroidal dipole resonance. (b)-(c) Calculated optical forces acting on the toroidal nanostructure based on the source representation (b) and field representation (c).

Our main purpose in this work is to use optical force as a means to clarify whether toroidal moment is an indispensable or useful concept. Optical force is an excellent platform for such a consideration because mechanical effect is the most intuitively obvious consequence of abstract notions such as toroidal moments. We

found that there are two possible ways to understand the optical force. If we envision the optical force as a consequence of the incident wave interacting with the induced currents in a complex resonant structure, then the notion of toroidal moment is useful and indispensable. However, if we interpret the optical force as a momentum transfer between light and matter and we compute the momentum transfer by considering the scattered field in the far zone, then the toroidal moment does not appear in the description (see Figure 1). Both descriptions are correct and they complement each other, depending on whether we focus our attention on the near field or the far field. We also show that optical force enables the observation of the toroidal response of a nanostructure even when its effect on scattering power is overwhelmed by the conventional multipoles.

Toroidal cavity resonance in metal-dielectric-metal nanoantenna

Jun-Jun Xiao
College of Electronic and Information Engineering, Shenzhen Graduate School, Harbin Institute of Technology, Shenzhen 518055, China
E-mail: eiexiao@hit.edu.cn

Abstract- We show that in judiciously designed metal-dielectric-metal (MDM) nanoantenna, the toroidal dipole resonance may arise and dominate. Furthermore, toroidal-like cavity resonances can be excited and controlled. More interestingly, it is possible to tune the coupling interactions between such cavity modes and the antenna mode, yielding significant scattering enhancement and suppression of the MDM nanoantenna. The results are interpreted as Fano-like and/or electromagnetically-induced transparency like phenomena by a coupled oscillator model.

Dielectric nanoantennas: exploiting anapole modes and low-loss behavior for near-field localization of near-infrared and visible radiation

S. A. Maier[1]

[1] Imperial College London, London SW7 2AZ, UK

Abstract **– We discuss avenues for near-field focusing of electromagnetic radiation in the visible and near-infrared regime of the electromagnetic spectrum. A special focus will lie on the exploitation of anapole modes — coherent superpositions of electric and toroidal dipolar modes — in order to efficiently localize electric field energy in dielectric nanostructures. Materials systems to be presented include Ge, GaP, and hybrid dielectric/metallic nanoantennas.**

Dielectric nanostructures can localize electromagnetic radiation via the excitation of low-order Mie electric and magnetic modes. While not breaking the limit of diffraction, and providing a lower local field enhancement than their plasmonic counterparts, such structures show the advantage of low absorption losses due to the absence of free electron scattering. The first part of the talk will focus on the exploitation of anapole modes in order to efficiently maximize electric field enhancement in thin Ge nanodisks [1, 2], for applications in higher-harmonic generation. The nature of both first and higher-order anapole modes will be discussed, and the mode profile directly imaged using third-harmonic generation.

The second part of the talk will focus on GaP nanostructures, which due to the large bandgap show negligible absorption loss in the visible part of the spectrum [3]. Finally, hybrid dielecric/metallic nanoantennas allow the hybridization of anapole modes with plasmonic modes [4], boosting the local electric field enhancement.

Abstract— We discuss an all-dielectric integrated source of ultrafast optical pulses by finely tuning the mutual interaction and synchronization of near-field nanolasers emitting at the anapole frequency.

The generation of ultra-short pulses is standardly achieved by the mutual synchronization among a large number of cavity modes of the system, which, in most cases, is achieved by introducing external active components, such as Q-switching, saturable absorbers or optical modulators. Such components, due to their the required optical setups are complex and expensive and, more importantly, they are difficult to integrate at the nanoscale. As a result, the development of on-chip ultrafast pulsed nanolasers is still a challenging task [1].

In order to address these difficulties, we propose an integrated source based on the spontaneous synchronization of several near-field nanolasers emitting at the anapole frequency [2]. Anapoles, which have been experimentally demonstrated in silicon nanoparticles [3], are characterized by a radiation pattern which is entirely confined to the near-field, and they play a key role in the generation of scattering suppression states in dielectric nanostructures [4]. Due to their near-field emission, an ensemble of anapole-based nanolasers can be employed to investigate and engineer spontaneous synchronization phenomena in a silicon-compatible framework, as their mutual non-linear interaction is strictly confined to the near-field and can be precisely controlled within standard nanofabrication tolerances.

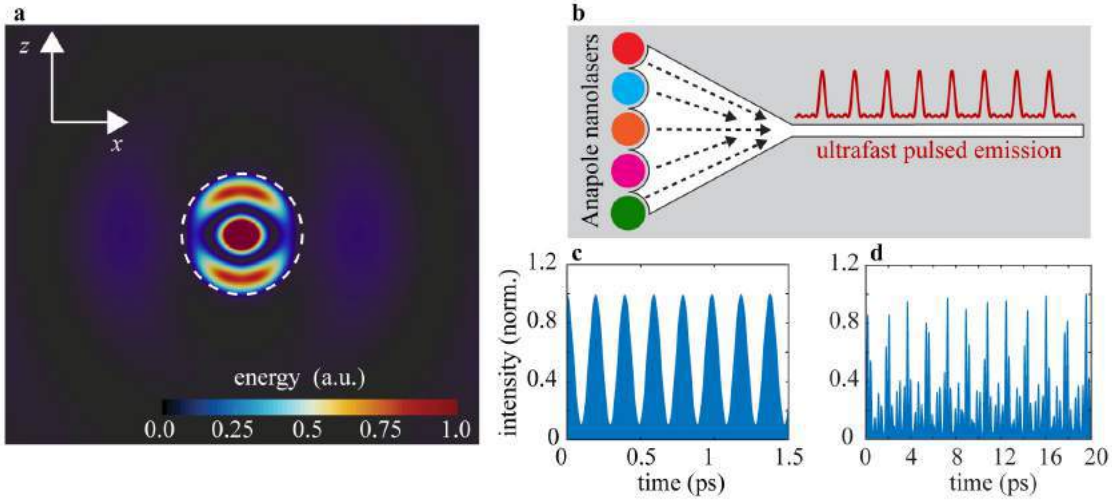

Figure 1: **Generation of ultrafast pulses from a chain of anapole-based nanolasers. (a)** Near-field emission from a three-dimensional anapole nanolaser. **(b)** Schematic representation of our ultrafast generation device, composed of an ensemble of nanolasers (green) and a Si waveguide (gray). **(c,d)** Steady-state emission from the system. The properties of the pulsed emission ranges from optical pulses of $\approx 100fs$ (b) to more complex configurations with *ps* optical pulses.

Results

We investigated the emission properties of an ensemble of anapole-based nanolasers with our Finite-Differences in Time-Domain simulator NANOCPP [5, 6, 7]. By solving a fully-dispersive set of Maxwell-Bloch equations with no approximations, we considered three-dimensional integrated nanolasers based on III-V semiconductors [8, 9]. In the Maxwell-Bloch model, the amplifying material is expressed in terms of a set of complex-valued density matrix equations. By optimizing the geometrical parameters of the system, we induced the formation of an anapole state in correspondence of the emission frequency of the amplifying semiconductor, obtaining a nonlinear emission composed of purely evanescent waves (Fig. 1-a). By combining different anapole nanolasers, the system behaves as an integrated ultrafast pulse generation device (Fig. 1-b), in which the collective emission of the interacting sources is convoyed into silicon waveguide. Due to the spontaneous synchronization of the anapole emitters, the system achieves a stable mode-locked state characterized by optical pulses of less than 100fs (Fig. 1-c). Interestingly, the pulse duration and the repetition rate of the emission can be finely tuned by acting on the spatial distribution of the anapole emitters, as shown in Fig. 1-d where we optimized the system to achieve *ps* optical pulses.

Steering light by tailored excitation of nano-antennas and applications to nano-metrology

Zheng Xi and H.P. Urbach*
Optics Research Group, Department of Imaging Physics, Faculty of Applied Sciences
Delft University of Technology, Delft, The Netherlands
*corresponding author: h.p.urbach@tudelft.nl

Abstract- Far field methods based on the interaction of spatial mode of light with ultra-compact resonant optical antenna are proposed to measure deep subwavelength displacement. The realm of combining optical antenna theory with spatial modes will open intriguing applications in nano-metrology and provide new insights into fundamental far field subwavelength detection technique.

The field of nano optics involves the study of light and matter interactions at nano-scale. One of the key elements is nano-antenna: nano-scaled particle that interacts resonantly with free space light[1,2]. Using the so-called antenna effect, free space light can be focused down to extremely small point, and then reemitted in a highly directional way through the interference of different antenna modes. The reshaping of the light field by nano-antennas has propelled many intriguing applications ranging from holography to imaging devices.

Attractive ideas have been developed to use different spatial modes of light for the excitation of different antenna modes[3-8]. For example, it has been shown cylindrical vector beams such as radially polarized beam and azimuthally polarized beam can excite the electric and magnetic resonances of the nano-antenna respectively[5]. However, the true power of this selective excitation lies in designing the excitation field on purpose for better antenna directivity. This would require optimization of the excitation field in terms of polarization, amplitude and phase.

If the nano-antenna is placed in a strongly inhomogeneous field, its far-field scattering directivity can be largely changed depending on its relative position[6-9]. If the incoming field contains rapidly changing features, the displacement sensitivity of the nano-antenna within the field can be extremely large. In this talk, we will talk about our recent works on this subject. In particular, we will show that extremely high far-field scattering sensitivity for a displacement much smaller than the wavelength can be achieved using the optimized illumination and nano-antenna structures. This method could bring about important understandings of super-resolution technique involving spatial modes of light as well as interesting applications in optical subwavelength metrology.

Nano-Plasmonics for Sensing

Tunable plasmonic sensing through enhanced Raman spectroscopy

Bikas Ranjan[1,2], **Akihiro Kuno**[1], **Takayuki Umakoshi**[1], **and Prabhat Verma**[1*]

Abstract-Plasmonic enhancement is the key phenomenon for sensing a molecule or a sample that has weak scattering, through enhanced Raman spectroscopies, such as SERS or TERS. In such techniques, there can be two different resonances, one associated with the oscillations of the localized surface plasmons and the other associated with the Raman scattering. If the two resonances are tuned to the same wavelength, the resultant enhancement can be huge and hence makes a better sensing device. We will discuss how tuning the plasmon resonance to the resonance in Raman allows one to achieve better sensing at nanoscale.

Both surface-enhanced Raman spectroscopy (SERS) and tip-enhanced Raman spectroscopy (TERS) have been utilized as plasmonic techniques for sensing and detecting tiny amount of specific molecules, as well as for spectroscopy and imaging at the nanoscale. The most important phenomenon in such measurements is the enhancement of Raman signal, which makes it possible to detect or study a sample that is extremely small in size or weak in scattering. A large amount of research in both SERS and TERS has therefore been dedicated to improve the enhancement factor. Since the localized surface plasmon polariton resonance (LSPR) depends on the size and shape of the metallic nanoparticles, as well as on the kind of the metal, it is very crucial to properly design the surface roughness for SERS substrate or the metallic nanoparticle at the apex of the tip in TERS. Further, if the LSPR is tuned to match the resonance in Raman scattering of the given sample, then one would expect even better enhancement as both resonance effect would work together. Once one decides the sample to be measured to detected, the incident wavelength for resonant Raman scattering from that sample is known. Now, one can design the plasmonic nanostructure in such a way that the LSPR of that plasmonic nanoparticle matches with the wavelength of resonant Raman scattering. In this way, when the decided wavelength is used as the incident light, both LSPR and resonant Raman scattering are simultaneously invoked.

In order to demonstrate this phenomenon, we designed a plasmonic nano-tip for TERS measurement, where a small triangular silver nanoparticle was attached to the tip apex. By changing the size of this silver nano-triangle, we confirmed through both simulation and experimental results that one can easily tune the LSPR within the entire visible spectrum. We demonstrated that for different size of the nano-triangle, the enhancement in Raman scattering can be obtained for different incident wavelengths, confirming the tenability in LSPR for better enhancement. We further demonstrated the selective detection of the presence of pesticide molecules on a food item, such as on an orange, by tuning the LSPR to the resonant wavelength of Raman scattering. For this, we design gold and silver nanorods and control their lengths to tune the LSPR at a desired wavelength that matches with the resonant Raman scattering from the pesticide. We showed that we were able to detect very tiny amount of pesticides, which was not detectable by conventional techniques.

Ag/SiN_x sub-10 nm gap for ultra-sensitive SERS detection

Abstract-SiN_x sub-10nm nanogap is fabricated by stress induced cracking of SiN_x nanobridge. The width of the gap is determined by the shape of nanobridge and Ag coating thickness. FDTD simulation shows that there is a "bulk effect" of the suspending nanogap, making the nanogap to be better than traditional metal gap in light confinement. Take rhodamine 6G as a probe, this structure performs very good in SERS even at an ultra-low concentration of 10^{-16} M.

Nanogap has been widely used in surface-enhanced Raman scatting (SERS) or surface enhanced infrared absorption (SEIRA), for its ability to confine light in a point or line-shape space[1-3], especially for the application of SERS. However, it is still a challenge to achieve large-area sub-10 nm nanogaps based on the existing techniques. Although a series of methods such as "break junctions" have been reported[4], problems still exists. For SERS devices applied in industry or medicine, the sub-10 nm nanogaps should be large-scale and stable. Stress induced film breaking is a promising technique to meet these requirement, however the existing technique can only be applied for brittle material[5], which restricting its application in metal structures for SERS application.

In this paper, stress induced SiN_x cracking method is introduced to achieve nanogaps with large-area, good repeatability and controllability. The bow-tie-shape is first fabricated by electron beam lithography (EBL) and reaction ion etching (RIE) on SiN_x film. TMAH is used to etch the substrate for suspending nanobridge, and in this process the stress concentrated on narrowest part of the nanobridge can release and result in SiN_x crack. By altering the shape of SiN_x nanobridge (Figure 1), the width of nanogap changes correspondingly. The gap width increases with the increasing of the bridge length and decreasing of the bridge width. In order to apply it on localized enhancement of electromagnetic, metallic nanogap is prepared by Ag deposition. Finite-different time-domain (FDTD) simulation shows that the suspending Ag/SiN_x nanogap provides strong electrical field than suspending Ag gap (Figure 2). R6G with an ultra-low concentration (10^{-16} M) can be detected.

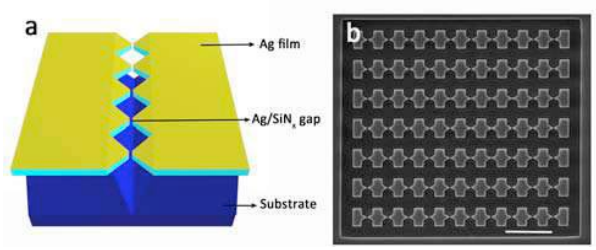

Figure 1 Schematic of Ag/SiN$_x$ nanogaps and SEM image of large-area samples.

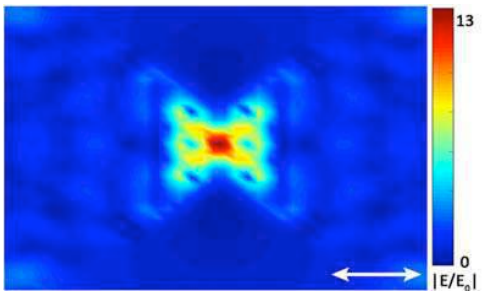

Figure 2 Field distribution of Ag/SiN$_x$ 8 nm-gap.

Abstract Fluorescence microscopy provides simple recipe to specific virus detection. Functionalized silver nanowires (AgNWs) with antibodies specific for T7 bacteriophage can be well seen in an optical microscope. By correlating fluorescence images of marked viruses with optical image of the silver nanowires we can efficient and easy define the presence of specific virus in a sample. The fluorescence will be concentrated around the viruses if the virus binds to the antibody-modified nanowires. Otherwise it will be distributed over the sample.

Sensitive detection of viruses and other relevant species has been considered recently as one of the most interesting and attractive research fields, both from fundamental and applied perspectives. The driving force behind these efforts is a need to prevent incubation and spreading of diseases among humans, animals, and plants. Binding of specific antibodies to targeted antigens is perhaps the most popular of all biosensor designs [1]. Among the numerous methods of detecting viruses are optical immunosensors based on surface plasmon resonance phenomenon, fluorescence detection or the application of optical fibers.

Since viruses labeled with fluorescent dyes are rather very small objects (20-300 nm) they cannot be directly observed using an optical microscope, however we can apply other nanostructures as “fishing rods” to detect them. While silver nanostructures have already been used to detect viruses [2], our idea was to apply silver nanowires as a geometric platform to hitch on antibodies and detect viruses by combining fluorescence and optical microscopy.

In our research we used two different bacteriophages: T7-SYBRGreen-intercalated and T4-SYTO62-intercalated. First bacteriophages are specific and the second are not-specific with respect to the antibody.

In the case with unmodified AgNWs there is no clear position correlation between the nanowires and the fluorescence spots (even for overnight incubation). Thus no specific interaction between viruses and nanowires took place. In ocntrast, for specifically functionalized AgNWs, where antibodies were attached that can bind T7-SYBRGreen intercalate bacteriophages, we observe clear correlation between these two images, as shown in Fig. 1. This effect is the most apparent after overnight incubation. We conclude that fluorescence microscopy imaginig indicates conjugtion of the antibodies attached to silver nanowires via specific attachment with T7-SYBRGreen intercalate bacteriophages. In many instances attachment of single wiruses can be demonstrated.

We belive that such an architecutre based on silver nanowires can be used for effective virus detection.

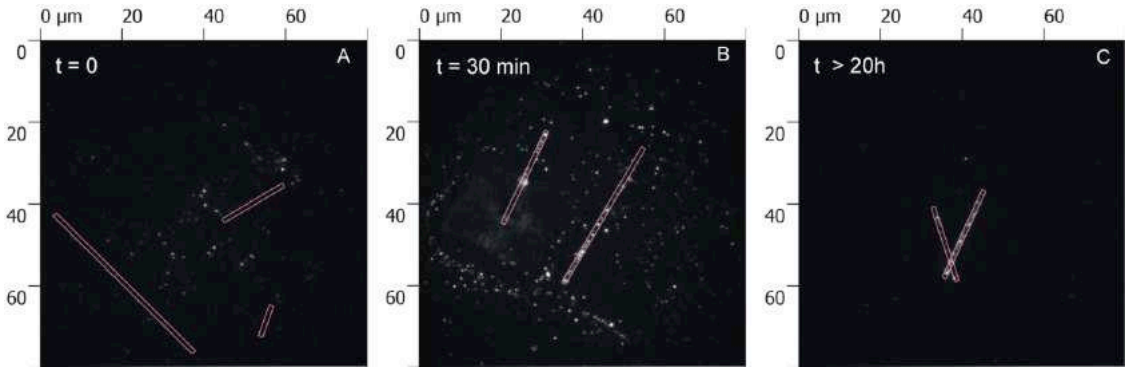

Fig. 1 Fluorescence intensity maps obtained using wide-field microscopy for T7-SYBRGreen intercalate bacteriophages mixed with AgNWs modified with anti-T7-tag antibodies after t = 0 (A), t = 30 min (B), t > 20 h (C). For excitation we used wavelength of 485 nm.

Abstract-We propose and investigate a hybrid photonic-plasmonic crystal nanocavity consisting of a silicon grating nanowire. The resonant defect mode exhibits a high quality factor of 567 and an ultrasmall mode volume of 1.9×10^{-3} $(\lambda/n)^3$. The cavity mode also reaches a sensitivity of 443 nm/*RIU* and a FWHM of 3.4 nm aiming at applications such as biosensing.

Plasmonic nanocavities that integrate surface plasmon polariton (SPP) with optical cavities usually significantly lower the effective mode volume (V_m) [1]. With the advantage of SPPs, various plasmonic cavities, especially utilizing the gap mode of SPP, have been proposed recently [2-4]. However, the quality factor of this type of cavities is compromised by parasitic loss of metal substrate..In this work, we propose and study a hybrid photonic-plasmonic nanocavity containing a silicon nanowire (*NW*) photonic crystal (*PhC*) near a metal substrate using finite-element method (*FEM*). With the periodic dielectric lattice atop the metal layer, hybrid plasmonic crystals are formed to support a complete two-dimensional band-gap [5] for the hybrid plasmonic gap structure. A defect is then introduced into the *PhC NW* to build up a nanocavity.

The proposed hybrid plasmonic nanocavity is illustrated in Fig. 1 (a). The structure consists of a patterned silicon *NW* and a silicon dioxide gap layer on silver substrate. The Si *NW*-SiO2-silver film structure supports hybrid plasmonic gap modes. These modes are coupled to the dielectric *NW PhC* Bloch modes to form a hybrid plasmonic crystal. The hybrid plasmonic structure as high-low-index dielectrics on a metal substrate brings about even small footprint inside the low-index region. Several dimensions of the proposed structure such as the *NW* etch depth *d*, the gap layer thickness *h*, and lattice constant Λ are varied to achieve the optimal design of high *Q*-factor and low mode volume. In addition, to achieve high-reflection Bragg diffraction, we look for the high refractive index contrast along the *NW*s.

In order to lower the mirror losses, different number of periods of each side by the cavity is varied to resolve the corresponding reflectivity by using three-dimensional (*3D*) *FEM* and orthogonality theorem [3]. The result shows that the reflectivity is proportional to the number of periods and gradually convergent. We obtain sufficiently small mirror loss when the cavity is accompanied with a pair of gratings of 8 periods. We then look into the field profiles of the high-*Q* resonant mode at λ = 1550 nm. As shown in Fig. 1 (b), the side view (*y*-*z* plane) of the field profiles of the cavity eigenmode reveals strong localization below the *NW*, whereas the top-view (*x*-*z* plane) shows that the field quickly decays inside the mirror region. Only one resonant mode with even symmetry along the z-axis is supported in this cavity. In addition, we solved for the quality factor *Q* of the nanocavity. In *3D FEM* calculations, we excited the nanocavity with a *y*-polarized plane wave. The spatial

integration of the squared magnitude of the electric field inside the gap region at various wavelengths was then recorded in the Fig. 1 (c). Next, resolving the field distributions of the resonance modes enables us to evaluate the mode volume V_m. A high sensitivity is essentially required for the better performance of an index sensor. We immerse the proposed nanocavities into water (n_c) or other aqueous solutions to examine the sensitivity S, as shown in Fig. 1 (d).

We proposed a hybrid photonic-plasmonic crystal nanocavity containing a silicon grating nanowire near a metal substrate with a gain gap between. We analyzed the modal characteristics of the hybrid plasmonic waveguide modes using finite-element method. We also numerically solved the band structure of the hybrid crystal modes. As a single defect is introduced to the photonic crystal, a resonant defect mode forms and exhibits strong confinement inside the gap region. For such cavities with a short defect length, a high quality factor near 567 and ultrasmall modal volume lower than 1.9×10^{-3} $(\lambda/n)^3$ are achievable. The results demonstrate that the defect mode can reach a sensitivity of 443 nm/*RIU* at the wavelength around 1550 nm aiming at biosensing applications.

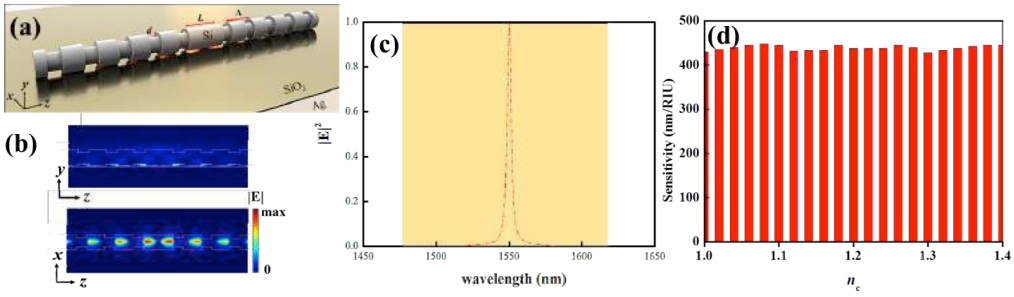

Figure 1 (a) The proposed photonic-plasmonic crystal nanocavity. (b) Side views of the defect resonant mode profiles by 3D FEM (c) The resonance line shape corresponds to a FWHM of 2.7 nm and the Q factor is 566.5. (d) The sensitivity S as function of the refractive indexes of the surrounding environments.

Nanoantennas for Enhanced THz Radiation – Matter Interaction

L. Razzari[1,*]

[1] INRS-EMT, 1650, Boul. Lionel-Boulet, Varennes, Quebec, J3X 1S2, Canada

[*]razzari@emt.inrs.ca

Abstract- We present our recent investigations regarding the interaction of localized terahertz (THz) radiation with nanomaterials. Details about the design of resonant metallic nanostructures for THz field confinement will be given, together with some examples of applications.

During the last few years, we have explored the use of metallic nanoantennas for applications in THz science and technology. We have shown that these devices can confine THz radiation well beyond the diffraction limit and are characterized by a large electric field enhancement close to their extremities [1,2]. We have also demonstrated that such properties can be further optimized (reaching enhancement values > 1,000) exploiting the end-to-end coupling of THz nanoantennas through nanogaps (down to 20 nm in width). The effective absorption of an object scales with the local electric field squared, and it can thus be increased by several orders of magnitude within antenna nanocavities. This can be used to enhance the interaction of THz radiation with nanomaterials and molecules. In particular, we have recently studied the coupling between the phonon resonance of semiconducting nanocrystals and the plasmon resonance of nanoantenna arrays. When the two resonances are matched, the combined system shows a clear destructive-interference feature in THz extinction measurements. We have first employed this effect to perform enhanced THz spectroscopy of a single layer of cadmium selenide quantum dots [3]. Intensified THz radiation - matter interactions within nanoscale volumes are also found to lead to other interesting phenomena that will be discussed on site.

Laser nano-engineered functional surfaces for high-performance organic optoelectronic devices

Hong-Bo Sun[1*], Xu-Lin Zhang[1], Jing Feng[1]

[1] State Key Laboratory on Integrated Optoelectronics, College of Electronic Science and Engineering, Jilin University, 2699 Qianjin Street, Changchun 130012, China

Abstract- We report high-performance organic optoelectronic devices including organic light-emitting devices (OLEDs) and organic solar cells (OSCs) employed with laser nano-engineered functional surfaces. The proposed laser induced functional surfaces can help manipulate light-structure interactions in these devices. As a result, the electroluminescence efficiency of OELDs and photon-to-electron conversion efficiency of OSCs are considerably improved.

Organic optoelectronic devices such as organic light-emitting devices (OLEDs) and organic solar cells (OSCs) have been attracting various attentions owing to their merits of lightweight, low cost, stretchable, and ultraportable. The electroluminescence efficiency of OLEDs and photon-to-electron conversion efficiency of OSCs are key factors for their commercial applications. Manipulating the surface profiles using laser micro-nano fabrication techniques is an effective way to improve their performance. Here we report some of our recent works related to this topic.

Stretchable OLEDs are becoming more and more important in the fields of wearable displays and health-monitoring technology. We report a laser-programmable buckling process to introduce micrometer gratings into OLEDs [1]. We realized a highly stretchable OLED with mechanical robustness and unprecedented efficiency. The strained device luminous efficiency, 70 cd A^{-1} under 70% strain, is the largest to date, which may pave the way for commercial applications of stretchable OLEDs. The loss of surface plasmon-polaritons (SPPs) in OLEDs employed with metallic electrodes always sets obstacles for high efficiency of the devices. To deal with this issue, we patterned the electrodes using a laser assisted soft nano-imprinting lithography. SPPs could then be extracted successfully and the device efficiency is considerably increased [2].

Broadband absorption enhancement is an effective way to improve the performance of OSCs. We introduced two-dimensional nanostructured electrodes into OSCs to excite SPPs supported in the cathode/organic interface. We performed numerical simulations and experiments and found that light absorption in the active layer can be enhanced in broadband due to the effect of SPP-induced field enhancement [3].

To conclude, we have proposed various laser induced micronanostructured surfaces in OLEDs and OSCs, which may pave the way for the commercial applications of high performance organic optoelectronic devices.

Nanoscale optical force spectroscopy in the vicinity of plasmonic and dielectric nanostructures

Taka-aki Yano[1,2*], **and Masahiko Hara**[1,2]
[1] Tokyo Institute of Technology, Yokohama, Japan
[2] RIKEN, Saitama, Japan
[*]yano@echem.titech.ac.jp

Abstract- We performed atomic force microscope (AFM)-based optical force spectroscopy to quantitatively characterize optical forces generated in the vicinity of plasmonic and dielectric nanostructures. The optical forces were either attractive or repulsive, which was controlled by size- and shape-dependent unique optical resonances of the nanostructures.

Plasmonically-induced optical forces in the vicinity of metallic nanostructures have received considerable attention because of their applications in local positioning and manipulation of nano-objects. There have been a variety of works on nano-optical forces controlled by various geometric configurations of metallic nanostructures [1].

Here in this work, we proposed the use of AFM-based near-field optical techniques [2] with high force detection sensitivity in order to quantitatively and qualitatively characterize optical forces generated in the proximity of various metallic nanostructures. In particular, the optical forces exerted between two metallic nanostructures were experimentally characterized, and were found to be either attractive or repulsive depending on the separation distance, incident angle, incident polarization and excitation wavelength. Furthermore, we also applied the plasmonically-induced optical forces for controlling biomolecular recognition reaction (ligand-receptor binding).

In addition to plasmonic materials, dielectric materials with high indices of refraction and low energy losses have recently been recently regarded as promising resonant scatterers to generate strong optical forces [3]. Among the high index materials, silicon (Si) nanoparticles with diameters of 100–200 nm have gained much attention owing to their multiple electromagnetic resonances in the visible region [4, 5]. We performed nanoscale optical force spectroscopy of a silicon nanodimer, and found that multiple excitation of electric- and magnetic-dipoles in the Si nanostructures played a crucial role in achieving the reversed optical binding force of the Si nanodimer.

Abstract— We investigated the effect of combined interband and intraband nonlinearities in aluminium zinc oxide thin films. We show that suitably timed two-colour pulsed excitations increase the material modulation bandwidth at near-infrared wavelengths and unlock novel functionalities including ultrafast modulation of the transmitted and reflected radiation frequency.

1. INTRODUCTION

Transparent conductive oxides (TCOs) are wide-bandgap semiconductors supporting large doping values ($\simeq 10^{21}$ cm^{-3}) and low effective electron mass, thus presenting a metallic response in the near-infrared (NIR) spectral region and high optical transmission in the visible part of the spectrum. This class of materials recently acquired a relevant role for nano-photonics for the large extent their optical properties can be controlled during the fabrication process and dynamically, via optical or electrical excitations [1, 2, 3]. Transparent conductive oxides also feature an epsilon-near-zero (ENZ) condition in the near-infrared spectral region, in the technologically relevant telecommunication band. At the ENZ wavelength, the effect of optical nonlinearities is enhanced [4, 5, 6], enabling ultrafast photonics applications such as all-optical switching [7]. Aluminium zinc oxide (AZO) is a TCO with reduced optical losses and low fabrication costs compared to other TCOs, showing strong, sub-picosecond interband nonlinear effects at the ENZ wavelength when excited by an above-bandgap optical pulse (UV, 325 nm) [7]. Even faster nonlinear effects have been observed when AZO is driven by longer wavelength pulses, as a consequence of the interband carrier dynamics [6]. Here, we show that the optical properties of AZO at the ENZ wavelength can be tailored in unique ways by a properly shaped two-colour optical excitation.

2. RESULTS

We experimentally investigated the change in the transmission and reflection at $\simeq 1300$ nm (ENZ wavelength) of a 900 μm thick AZO film when simultaneously excited by above ($\lambda = 262$ nm) and below ($\lambda = 787$ nm) bandgap ultrashort pulses ($\simeq 100$ fs), with a controllable relative delay. The time-resolved reflection and transmission measurements reported in Fig. 1 show that the two nonlinearities can be combined to increase or cancel the film nonlinear response. We also observed that the two-colour excitation enables to increase the modulation bandwidth above the limits of a single-pulse excitation. Further, we experimentally investigated the effect of such an ultrafast modulation on the transmitted and reflected pulse at the ENZ wavelength, reporting tunable wavelength shifts.

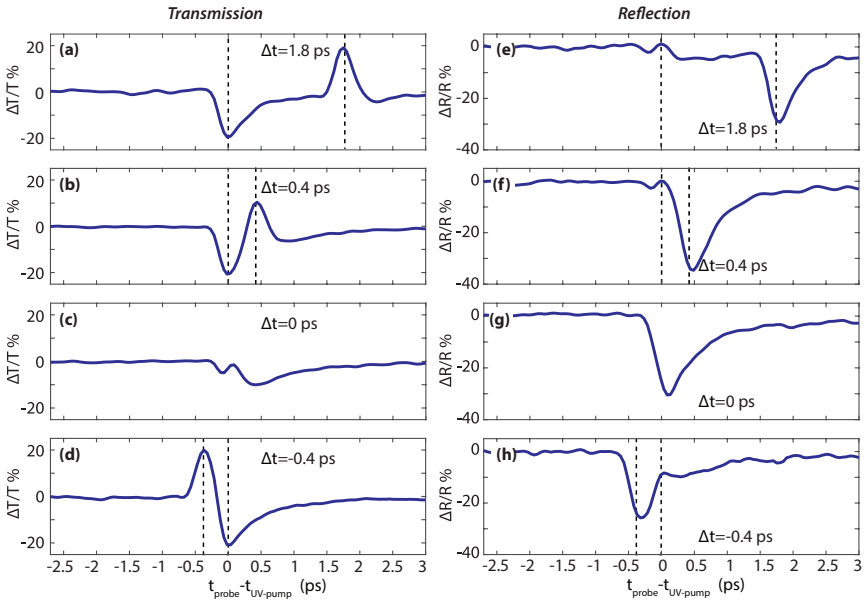

Figure 1: Relative changes in the transient transmission (a)-(d) and reflection (e)-(h) of an optical pulse at $\lambda = 1300$ nm from a 900 μm thick AZO film as a function of the delay between the UV pump and the 1300 nm probe pulse ($t_{probe} - t_{UV\text{-}pump}$). Different panels show the measured quantities for various relative delays Δt between the UV and the NIR pump pulses.

In conclusion, we shall report our measurements performed on AZO films and other commercial TCOs, and discuss the novel opportunities provided by the combination of intraband and interband nonlinearities, such as optical three-state logic and ultra-fast routing of the transmitted near-infrared radiation.

Abstract-Optical transformer is a plasmonic antennas that can focus the light in few nanometers space efficiently and broadband. By means of Nano Imprinting Lithography, it has been fabricated on top of an optical fiber in a configuration called "Campanile Tip". It is an efficient probe tip for Scanning Near Field Optical Microscopy and Spectroscopy. We will show the fabrication process, the optical characterization and the performances as high resolution SNOM tip.

One of the major challenges to the widespread adoption of plasmonic and nano-optical devices in real-life applications is the difficulty to mass-fabricate nano-optical antennas in parallel and reproducible fashion, and the capability to precisely place nanoantennas into devices with nanometer-scale precision [1]. In this talk, we present a solution to this challenge using the state-of-the-art ultraviolet nanoimprint lithography (UV-NIL) to fabricate functional optical transformers [2,3] (figure 1) onto the core of an optical fiber[4,5] in a single step, mimicking the 'campanile' near-field probes. Imprinted probes were fabricated using a custom-built imprinter tool with co-axial alignment capability with sub < 100 nm position accuracy, followed by a metallization step (figure 2) [6,7]. Scanning electron micrographs confirm high imprint fidelity and precision with a thin residual layer to facilitate efficient optical coupling between the fiber and the imprinted optical transformer. This novel nano-fabrication approach promises a low-cost, high-throughput, and reproducible manufacturing of advanced nano-optical devices. We demonstrate the capability to imprint 3D structures with sub-70 nm scale features and sub-100 nm positioning precision, creating functional 'campanile' near-field probes. The functionality of the imprinted probes was validated by performing hyperspectral nano-PL mapping of a dispersed film of 40 nm polystyrene fluorescent beads. Both the topography scans and the PL maps exhibited features consistent with the behavior of traditional FIB-fabricated optical transformer probes. Results show that imprinted campanile probes enable sub-diffraction-limit imaging with a resolution of ~ 80 nm, determined by the gap size at the tip apex. The fabrication process presented here can be scaled and parallelized for higher throughput and offers a promising route for mass production of nano-optical devices.

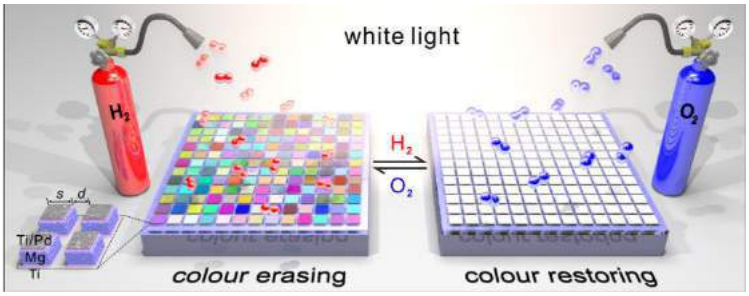
Abstract-Plasmonic color generation based on metallic metasurfaces provides resolutions far beyond the diffraction limit of light enabling new possibilities for printing color images or high-density optical data storage. However, the realization of dynamic plasmonic displays remains a challenging task. In the present paper, we utilize catalytic magnesium nanostructures, which change their optical properties during exposure to hydrogen, to demonstrate dynamic color generation. The technique could pave the way for animating high resolution images and could provide new routes for encrypting information or detecting counterfeits.

Plasmonic color printing based on tailored metallic metasurfaces provides resolutions several times higher than conventional printing techniques.[1] Due to its unprecedented subwavelength resolution, applications such as high-density optical data storage, stereoscopic imaging, or anticounterfeiting features are within reach. However, the realization of dynamic plasmonic color generation for displays with advanced functionalities still remains a challenging task.

In the present paper, we demonstrate two approaches of dynamic plasmonic displays exploiting catalytic magnesium nanostructures arranged in engineered metasurfaces.[2] First, brilliant colors are generated by tailoring the particles' sizes as well as their interparticle distances.[3] Secondly, dynamic displays based on cavity modes in a nanostructured dielectric layer, which is coated with magnesium, are demonstrated. In both approaches, a controlled hydrogenation and dehydrogenation of the magnesium trigger a metal to dielectric phase transition resulting in a dramatic change of their optical properties.



Figures 1 Schematic of the plasmonic metasurface composed of hydrogen-responsive magnesium metasurfaces interacting with incident unpolarized white light. Hydrogen loading is achieved by exposing the display to H_2 whereas dehydrogenation is achieved by oxygen exposure.

The technique could pave the way for animating ultra-high-resolution images as we demonstrated by reversibly erasing and restoring plasmonic color paintings. Furthermore, through a smart design of the nanostructures, information can be encoded on selected pixels enabling secure encryption.

Functional Materials and Devices for Acoustic and Elastic Waves

Parity Time Synthetic Phononic Media.

J. Christensen
[1]Universidad Carlos III de Madrid, Spain
corresponding author: johan.christensen@uc3m.es

Abstract- Classical systems containing cleverly devised combinations of loss and gain elements constitute extremely rich building units that can mimic non-Hermitian properties, which conventionally are attainable in quantum mechanics only. Parity-time (PT) symmetric media, also referred to as synthetic media, have been devised in many optical systems with the ground breaking potential to create nonreciprocal structures and one-way cloaks of invisibility. Here we demonstrate a feasible approach for the case of elasticity where the most important ingredients within synthetic materials, loss and gain, are achieved through electrically biased piezoelectric semiconductors [1]. We study first how wave attenuation and amplification can be tuned, and when combined, can give rise to a mechanical PT synthetic media with unidirectional suppressed reflectance, a feature directly applicable to evading sonar detection [2].

Abstract- Focal spot of a wave is bounded by diffraction limit, which has a dimension of half of the wavelength. This limit arises through the destructive interference between converging and diverging waves, which eliminate the singularity at the center of the focal spot, and gives rise to its sinc-function shape. We design a three-dimensional sub-wavelength absorber using acoustic metamaterial, and show with a time-reversal focusing experiments that by reducing the diverging waves, the focal spot is smaller than the diffraction limit.

We form a focal spot by converging, from the far-field regime, a spherical wavefront $P_{in} = \exp(-ikr - i\omega t)/r$ to a point defined as $r = 0$. Here, $k = 2\pi/\lambda$ is the incoming wave vector. However, after reaching the point $r = 0$, the wave does not disappear, instead it diverges, forming another spherical wavefront $P_{out} = \exp(ikr - i\omega t)/r$. Note that a singularity can be found in the spatial distribution of both the incoming and outgoing wavefronts *alone* at $r = 0$, at which point the wave's amplitude diverges. However, this singularity does not usually exist. This is because the total wave field in the medium given by the superposition of the two wavefronts

$$P = P_{in} - P_{out} = \left(\frac{e^{-ikr}}{r} - \frac{e^{ikr}}{r}\right)e^{-i\omega t} = \frac{2i\sin(kr)}{r}e^{-i\omega t}$$

It follows that the destructive interference between the incoming and outgoing waves eliminates the singularity at $r = 0$. The resultant total wave field takes a finite value at the origin, and the major peak of the focal spot has a FWHM of $\sim\lambda/2$. This interference process is also responsible for the formation of side lobes.

The above analysis suggests that one may restore the singularity by simply modifying the ratio of P_{in} and P_{out}. In the extreme case that $P_{out} = 0$, i. e., the wave converges to $r = 0$ but without subsequently diverging, interference no longer occurs, therefore side lobes of the

focal spot vanishes, and the singularity at $r = 0$ shall be restored.

We construct a subwavelength acoustic metamaterials that is highly absorbing for a spherical wavefront. By using this metamaterial absorber, we are able to significantly reduce the outgoing waves of thereby successfully observe that a wave can be focused to dimension smaller than the diffraction limit. Experimental evidence also show signs of singularity at the center position.

Optimal Sound-Absorbing Structures*

Ping Sheng
Department of Physics, HKUST, Clear Water Bay, Kowloon, Hong Kong, China
and
Institute for Advanced Study, HKUST, Clear Water Bay, Kowloon, Hong Kong, China
sheng@ust.hk

Causal nature of the acoustic response dictates an inequality that relates the absorption spectrum of the sample to its thickness. We use the causal constraint to delineate what is ultimately possible for sound absorbing structures, and denote those which can attain near-equality for the causal constraint to be "optimal." By using acoustic metamaterial as backing to conventional porous absorbers, a design strategy is presented for realizing structures with target-set absorption spectra and a sample thickness close to the minimum value as dictated by causality. By using this approach, we have realized a 10.86 cm-thick structure that exhibits broadband, near-perfect flat absorption spectrum starting at around 400 Hz, while the minimum sample thickness as calculated from the causal constraint is 10.36 cm. To illustrate the versatility of the approach, two additional optimal structures with different target absorption spectra are presented. This "absorption by design" strategy would enable the tailoring of customized solutions to difficult room acoustic and noise remediation problems.

Abstract-Due to the spinless nature of sound, the "spin-like" degree of freedom crucial to topological states in acoustic systems is commonly realized with circulating background flow or pre-set coupled resonator ring waveguides, which drastically increases the engineering complexity. Here we realize the acoustic pseudospin multipolar states in a simple flow-free symmetry-broken metamaterial lattice. Topologically protected edge states and reconfigurable topological one-way transmission for sound are further demonstrated.

The application of topology, the mathematics of conserved properties under continuous deformation, is creating a range of new opportunities in acoustic systems. This field was inspired by the discovery of topological insulator which shew insulating behavior in the bulk and transmission states without dissipation in the interface. Because of the spinless nature of sound, the "spin-like" degree of freedom crucial to topological states in acoustic systems is commonly realized with circulating background flow[1,2] or pre-set coupled resonator ring waveguides[3], which drastically increases the engineering complexity.

In this paper, we demonstrate the "spin-like" degree of freedom crucial to topological states in a simple flow-free metamaterial lattice, without using any complicated material or structure. Starting with the honeycomb acoustic metamaterial lattice, we make the primitive cell rotated and enlarged to obtain a metamolecule, which constructs double Dirac cone at the center of the 1st Brillouin zone. We make sound circulating in the lattice and the direction of sound propagation within each hexagonal cluster (i.e., clockwise or anticlockwise) plays the role of pseudospin (i.e., pseudospin-down or pseudospin-up). Tuning the strength of intermolecular coupling by simply contracting/expanding the metamolecule can induce band inversion effect between pseudospin dipole and quadrupole, which leads to a topological phase transition (shown in Fig. 1).

As a result of the spin-orbital coupling, these artificial pseudospin multipoles can support topologically protected one-way transmission, in which the route of sound propagation can be reconfigured to whatever you want. The two pseudospin states will not affect each other at the same frequency and between different frequencies. What is worth noting is that the pseudospin modes will not change after encountering the local defects. These results open new avenues for the novel acoustic topological insulators with versatile applications, such as acoustic modulators, transducers and isolators.

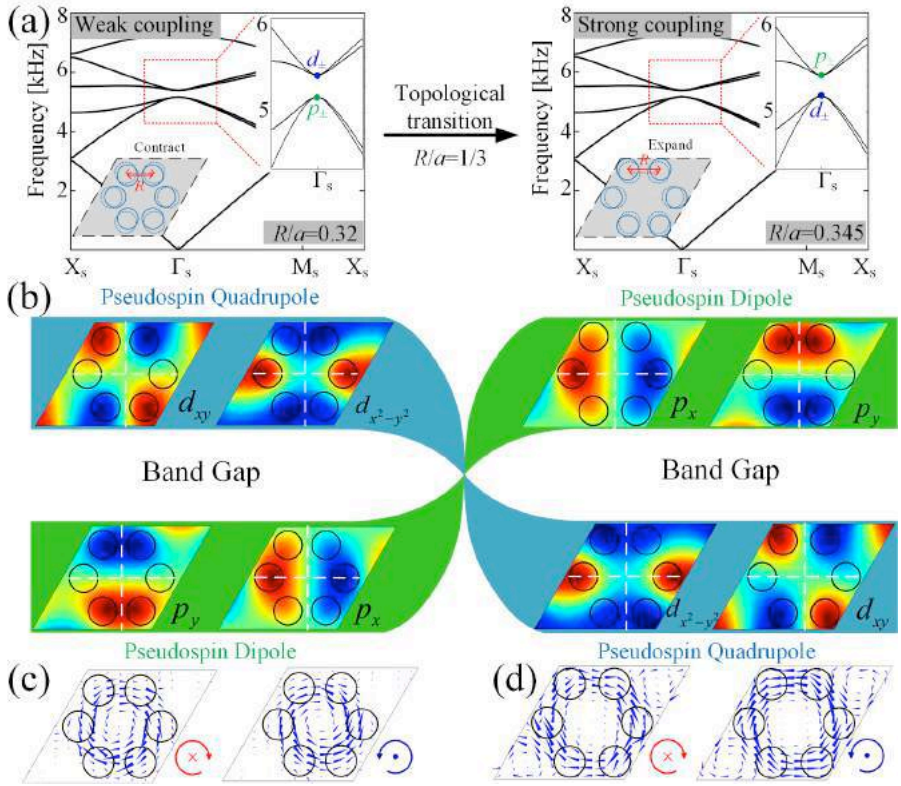

FIG. 1. (a) Topological transition as the coupling strength is tuned from weak (*Left*: R/a=0.320) to strong (*Right*: R/a=0.345). Critical coupling appears at R/a=1/3 with double Dirac cone. (b) Topological modes inversion underlying the transition. Sound intensity I associated with pseudospin-down and pseudospin-up modes below the band gap in the (c) trivial regime (R/a=0.320) and (d) nontrivial regime (R/a=0.345). The rainbow colour represents the amplitude of acoustic pressure, and the arrows show the direction and amplitude of the intensity.

Anisotropic metasolids for elastic wave control

Yong Cheng, Jiahui Huang, Hongkuan Zhang and Xiaoming Zhou*
Key Laboratory of Dynamics and Control of Flight Vehicle, Ministry of Education and
School of Aerospace Engineering, Beijing Institute of Technology, Beijing 100081, China
*corresponding author: zhxming@bit.edu.cn

Abstract-We have proposed a structured metasolid, which can be homogenized into an elastic continuum with both stiffness and inertial anisotropy. Effective medium parameters have been retrieved from band structure results and have shown the orthotropic properties in elasticity and inertial mass. This anisotropic metasolid fulfills the requirement of transformation elastic mediums under some special coordinate transformations in which the Navier elastodynamic equation retains its original form. We study some elastic wave controlling examples based on the proposed metasolids.

Transformation method has now been recognized as a powerful tool for generating parameter inhomogenity in order to manipulate wave propagation in ways as one will. The concept is initiated in electromagnetics realm [1,2], and later extended rapidly to acoustics[3] and elastic waves[4]. In elasticity, Navier elastodynamic equation doesn't retain its original form under a general coordinate transformation; however elastic wave controlling based on special form-invariant transformation is still significant, which requires both elastic and inertial anisotropy in solids. The practical design of this solid can be made possible based on the metamaterial concept.

Based on the recent advances of elastic metamaterial design [5-8], we have proposed a preliminary version of the anisotropic metasolid. The element consists in a periodic hexagonal frame structure, inside which the resonator-like inclusions are inserted. Anisotropic stiffness is realized by the non-regular hexagon geometry of the frame structure. Anisotropic inertial mass is achieved due to the different resonant frequencies in two perpendicular principle directions. Band structures of the periodic lattice have been calculated, which have shown the purely longitudinal and transverse branches of our interest at a finite frequency range. Utilizing the modal fields of band structure results, we have defined average stress and strain fields for the cell structure, and retrieved all orthotropic effective parameters according to macroscopic elasticity and inertial motion equations. Effective medium analysis has been fully conducted, from which the influence of microstructure geometry to the overall anisotropy is well identified.

As an example of elastic wave controlling, we have considered a wave beam shifting medium, obtained by using the linear transformation. The parameters of this transformation device are anisotropic in both stiffness and mass, thereby can be readily realized by the proposed metasolids. The cell structures of the beam shifting metasolids have been designed with their anisotropic parameters strictly satisfying the transformation results. Full-wave simulations have been conducted to verify the beam shifting performance of the designed device.

As a conclusion, this work has proposed the microstructure model of metasolids with both elastic and inertial anisotropy. The beam shifting effect achieved by the proposed metasolids is exampled. The study is expected to find potential applications in seismic wave protection.

Topological transport of sound vortices

Shubo Wang[1] **and C. T. Chan**[1*]
[1]Department of Physics and Institute for Advanced Study,
The Hong Kong University of Science and Technology, Hong Kong, China
[*]corresponding author: phchan@ust.hk

Abstract- We theoretically and experimentally demonstrated the geometric phase effect for sound using a helical waveguide. We show that the geometric phase can be used to control the flow of sound vortices inside an interferometer structure, resulting in geometric-phase-based sound vortex filter.

When a physical system undergoes a cyclic evolution, a non-integrable phase can arise in addition to the normal dynamical phase. This phase, depending only on the geometry of the path traversed in the parameter space and hence named geometric phase (also called Berry phase), has profound impact in both quantum-mechanical and classical physics, resulting in exotic phenomena such as Aharonov–Bohm effect [1] and light spin-Hall effect [2-3]. It has been experimentally observed for light travelling with a helical trajectory [4]. We show that it is possible for sound to manifest a similar effect, which may seem rather counter-intuitive as sound is a scalar wave without transverse polarization.

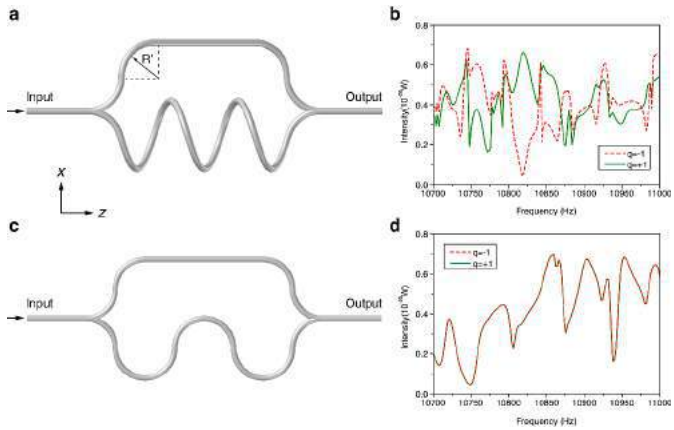

Figure 1. Designed interferometers with [(a)] and without [(c)] geometric phase. (b) and (d) show the transmissions of q = ±1 sound vortices for the configurations in (a) and (c), respectively.

Consider sound propagating inside a waveguide with hard boundary. For high-order waveguide modes such as dipole, the corresponding pressure field has a non-uniform phase on the transverse plane and hence plays a similar role as the transverse polarization field of light. The linear combination of two orthogonal dipole components is essentially a sound vortex carrying topological charge q = ±1. When the waveguide is slowly bended into a helical shape, the dynamics of the sound vortices inside are governed by an equation that is formally identical to the one describing the spin evolution under a slowly varying magnetic field [5]. The helical shape of the waveguide induces a Berry curvature (effective gauge field) that corresponds to an effective

magnetic monopole located at the origin of the momentum space, which leads to a geometry phase with a sign dependence on the topological charge of the sound vortex. So opposite sound vortices have different transmissions when they propagate through an interferometer (Fig.1a,b). However, if the waveguide has in-plane bending feature, the geometry phase vanishes and one get equal transmission for opposite vortices (Fig.1c,d).

The study here demonstrates that scalar waves such as sound also have interesting topological features that can be used for designing structures to modulate wave transport.

A metamaterial approach to the cochlear wave

M. Rupin[1], G. Lerosey[1], J. de Rosny[1], and F. Lemoult[1*]
[1]Institut Langevin, CNRS UMR 7587, ESPCI Paris, PSL Research University, 1 rue Jussieu, 75005 Paris, France

Abstract- We show that the physics of the inner ear, responsible for the mammalian's audition, can be modelled by a one-dimensional active metamaterial. More precisely, quarter wavelength resonators, with a gradient in their resonance frequency, side coupled to a main waveguide, give rise to the travelling wave typical of the dead cochlea. By introducing a feedback loop in each resonator, we then reproduce all of the salient non-linear properties of the living cochlea.

The human ear is a fascinating sensor, capable of detecting sounds over three decades of frequency and twelve orders of magnitudes. The ability of the cochlea to enhance low-amplitude sounds is referred to as the cochlear amplification effect [1,2]. This effect is attributed to the hair cells of the organ of Corti which lies on the basilar membrane that are believed to work as subwavelength non-linear resonator operating at the particular regime of the so-called Hopf bifurcation. In this work, we propose to implement this model experimentally to study an artificial cochlea based on an active metamaterial [3], and we show that it reproduces all of the salient characteristics of the mammalian's living cochlea [4].

To mimic the frequency-dependent cochlear response, we take our inspiration from the so-called rainbow trapping effect, initially proposed in optics and more recently in acoustics [5]. The basis of our method lies in the realization of a gradient of the propagation properties, resulting in the spatial encoding of the frequency information through the slow light/sound effect. This is achieved in an elegant way using so-called locally resonant metamaterials: these propagating media are composed of an assembly of subwavelength resonators, each of which causes interferences near its respective resonance frequency [6]. Due to these local resonators, wave propagation through the metamaterial is macroscopically observed to be strongly dispersive. Then, using a different resonance frequency at every resonator location, one can obtain the desired gradient for the effective propagating wave. Experimentally, this strategy is simply implemented by side coupling quarter wavelength resonators made of rigid-walled pipes to a single mode airborne acoustic waveguide and we phenomenologically well-reproduce the tonotopic mapping of the dead cochlea (Figure 1).

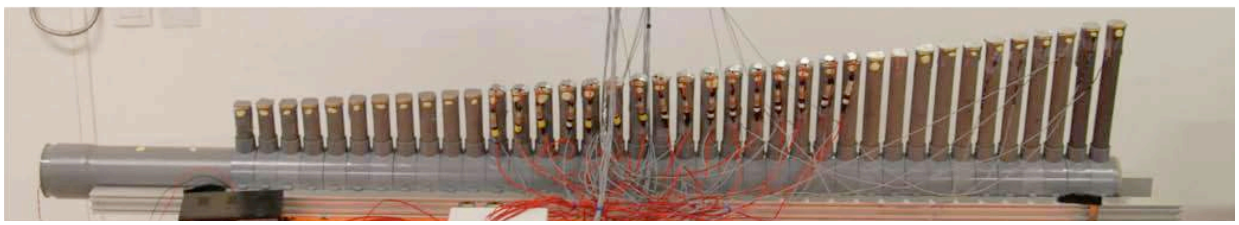

Figure 1: Photograph of the experimental gradient-index metamaterial for airborne sounds, made from 38 quarter-wavelength acoustic resonators of different heights.

Then, following a proposed biophysical model [2] which has yet to be universally accepted, we mimic a living cochlea using an active acoustic metamaterial. Each subwavelength resonator constituting the previous metamaterial is turned to an active one by adding a feedback loop with a speaker emitting sound linked to the field measured inside the resonator with a microphone. By choosing the parameters of the loop we build resonators that operate near a Hopf-bifurcation as the biophysical model of the cochlea requires. The dynamical response of the medium now becomes non-linear as it is the case for the response of the living basilar membrane. Among all of the non-linear effects that have been reported, we focus here on the cochlear amplification. By measuring the dynamical response for different amplitudes of excitation we can extract the sensitivity curve of Figure 2 which is very similar to the characteristic response of living cochleae.

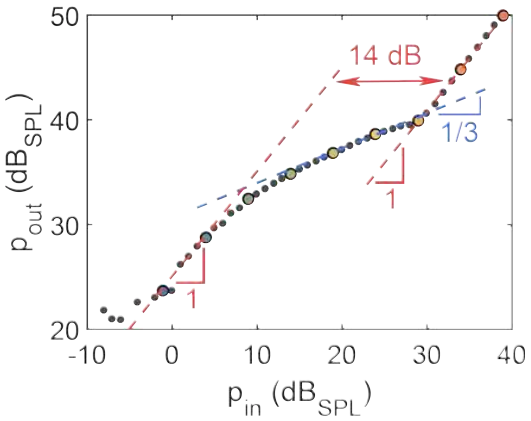

Figure 2: Non-linear dynamic of the evolution of the acoustic pressure in one resonator as a function of the excitation amplitude. This curve is analogous to experimental measurements realized on living cochleae

To conclude, we would like to emphasize that very few ingredients are necessary to reproduce the active cochlear wave. First, an adequately dissipative gradient-index locally resonant metamaterial well mimics the passive travelling wave. The active processes, as a price to pay for hyper-sensitivity to low-amplitude sounds, are created simply by replacing the resonant unit cells of the metamaterial by active resonators. As a result, the response of the medium becomes dependent on the excitation amplitude, and we have clearly reproduced the active amplification of low level sounds that characterizes the mammalian hearing abilities.

Abstract- Negative refraction is observed at ultrasonic frequencies in underwater acoustic experiments. The phenomenon is evidenced through the deflection of an ultrasonic beam emerging from a prism-shaped negative-index metafluid composed of soft porous micro-beads randomly dispersed in a water-based gel matrix. These experiments are compared with theoretical predictions based on multiple scattering theory models revealing a good agreement for various volume-fractions of particles.

In most (negative) refraction experiments, the conventional way consists in measuring the scattering angle of the transmitted beam through a *prism* fabricated with the (negative index) material. By using this configuration, the first experiments were conducted at microwave frequencies in 2D resonant structures in 2001 [1]. Then, many other experiments were reported in optics [2] until the fabrication of 3D optical metamaterials in 2008 [3]. In the same year, negative refraction was also observed using a prism-shaped phononic crystal in acoustics [4]. Since then, negative refraction has been reported in various (non resonant) periodic systems [5] but no experiment has been conducted in random acoustic metamaterials up to now.

In this talk, we report negative refraction experiments performed at ultrasonic frequencies by using a soft 3D acoustic metafluid with a negative acoustic index [6]. This metafluid, composed of soft porous micro-beads randomly dispersed in an aqueous matrix, was confined in a prism-shape box deposited on the surface of an ultrasonic transducer. Then, the scattering angle of the transmitted ultrasound beam emerging from the prism was measured at different frequencies, evidencing negative refraction around 160 kHz as shown in the figure.

Topological sound in active liquid metamaterials

Liquids composed of self-propelled particles have been experimentally realized using molecular, colloidal, or macroscopic constituents. These active liquids can flow spontaneously even in the absence of an external drive. Unlike spontaneous active flow, the propagation of density waves in confined active liquids is not well explored. Here, we exploit a mapping between density waves on top of a chiral flow and electrons in a synthetic gauge field to lay out design principles for artificial structures termed topological active metamaterials. We design metamaterials that break time-reversal symmetry using lattices composed of annular channels filled with a spontaneously flowing active liquid. Such active metamaterials support topologically protected sound modes that propagate unidirectionally, without backscattering, along either sample edges or domain walls and despite overdamped particle dynamics. Our work illustrates how parity-symmetry breaking in metamaterial structure combined with microscopic irreversibility of active matter leads to novel functionalities that cannot be achieved using only passive materials.

Non-reciprocal acoustic systems: from sound isolation to topological propagation

Abstract-We discuss the possibility to largely break Rayleigh reciprocity in compact, linear acoustic systems with broken time-reversal symmetry. These subwavelength systems can be used as building blocks to construct non-reciprocal metamaterials. Interestingly, the obtained metamaterials support one-way edge modes that are topologically protected against defects and disorder, highlighting a fruitful design strategy, from engineering non-reciprocal acoustic metamolecules to building acoustic Chern topological insulators.

Non-reciprocal acoustic systems that let sound flow in one direction but block it in another may be of fundamental interest in many application fields, from underwater communication to imaging systems. However, largely violating reciprocity is not an easy task in a compact acoustic system as it requires either strong non-linear effects or a breaking of time-reversal symmetry or time invariance[1].

We discuss two different solutions to achieve large acoustic non-reciprocity in a linear subwavelength device by coupling a weak external time-odd bias to an acoustic resonance. The first system consists of a ring acoustic resonator filled with air and coupled to three output waveguides, in which we impart a slow rotating air motion (Fig. 1a). We demonstrate experimentally 30 dB of acoustic isolation for airborne audible sound in a subwavelength device[2]. The second system consists of a resonant acoustic trimer, which undergoes a weak rotating temporal modulation of the acoustic index, at a frequency much slower than the acoustic frequency (Fig. 1b). This device allows for more than 40 dB, with 0.3 dB insertion loss in a system whose total size does not exceed a sixth of a wavelength[3].

Finally, we investigate the intriguing properties of non-reciprocal metamaterials built from a periodic arrangement of these non-reciprocal metamolecules. We obtain a metamaterial that behaves as the acoustic equivalent of Chern topological insulators, in which a nontrivial topology is initiated by a breaking of time-reversal symmetry[4]. These artificial materials are characterized by the fact that they do not support acoustic propagation in their bulk, but possess one-way topological edge modes (Fig. 1c). Like their electronic counterpart, since local perturbation to the edge cannot affect the topology of the bulk, these states are topologically protected against a large class of defects and even disorder. We also discuss an acoustic equivalent of Floquet topological insulators, built from a hexagonal lattice of time-modulated, non-reciprocal trimers (Fig. 1d). This last design presents interesting robustness to site-to-site disorder in the modulation phase[5].

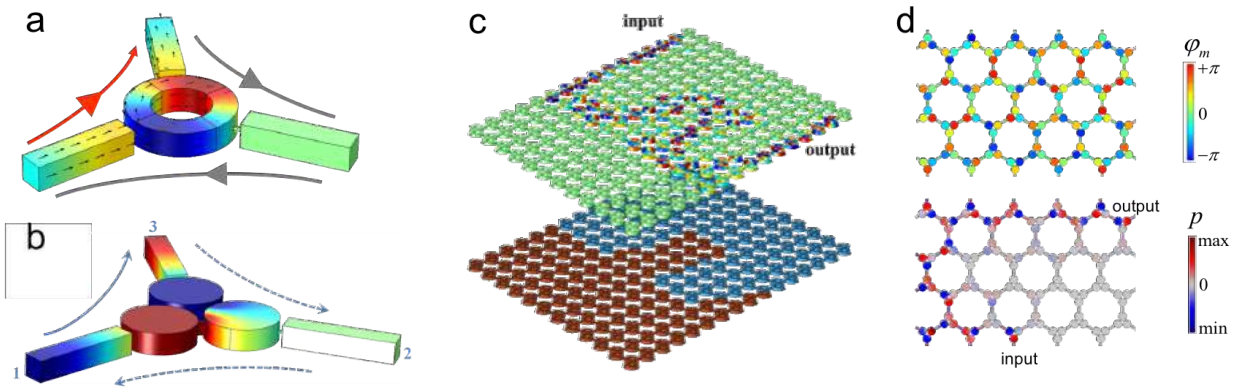

Figure 1: a) An acoustic circulator built from a resonant ring in which we rotate the air in the clockwise direction strongly breaks Rayleigh reciprocity. b) An ultrasonic circulator achieves the same functionality without resorting to motion, but using a rotating temporal modulation. c) An array of non-reciprocal elements like the ones in a) makes an acoustic Chern insulator, obtaining one-way robust reconfigurable acoustic waveguides. d) An array of non-reciprocal metamolecules like the one in b) makes the acoustic equivalent of a Floquet topological insulator, and supports some level of disorder in the modulation phase (top) and non-reciprocal Floquet edge mode propagation.

Conclusions- Compact, non-reciprocal acoustic systems can therefore be used to build non-reciprocal metamaterials that possess non-trivial topological properties, in particular one-way edge modes with topological robustness. Compared to their constituting metamolecules, such topological materials may offer significant advantages in their bandwidth of operation, robustness, and reconfigurability. Our study provides the opportunity to increase our ability to control sound propagation with broadband, backscattering-immune, reconfigurable acoustic waveguides that are immune to defects and disorder.

Abstract- Starting from the very simple example of a soda can metamaterial (an acoustic medium made of Helmholtz resonators), we explain the propagation of waves in locally resonant media without involving homogenized parameters. This allows us to highlight the importance of multiple scattering even at this deep subwavelength scale. This, in turns, permits to envisage exotic phenomena such as subwavelength control of waves, slow waves, negative refraction with a single negative medium or topological metamaterial crystals.

In this talk, we will show how going beyond the paradigm usually introduced in the context of locally resonant metamaterials, namely to consider them as homogeneous materials presenting effective properties, permits to enrich the physics associated with them in a drastic way. We will first show, using a microscopic approach based on the transfer matrix, that the properties of many metamaterials made out of resonant unit cells are strictly governed by interferences, propagation effects and multiple scattering.

Then we will demonstrate how this observation allows one to tailor locally this kind of composite media at the scale of the unit cell, hence going much further than in the homogenization approximation. We will show how this allows to design various components such as cavities, waveguides, filters, that present deep subwavelength dimensions, much smaller than that of their phononic crystal counterparts. We will also demonstrate the possibility to slow down waves drastically using this kind of components, while keeping reasonable bandwidths, hence achieving delay bandwidth products 10 times higher than the state of the art in photonics or phononics.

Concentrating now on structural modifications, we will explain how a single negative metamaterial can turn double negative simply thanks to multiple scattering, provided that it is judiciously structured, hence introducing the concept of metamaterial crystals. We will show that this approach is very rich and can be used to demonstrate various analogs of solid state crystals in acoustics, such as an acoustic equivalent of graphene, or acoustic metamaterials that present topological properties at the deep subwavelength scale. We will finally show that these ideas can be straightforwardly transposed to the electromagnetic domain.

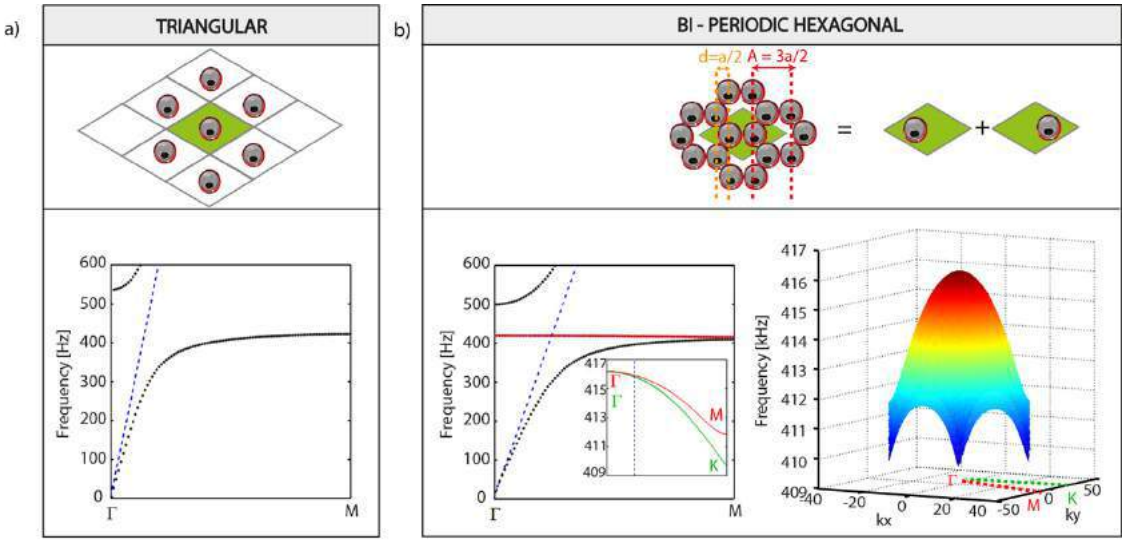

Fig. 1. A triangular Helmholtz resonator based single negative metamaterial can be turned double negative, acquiring its negative index from its symmetry broken structure.

Abstract-Graphene, a honeycomb lattice of carbon atoms ruled by tight-binding interaction, exhibits extraordinary electronic properties, due to the presence of Dirac cones within its band structure. Here we explain how we induced tight-binding coupling within a locally resonant metamaterial made of mere soda cans (Helmholtz resonators) and how it allows to obtain an acoustic analog of graphene. These numerical and experimental results demonstrate the potential of crystalline metamaterials as a tabletop platform for the study of solid state physics.

In this talk, we will show how going beyond the usual description of locally resonant metamaterials in terms of effective parameters allows to construct a classical acoustic analog of graphene[1]. First we show that a triangular lattice of empty cans creates a hybridization bandgap. Within this bandgap, we then place resonant defects simply made by increasing the resonance frequency of resonators, which is easily done filling cans with water[2]. Because of the absence of propagating waves thanks to the bandgap created by the initial triangular lattice, these defects are solely linked by nearest neighbors interactions, that is tight-binding coupling[2,3]. Therefore, we design a honeycomb lattice of resonant defects around the previous triangular lattice in order to emulate the physics of graphene in such a crystalline metamaterial.

After presenting the concept behind this work, we show the experimental setup we used and the results we obtained. We compare the field maps we measure and the corresponding analytically calculated ones for a tight-binding model of graphene. This demonstrate a very good matching between both: monitoring the structure and the composition of a metamaterial[4] is indeed a powerful strategy to create an acoustic analogue of graphene.

Then, we show that the properties of the bandgap within the metamaterial permits to change easily the strength of the coupling between the defects. We present several experimental band structures and their numerical counterparts realized for different volume of water within the defect cans. Hence, this simple change allows to study a transition between a tight-binding and a polaritonic coupling within the lattice of defects. We finally show that these ideas can be straightforwardly transposed to the electromagnetic domain.

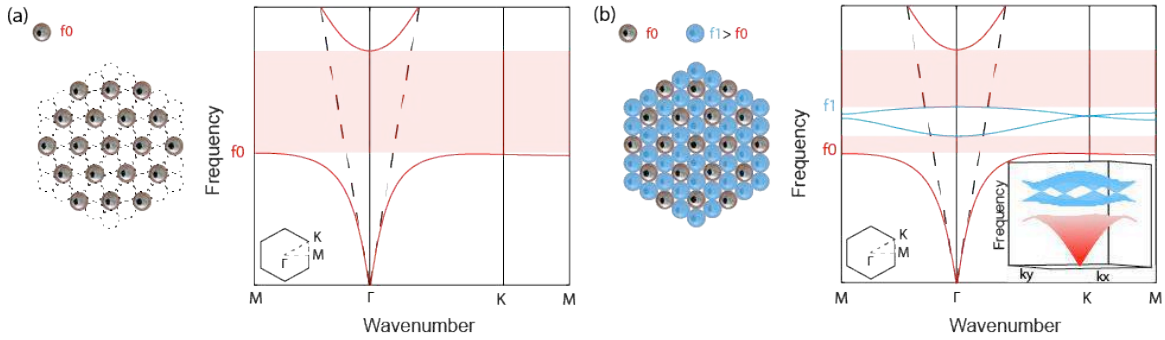

Fig. 1. A triangular lattice of empty soda cans creates a hybridization bandgap (a). This allows to induce tight-binding coupling within the honeycomb lattice of filled cans and to mimic the band structure of electronic graphene (b).

Abstract-Two- and three-dimensional bubble metamaterials can be tuned to enable a variety of interesting functionalities for acoustic waves by exploiting the low-frequency Minnaert resonance of the bubbles. Here we show how a broadband coherent perfect absorber for ultrasonic waves can be created from a bubble metalayer, and how doubly negative behaviour can be realized in three-dimensional bubble metamaterials.

Bubbles in a yield-stress fluid or soft solid are excellent candidates for creating acoustic metamaterials, as they exhibit a strong low-frequency monopolar resonance, which can lead to interesting effective acoustic properties at wavelengths that can be hundreds of times larger than the radius of the bubbles. Since bubbles are strongly coupled to water-borne acoustic waves, bubble metamaterials are especially well suited for applications in underwater acoustics, where, for example, ultrathin metalayers consisting of a single layer of bubbles entrapped in a soft elastic solid have been shown to act as very effective reflectors or absorbers of ultrasound [1,2]. In this presentation, we show how a bubble metalayer can be optimized to create a coherent perfect absorber for acoustic waves, and then consider how three-dimensional structures assembled from spatially correlated bubble pairs can be designed to exhibit a transparency window with a negative index of refraction.

Since the concept of a coherent perfect absorber, or "anti-laser", was first proposed in optics [3], there has been growing interest in developing coherent perfect absorbers for acoustic waves [4,5]. Such a device can be implemented by coherently illuminating a metamaterial or metalayer using two oppositely propagating incident beams. For water-borne acoustic waves, a metalayer consisting of a single layer of bubbles has several advantages for realizing an acoustic coherent perfect absorber experimentally. An important first step is to develop a soft matrix, into which the bubbles can be embedded, that is impedance-matched to the water surrounding the metalayer, so that water-matrix reflections can be eliminated; this has been achieved by mixing sub-micron TiO_2 particles into PDMS so that the longitudinal velocity and density of the cured mixture leads to the same acoustic impedance as water. It is also crucial to optimize the structure of the bubble layer so that the magnitude of the amplitude reflection and transmission coefficients (r and t) of the layer are equal to 0.5 (they are intrinsically of opposite sign), a process that was guided by the predictions of a simple analytic model whose accuracy has been tested previously [1,2]. For the optimized structure, the critical coupling condition is satisfied so that the bubble layer's radiative and dissipative damping are equal, implying a unique relation between the bubble radius a and separation d, which is given by $a^3/d^2 = 4\eta/\pi Z$, where η is the viscosity of the matrix. When two counter-propagating coherent beams of equal amplitude and phase are incident on a

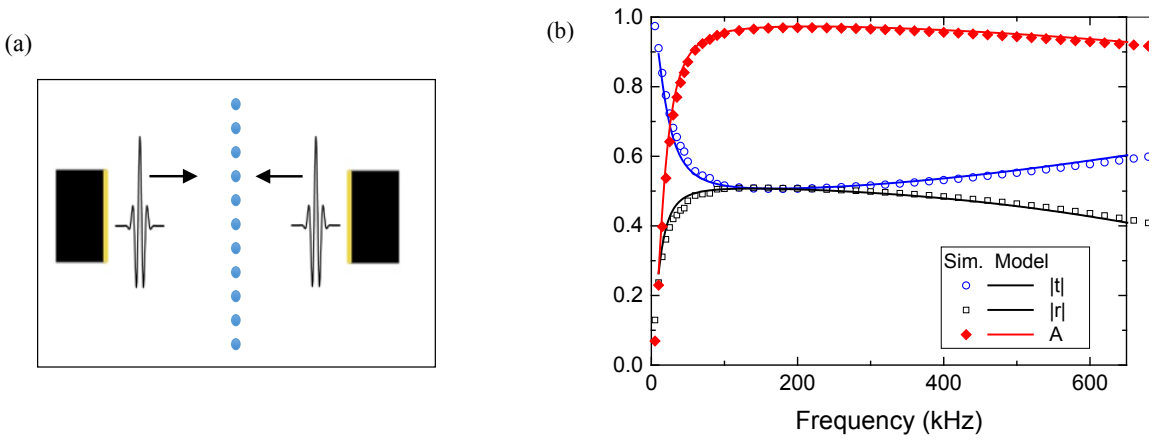

Fig.1: **(a)** Experimental setup for turning an optimized bubble metalayer (blue circles) into an acoustic coherent perfect absorber. Two ultrasonic transducers (gold and black rectangles, on the left and right) emit coherent counter-propagating pulses that arrive from opposite directions with the same incident phase at the metalayer.
(b) Predictions from finite element simulations and the analytic model for an example of a metalayer with a square array of bubbles with a = 50 μm, d = 240 μm, and η = 5.1 Pa s. Here $|r|$ and $|t|$ are the magnitudes of the amplitude transmission and reflection coefficients, and A is the absorption. For these parameters, broadband absorption is predicted to be greater than 97% for 150 kHz < f < 300 kHz, and greater than > 95% for 90 kHz < f < 510 kHz.

well-optimized metalayer, virtually all of the incident radiation is absorbed, as illustrated for one choice of model parameters in Fig. 1. This example compares the model predictions with finite element simulations, and shows that broadband near-perfect absorption can be achieved.

For three-dimensional structures with pair-wise correlated bubbles ("bi-bubbles"), strikingly different behaviour can be observed when the bubble pairs are arranged in either random or periodic arrays. Then, overlap between monopolar and dipolar resonances can lead to a frequency band with a negative refractive index, demonstrating how deeply-subwavelength spatial patterning of inclusions in metamaterials can play a crucial role in determining material properties and functionality [6]. Predictions for both types of structure will be presented and the influence of dissipation on doubly negative behaviour discussed.

Abstract

The emerging field of topological acoustics that explores novel gauge-field-related phenomena for sound has drawn attention in recent years. However, previous approaches constructing synthetic gauge field for sound predominantly relied on a periodic system, being unable to form a uniform effective magnetic field, thus lacking access to some typical magnetic-induced quantum phenomena such as Landau energy quantization. Here we introduce strain engineering, previously developed in graphene electronics and later transferred to photonics, into an aperiodic two-dimensional acoustic structure in order to form a uniform effective magnetic field for air-borne acoustic wave propagation. Landau levels in the energy spectrum can be formed near the Dirac cone region. We also propose an experimentally feasible scheme to verify the existence of acoustic Landau levels with acoustic measurement.

Air-borne sound waves have no intrinsic spins and do not respond to magnetic field. Recently several approaches of synthetic gauge field construct magnetic-like effects (such as quantum Hall effect) for sound, which have enabled the emergence of a new field of topological acoustics [1-5]. However, previous approaches constructing synthetic gauge field for sound predominantly relied on a periodic system, being unable to form a uniform effective magnetic field, thus lacking access to some typical magnetic-induced quantum phenomena such as Landau quantization [6].

Here we introduce strain engineering into a two-dimensional acoustic structure in order to effectively form a uniform magnetic field for air-borne acoustic wave propagation, and consequently, acoustic Landau levels. Typical acoustic Landau levels (labelled with numbers of 0, ±1, ±2) are shown in panel (a) of the following figure. Panels (b-e), which show the change of acoustic pressure with increase of frequency, demonstrate the process of localization (b) – spreading (c) – localization (d) – spreading (e), as a clear evidence of acoustic 0^{th}-order and $\pm1^{st}$-order Landau levels and the significant band gaps between them. As a new freedom of constructing synthetic gauge field for sound, our study has offered a path to previously inaccessible magnetic-like effects in traditional periodic acoustic structures.

Observation of topological interface state of elastic wave in a silica 1D phononic crystal

***Ingi Kim[1], Satoshi Iwamoto[1,2], and Yasuhiko Arakawa[1,2]**

Abstract-We demonstrate a topological interface state of elastic wave in solid-structured 1D phononic crystals (PnCs). Two PnCs with different structural parameters can possess a common phononic bandgap with different topological nature. At the interface between the two PnCs, a topologically confined state of elastic wave in the bandgap appears. We observe the topologically confined mode with a quality factor of ~5,650 in the transmission experiment, while no interface state exists at the interface between PnCs with the same topological characteristic.

There is currently a great interest in the study of topological properties in metamaterials that draw inspiration from quantum spin Hall and quantum Hall effects in solid state physics. Recently, some pioneering demonstrations of topological edge states in acoustic systems have been reported [1,2]. On the other hand, controlling elastic waves in solids using topological properties will pave the way to practical high-speed phononic applications. Although some theoretical studies aiming the control of elastic waves in solids have been reported [3,4], there is a lack of experimental study demonstrating such topological edge states even in one-dimensional periodic systems. Here we report the experimental realization of topological interface state in solid-structured quasi 1D PnC.

In this study, we use quasi 1D PnCs [5] made of fused silica. As shown in Fig. 1(a), each unit cell with period $D = 16$ mm along with x-direction has two wider blocks sandwiching an inner block. We designed topologically distinct PnCs, U1 ($W_{in}/D = 0.3, d_{in}/D$ =0.59) and U2 ($W_{in}/D = 0.501, d_{in}/D$ =0.72), by tuning the structural parameters of unit cells. In a 1D periodic system, the topological invariant of Bloch bands, so called Zak phase, characterizes the property of bulk band. The phononic band diagrams shown in Fig. 1(b) and (c) indicate that two

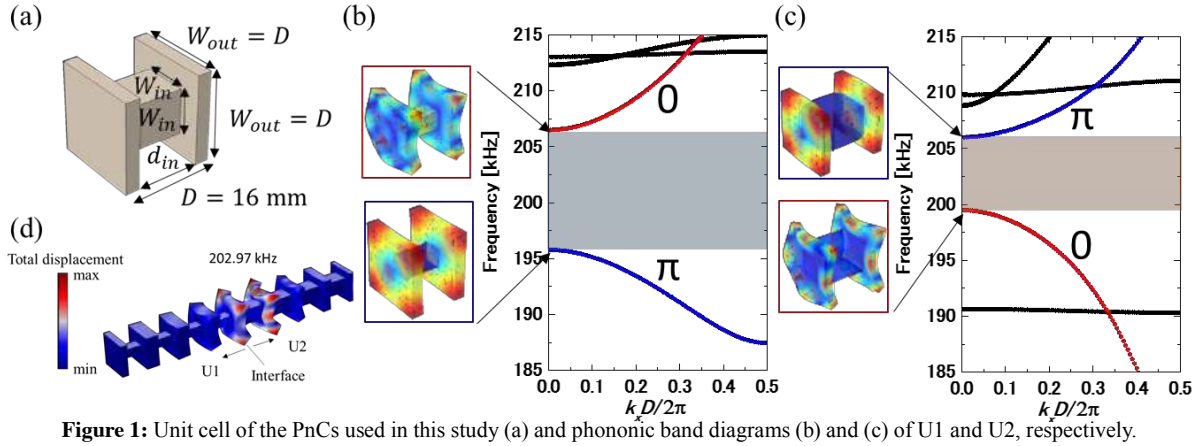

Figure 1: Unit cell of the PnCs used in this study (a) and phononic band diagrams (b) and (c) of U1 and U2, respectively. Mode shapes at the center of the Brillouin zone are shown in the insets, which exhibit the inversion of the two related bands. (d) Displacement distribution of the topological interface mode at the interface between U1 and U2.

PnCs, U1 and U2, have a topologically distinct bandgap. The characters of the bands at the upper and lower bandgap edges are inverted as shown in the insets and the Zak phase of the bands changes, resulting in a change in the topological properties of the bandgap. Therefore, at the interface of these two PnCs, a topologically protected mode is predicted to exist inside the overlapped bandgap from bulk-edge correspondence principle. Figure 1 (d) shows the displacement distribution of the topological interface mode at the interface of U1 and U2 where the each PnC has the number of period N=4. The interface mode is well confined at the interface and works as a cavity of elastic wave.

The pictures on the left of Fig. 2 (a) and (b) show the samples having a non-trivial junction of two topologically distinct PnCs (U1+U2) and a trivial junction composed of two PnCs with same topological characteristic of the bandgap (U1+U1′), respectively. Both samples were made of fused silica by ultrasonic machining process. U1′ has a slightly thicker inner block than that of U1 but a topologically identical bandgap with U1, which expects that no topological interface state exists. We measured transmission spectrum of elastic waves through the samples by a network analyzer. In the measured transmission spectrum for U1+U2 (Fig. 2 (a)), a peak indicating the topologically confined state is clearly observed in the bandgap. The topological interface state is observed at 202.38 kHz with mechanical quality factor of ~5,650. In contrast, no such peak was measured for U1+U1′ (see Fig. 2 (b)) since they have the topologically identical bandgap. The measured spectra for both samples show good agreement with numerical simulations also shown in the same figures.

In conclusion, we experimentally demonstrate a topological interface state of elastic wave in a solid-structured 1D system. Higher operating frequency above MHz can be achieved by scaling down the size of structures. Our result is an important step for the advanced control of elastic wave in solid structures by their topological characters.

In this talk, I will introduce some of our latest works on production and manipulation of acoustic OAM with the aid of metamaterials. We have designed and fabricated an acoustic vortex emitter with multi-arm coiling slits that utilize diffraction effect to generate vortex beam, with broadband functionality and stable topological charge. Based on this, we further propose a new mechanism for producing acoustic OAM by converting acoustic resonances to OAM. As an implementation, we have designed and fabricated a thin planar device with high efficiency to verify our scheme. In comparison with existing ways for OAM production by phased spiral sources that need sophisticated electronic control and by physically spiral sources that need screw profiles and may also have a bulky size, our acoustic resonance-based OAM production bears the advantages of high efficiency, planar profile, compact size, no spiral structure and can be freely tuned to produce different orders of OAM. I will also briefly discuss the potential of acoustic OAM devices to revolutionize various applications such as in medical ultrasound or acoustic communication.

Ultra-thin Acoustic Metasurface-Based Schroeder Diffuser

Abstract - "Schroeder diffuser" is a classical design, proposed over 40 years ago, for artificially creating optimal and predictable sound diffuse reflection. It has been widely adopted in architectural acoustics and it has also shown substantial potential in noise control, ultrasound imaging, microparticle manipulation, among others. The conventional Schroeder diffuser, however, has a considerable thickness on the order of one wavelength, severely impeding its applications for low frequency sound. In this paper, a new class of ultra-thin and planar Schroeder diffusers are proposed based on the concept of acoustic metasurface. Both numerical and experimental results demonstrate satisfactory sound diffuse reflection produced from the metasurface-based Schroeder diffuser despite it being one order of magnitude thinner than the conventional one. The proposed design not only offer promising building blocks with great potential to profoundly impact architectural acoustics and related fields, but also constitutes a major step towards real-world applications of acoustic metasurfaces.

Topological subspace induced bound states in continuum

Yi-Xin Xiao[1], **Guancong Ma**[1], **Zhao-Qing Zhang**[1], **C. T. Chan**[1]

Abstract-We propose a new kind of bound states in continuum[1-3] (BIC) in a class of systems constructed by coupling multiple identical one-dimensional (1D) chains each with inversion symmetry. The BIC existence is enabled by a specific separation of the Hilbert space into topological and non-topological subspaces. Bulk-boundary correspondence in the topological subspace guarantees the existence of a localized interface state which can lie in the continuum of extended states in the non-topological subspace, forming a BIC. Such topological BIC is observed experimentally in a coupled-acoustic-resonators system.

We couple two identical Su-Schrieffer-Heeger (SSH) chains in a way so that the chains outnumbers the coupling channels between them. With only one coupling channel, two bands remain topological characterized by quantized Berry phase, despite the overall inversion symmetry is broken by the introduction of coupler chain. A bound state occurs at the interface between two topologically different phases due to bulk-boundary correspondence. By choosing appropriate system parameters, we can make the topological interface state to overlap with the continuous spectrum of the extended states in the non-topological subspace. In this way, a BIC is formed. We emphasize this is a new scheme which relies on bulk-boundary correspondence to construct a BIC. We experimentally demonstrated our proposal in a system consisting of coupled acoustic resonators. The dipole modes of acoustic resonators are used to represent the orbitals.

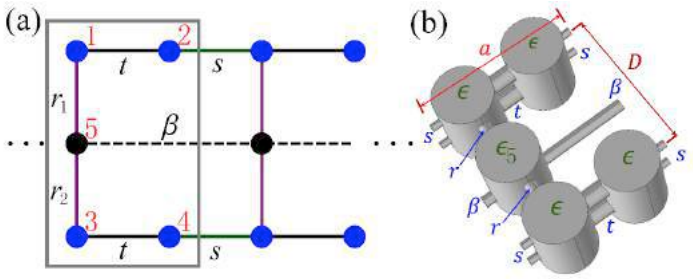

Fig. 1 (a) Two identical SSH chains coupled by a coupler "atom" per unit cell. The hopping parameters and indices of the "atom" orbitals are labeled. The on-site energies are $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = \varepsilon_4 = 0$ and ε_5. (b) A unit cell consisting of coupled acoustic cavities.

Analytic Materials

G. W. Milton[1],

[1]Department of Mathematics, The University of Utah, Salt Lake City, Utah, U.S.A.
milton@math.utah.edu

Abstract— This talk presents new classes of inhomogeneous media for which one can easily get exact solutions for the fields. They are called analytic materials, as the moduli involve analytic functions. The partial differential equations solved by the fields are reduced to a set of ordinary differential equations. We present explicit examples of analytic materials for elastodynamics and for electromagnetism. This greatly expands the array of examples of exactly solvable materials that one can obtain using other techniques, such as the transformation optics technique introduced by Dolin in 1961.

The theory of inhomogeneous analytic materials is developed. These are materials where the coefficients entering the equations involve analytic functions. Three types of analytic materials are identified. The first two types involve an integer p. If p takes its maximum value then we have a complete analytic material. Otherwise it is incomplete analytic material of rank p. For two-dimensional materials further progress can be made in the identification of analytic materials by using the well-known fact that a 90 degrees rotation applied to a divergence free field in a simply connected domain yields a curl-free field, and this can then be expressed as the gradient of a potential. Other exact results for the fields in inhomogeneous media are reviewed.

Underwater acoustic cloak with pentamode material

Y. Chen, M.Y. Zheng, X.N. Liu, G.K. Hu
School of Aerospace Engineering, Beijing Institute of Technology, Beijing 100081, China
*corresponding author: hugeng@bit.edu.cn

Abstract-A cylindrical underwater acoustic cloak is designed from pentamode material that mimics meta-fluid with anisotropic modulus. The machined cloak is tested in a designed 2D waveguide through transient cylinder wave experiments. Experiment results verify excellent cloaking performance over a broadband frequency range 9-15 kHz, and therefore confirm superior wave manipulating capability of pentamode metamaterial particularly for underwater acoustics.

Inertial acoustic cloak requires anisotropic density to deflect wave trajectory to achieve invisibility, however conventional metamaterial technique, such as perforated plate or alternating fluid layer, cannot offer sufficient anisotropy in dense fluid like water and also suffers from the infinite mass catastrophe[1]. To circumvent these difficulties, an alternative approach using pentamode material is adopted[1, 2] in this research to design cloak for underwater acoustics. Pentamode material, specially designed microstructure solid, can mimic anisotropic modulus meta-fluid, and has much stronger anisotropy than available in density through any conventional metamaterial technique. Numerical investigations[3] have shown its broadband performance for acoustic manipulation, while experiment has never been reported. Here, we experimentally demonstrate superior wave steering ability of pentamode material by designing a broadband underwater acoustic cloak[4].

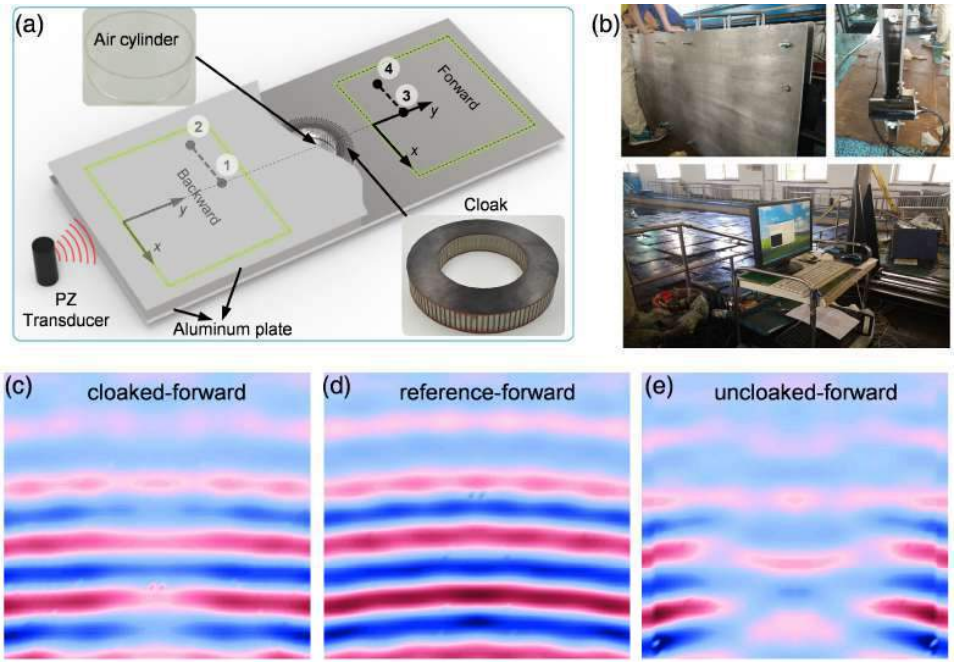

Figure 1. (a) Experiment setup demonstration; (b) Experiment test platform; (c) (d) (e) Snapshot of measured acoustic pressure field in forward region for cloaked, reference and uncloaked cases, respectively.

A new geometry is first proposed as pentamode unit cell with larger effective parameters space. A cylindrical cloak, aim at underwater acoustic wave, is designed from proposed unit cell using transformation approach as well as optimization algorithm. Geometry of pentamode cell in the cloak has been calibrated to acquire effective material parameter required by transformation approach. The cloak is finally machined from an aluminum block using advanced electric discharging machining technology with high accuracy.

Due to small size of the fabricated cloak in height direction, a 2D underwater waveguide is also proposed to test the cloak. Transient cylindrical wave emitted from a piezoelectric transducer is used to verify broadband performance of fabricated cloak. Scanned acoustic pressure field indicates obvious difference between uncloak and cloaked air scatter in both forward and backward regions. Strong scattering effect, due to severe impedance mismatch between air and background water, has been substantially eliminated when the scatter is covered with cloak, and the rectified pressure field approaches that of reference case with empty waveguide. Target Strength Reduction (TSR) has been calculated from measured signal at specific backward location, and also shows excellent cloaking performance of designed cloak over remarkable frequency range, with an averaged reduction 6.3dB in TSR over 9-15 kHz.

The experiment proves expected excellent and broadband wave steering capability of pentamode material with cloak application for the first time. It should be noted, although measurements here only indicate excellent performance of designed cloak over the given range owing to transducer frequency limitation, the designed cloak can in principle work from zero frequency, since only quasi-static material properties are employed, in contrast to inertial cloaks based on local resonance mechanism. Solid and broadband advantages together with achievable strong anisotropy make pentamode material a perfect candidate for controlling acoustic wave propagation, and may bring forth new applications, such as wave bender, metasurface, particular for underwater acoustics.

Abstract— Building architectures able to demonstrate asymmetric transmission became a real challenge in the last decades. Here, we propose two devices with capabilities of breaking acoustic reciprocity. The first device uses nonlinear conversion in granular matter meanwhile the second allows to avoid frequency conversion during the propagation process. Helping by the experimental results, the advantages and drawbacks of each architecture are compared. The possibility to break the reciprocity introduces new capabilities for information processing and for improving acoustic imaging.

For breaking the reciprocity of a wave system, i.e. allowing the transmission through the device in one direction of propagation but not in the other [1, 2], the most common solution consists to use frequency conversion process combined with a frequency filtering process [3]. An other common solution consists to introduce a energy bias like gravity or circulating air flow [4]. The main drawback of these existent solutions is their narrow frequency band working regime where these asymmetric proprieties are obtained. Moreover, using conversion process or external energy supply is not promising for long term and energy efficiency applications in information processing. Here, we report on the design and experiments on two different architectures of asymmetric acoustic devices with and without frequency conversion process to going beyond the previous limits.

The first architecture is based on the nonlinear self-demodulation process in a one-dimensional structure made of a nonlinear granular medium and a phononic multilayer solid as shown on Fig. 1.

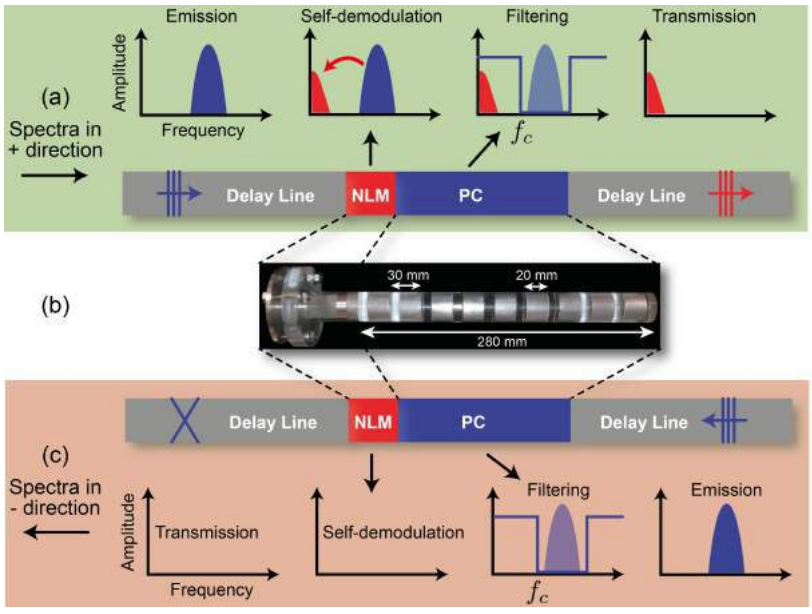

Figure 1: **(a)** Schematics of the proposed acoustic rectifier in "+" direction. **(b)** Picture of the experimental system. **(c)** Schematics in "-" direction.

Implementing upstream and downstream ultrasonic delay lines, we characterized first the two parts of this rectifier. The conversion part is assumed by 3D unconsolidated granular medium which consists of a layer with a thickness of 3.0 cm of steel powder (Fe3Cr1Mo0.5Mn0.2V) with

an average grain diameter of $d = 300$ μm. Alternating nine layers of Lucite with ten layers of aluminum, we built the phononic crystal (i.e. the selection part) where thicknesses are $d_p = 10$ mm and $d_a = 20$ mm, respectively, along with diameters of 30 mm. After characterized the two parts of this rectifier, we analyze the broadband character of this asymmetric effect, which could allow for information processing in the future. With the help of the delaylines, we also measure quantitatively the incident, reflected and transmitted wave packets, and demonstrate a ratio larger than 10^6 in transmitted acoustic wave energies for the two opposite directions of operation. The drawbacks of this device are a modification of the transmitted signal spectrum and a weak transmitted amplitude compared to the incident one.

In the second part of the presentation, we present a solution to avoid the frequency conversion process involved in the most part of asymmetric device as the first proposed using the granular matter. Interestingly, this architecture mimics the intrinsic behavior of the most known asymmetric device: the electrical diode. After detailing all processes and mechanisms involved in this asymmetric device, we demonstrate experimentally a very high efficiency with an energy transmission ratio of ! 10^6 between the two direction of propagation, as well as tunability and broadband characteristics. The most interesting aspect is that the transmitted signal does not show signs of distortion without external energy supply. Moreover, the transmitted amplitude in the allowed propagation direction is close to 1. Due to simple design and the mechanisms involved, the proposed device is also able to become a key element to realize an acoustical switch.

In conclusion, we propose two new architectures for asymmetric propagation of acoustic waves to overcome the limits of the recent proposed architectures. Combining a granular layer with a phononic crystal, we demonstrate with the first architecture, the possibility to rectifying the energy for the wide band signal with a high contrast ratio σ ! 10^6. Secondly, we propose an another architecture to avoid the conversion process trough the propagation without energy supply. The second device is able to transmit almost all the energy in the allowed propagation direction without distortion effect. These experimental results on two proposed devices for asymmetric transmission extend the previously demonstrated effects (transmission ratio, frequency bandwidth, transmitted amplitude). The designs and tests of these architectures contribute to the field of acoustic diodes, which could open avenues for novel acoustic devices aiming at controlling waves.

sebastian.huber@phys.ethz.ch

Abstract – **Guiding mechanical energy in a reliable way between two points in space is an important ingredient for many technological applications such as energy harvesting or in mechanical computing. In particular, wave guides that are free from backscattering and can hence be bent without any losses would be a most welcome addition to the metamaterials toolbox. Here, we present a new design principle for wave-guides with exactly these properties. Owing to the intricate structure of the Bloch-wave structure of the bulk mechanical vibrations, surface modes with highly specialized properties are arising. We discuss a general formalism for the theoretical description of such "topological surface modes" and provide experimental implementations of two corner stones for topological wave guiding [1]. First, we introduce a mechanical analog of the quantum spin Hall effect, where a two-dimensional material nucleates one-dimensional surface states that can transport energy in a unidirectional fashion [2]. Second, we provide the first experimental observation of a quadruple (or higher order) topological insulator, where a n–dimensional systems stabilizes stable (n-2)–dimensional corner modes. This corner modes pave the way to concrete materials where stable one–dimensional waveguides are built in a three–dimensional sample.**

Abstract— We analyze the Purcell effect in a waveguide with a side-coupled microcavity and demonstrate that it can be considered as an interference phenomenon. Also we describe a growth of photoluminescence intensity at the low-frequency edge of the band-gap in a photonic crystal composed of alternating amorphous hydrogenated silicon with carbon and silica layers and attribute this with the Purcell effect. We suggest that Green's function calculated by the transfer-matrix method allows describing the Purcell effects in low-dimensional photonic structures.

In many applications of photonics the light is radiated from an energy source that can be either an excited quantum system or a resonator that accumulates energy in the form of standing waves. The engineering of dielectric environment allows to modify the emission rate due to the Purcell effect without changing the properties of the emitter itself. Here we study the Purcell effect for several photonic systems described by quantum and classical approaches. Since Edward Purcell published his landmark note [1] on the modification of quantum transition rates due to a cavity, this effect was considered in the framework of the quantum electrodynamics. Recently, it was reported that the Purcell effect in antennas with current loops can be described classically [2, 3]. Here we suggest a classical counterpart of the Purcell effect for pure photonic modes in a microcavity [4].

We describve the Purcell effect in a waveguide with a pair of partially reflecting defects forming an effective environment for a side-coupled resonator. This system was considered earlier as a system with a sharp Fano resonance [5], and it is described phenomenologically by means of the transfer-matrix method. We find the expression the Purcell factor in the form

$$f = \frac{\gamma}{\gamma_0} = (1 - r^2)\frac{1 + r^2 - r[\cos(2\delta_1) + \cos(2\delta_2)]}{(1 + r^2)^2 - 4r^2\cos^2\delta}. \quad (1)$$

Here γ and γ_0 are the resonator damping rate with and without environment respectively, r is reflection coefficient of the defects, $\delta_{1,2} = kd_{1,2}$, $\delta = \delta_1 + \delta_2$, k is wavenumber, $d_{1,2}$ is the distance between left or right defect and the resonator.

We implement the system in a photonic crystal composed of a square array of silicon rods with radius $r = 0.2a$ (a is the lattice constant) and refractive $n = 3.4$ (silicon in near infrared range). A waveguide is formed by removing a row of dielectric rods, and a resonant cavity is created by reducing the radius of a single rod to $0.1a$. The cavity is placed at the distance $3a$ away from the waveguide. Such a cavity supports a localized monopole-like defect mode with the resonant frequency $\omega_0 = 0.32821 \cdot (2\pi c/a)$ and the half-width at half minimum $\gamma_0 = 0.00026 \cdot (2\pi c/a)$. Cylinders of radius $0.1a$ introduce the pair of defects in the waveguide. The transmission spectra in this structure are calculated by employing the frequency-domain Wannier functions approach [6] that enables us accurate modeling of high-Q resonances. The calculated data appear to be in excellent agreement with the results of transfer matrix based theory. The adjustment of the distance between defects changes the damping rate over 25 times (the Purcell factor is in the interval from 0.18 to 5)

To analyze this result we calculate Purcell factor for a two-level quantum particle instead of the resonator using conventional quantum electrodynamic approach explaining the Purcell effect by modification of local density of photonic states (DOS), which can be evaluated through the imaginary part of Green's function for electric field. Quasi-one-dimensional structures considered in the present study allow the calculating of the Green's function by means of transfer matrix method. It appears that the Purcell factor found from the Green's function is exactly the same as one defined by Eq. (1).

For experimental confirmation of results obtained by the Green's function for quasi-one-dimensional structures calculated by transfer matrix method we examine photoluminescence from a photonic crystal. The density of photonic states is known to increase at the edges of photonic gaps. However the local DOS has a strong dependence on the emitter position relative the photonic crystal environment. For the regions occupied with a higher refractive index material the local DOS has a maximum at the low-frequency edge, while for a lower refractive index layers the local DOS has the maximum at the high-frequency edge. To measure experimental data allowing unambiguous interpretation we should take into account a number of circumstances. Emission centers have to be localized either in high-index layers or low-index ones. The width of photoluminescence contour has to be comparable with the photonic band gap, since we need to compare the luminescence intensity at the different edges at the same measurements.

We fabricate one-dimensional photonic crystal being an alternating a-$Si_{0.5}$:$C_{0.5}$:H and a-SiO_2 layers. A gradient in layer thickness is introduced for adjusting the photonic band gap with photoluminescence band. The addition of carbon to amorphous hydrogenated silicon allows a broadening of photoluminescence band (to be compatible with the photonic band gap) and an increasing quantum yield at room temperature. We excite the sample with a 405 nm continuous-wave semiconductor laser (the corresponding phonon energy exceeds the electronic energy gap width of a-$Si_{0.5}$:$C_{0.5}$:H). In addition, this wavelength falls outside the excitation spectrum of the photoluminescence associated with oxygen vacancies in a-SiO_2 films. As a result we obtain the increasing of the luminescence intensity at the low-frequency edge in a good agreement with spectra evaluated theoretically, which are obtained by means of the quasi-one-dimensional Green's function calculated using the transfer matrix method.

In summary, we have studied the Purcell effect in silicon-based photonic structures. The classical counterpart of the Purcell effect for pure photonic modes enables us to discuss Purcell effect in a more intuitive terms of interference. In quasi-one-dimension systems Purcell effect can be evaluated by Green's function calculated by transfer matrix method. This Green's function allows the description of experimentally measured photoluminescence of the layered photonic crystals.

Towards chip-scale light manipulation on silicon platform

(Invited Paper)

Jian Wang*

Wuhan National Laboratory for Optoelectronics, School of Optical and Electronic Information, Huazhong University of Science and Technology, Wuhan 430074, Hubei, China

*Corresponding author: jwang@hust.edu.cn

Abstract-Silicon photonics provides a promising integration platform facilitating chip-scale light manipulation. We will review our recent research progress in the fabrication of silicon nanophotonic devices and their wide applications in chip-scale light manipulation. We will talk about 1) design and fabrication of various silicon nanophotonic devices (ridge/slot/hybrid plasmonic waveguides, couplers, gratings, microring resonators, photonic crystal nanocavities, comb filter/interleaver, plasmonic/dielectric metasurfaces); 2) chip-scale optical interconnects (terabit-scale signaling); 3) chip-scale photonic signal processing (wavelength conversion, signal regeneration, optical computing); 4) chip-scale spatial light modulation (generation of orbital angular momentum light beams). The obtained results show favorable performance of chip-scale light manipulation on silicon platform.

In recent years, silicon photonics has become one of the most promising photonic integration platforms owing to its small footprint, low power consumption, and availability of complementary metal-oxide-semiconductor (CMOS) fabrication technology for low-cost mass production [1]. Typical silicon nanophotonic devices include waveguides, microring resonators, photonic crystal nanocavities and metasurfaces, showing unprecedented small size for potential large scale integration. The great success of silicon photonics facilitates miscellaneous chip-scale 1D and 2D light manipulation on silicon platform. In this paper, we will review our recent research progress in chip-scale light manipulation using silicon nanophotonic devices.

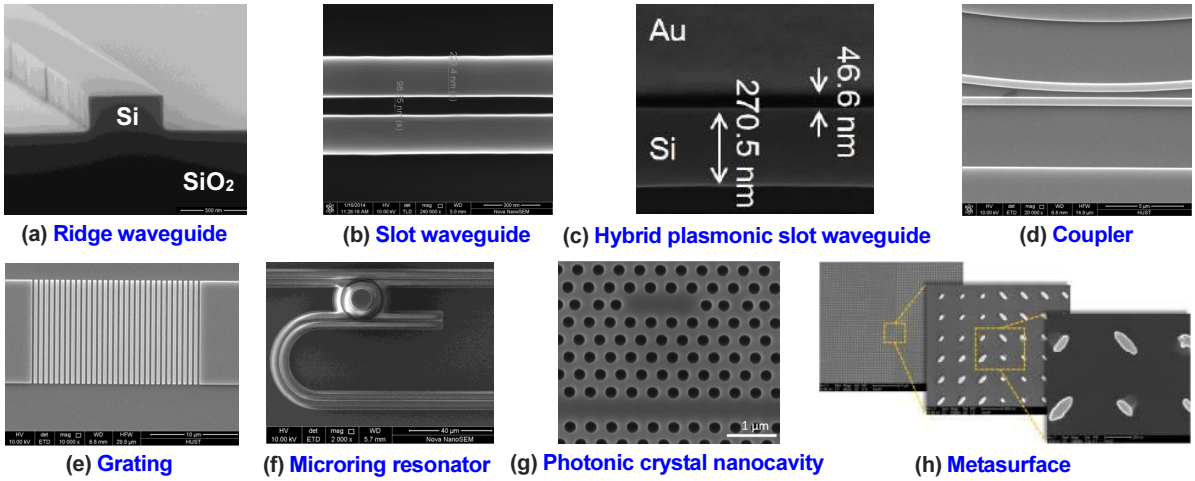

Fig. 1. Measured scanning electron microscope (SEM) images of the fabricated (a) silicon ridge waveguide, (b) silicon slot waveguide, (c) hybrid plasmonic slot waveguide, (d) silicon coupler, (e) silicon grating, (f) silicon microring resonator, (g) silicon photonic crystal nanocavity, and (h) silicon metasurface.

Design and Fabrication of Various Silicon Nanophotonic Devices: The designed various silicon nanophotonic devices were fabricated on silicon-on-insulator (SOI) using electron-beam lithography (EBL) followed by induced coupled plasma (ICP) etching. Shown in Fig. 1 are measured scanning electron microscope (SEM) images of the fabricated silicon ridge waveguide, silicon slot waveguide, hybrid plasmonic slot waveguide, silicon coupler, silicon grating, silicon microring resonator, silicon photonic crystal nanocavity, and silicon metasurface. Some more silicon nanophotonic devices, e.g. silicon comb filter/interleaver, plasmonic metasurface were also fabricated in the experiment. Using these fabricated silicon nanophotonic devices, chip-scale optical interconnects, photonic signal processing and spatial light modulation were demonstrated.

Chip-Scale Optical Interconnects [2, 3]: By exploiting the fabricated silicon microring resonator, silicon vertical slot waveguide and hybrid plasmonic slot waveguide, we demonstrated chip-scale data transmission with advanced multi-carrier multi-level modulation signals, e.g. orthogonal frequency division multiplexing based on offset quadrature amplitude modulation (OFDM/OQAM). OFDM/OQAM 64-QAM, 128-QAM, 256-QAM, 512-QAM signaling and 1.8-Tbit/s wavelength-division multiplexing (WDM) signaling were demonstrated in the experiment, showing potential chip-scale optical interconnects.

Chip-Scale Photonic Signal Processing [4-6]: By exploiting the fabricated silicon ridge waveguides and graphene-assisted silicon microring resonators, we demonstrated chip-scale wavelength conversion of OFDM m-QAM and Nyquist m-QAM signals, chip-scale signal regeneration of 4-ary pulse amplitude modulation (PAM-4) signals, and chip-scale high-base optical computing (quaternary/octal/decimal addition/subtraction).

Chip-Scale Spatial Light Modulation [7-9]: By exploiting the fabricated plasmonic metasurface and silicon metasurface, we presented broadband generation of orbital angular momentum (OAM) carrying vector beams and chip-scale N-fold OAM multicasting. We further demonstrated the generation and detection of different OAM beams in the experiment.

Abstract-We demonstrate an ultra-high efficiency and fast graphene microheater on silicon photonic crystal waveguide. By taking advantage of slow-light effect, a tuning efficiency of 1.07 nm/mW and power consumption per free spectral range of 3.99 mW. A fast rise and decay times (10% to 90%) of only 750 ns and 525 ns are achieved. The corresponding figure of merit of the device is 2.543 nW • s, one order of magnitude better than results reported in previous studies**.**

Micro-heater on silicon waveguide is one of the most important building blocks in silicon photonics. Silicon photonic integrated circuits based reconfigurable switches are relying on micro-heaters [1], which requires low power consumption and fast tuning. Traditional metallic microheater design requires a thick silicon dioxide layer introduced between the silicon waveguide and the metallic heater to avoid the light-absorption loss, inevitably impeding heat transport and dissipation owing to the low thermal conductivity of SiO_2. The unique properties of graphene, e.g. low optical absorption loss, high thermal conductivity (~5300 W • m^{-1} • K^{-1}) make graphene rather attractive as a heating material. Graphene heater can be in close contact to the silicon waveguide which significantly improves the tuning efficiency. However, the current performances of devices using graphene heaters are limited either by their relatively high power consumptions [2] or by their microsecond response times [3].

Here we report a new concept of enhancing the heater efficiency by the use of slow light in a silicon photonic crystal waveguide with a monolayer of graphene working as a heater. We demonstrate an energy-efficient graphene microheater with a tuning efficiency of 1.07 nm/mW and power consumption per free spectral range (FSR) of 3.99 mW, with the rise and decay times (10% to 90%) of only 750 ns and 525 ns.

A schematic of the slow-light-enhanced graphene microheater is shown in Fig. 1(a). A graphene monolayer is deposited onto the core-region of the silicon PhCW. The graphene is contacted by two gold/titanium (Au/Ti) pads. Ohmic heating is generated in the graphene via an applied voltage bias between two Au/Ti pads. The width of the graphene overlapping the photonic crystal line defect is designed to be narrower than the other part of the graphene to locally increase the Ohmic dissipation, which results in a more effective heating.

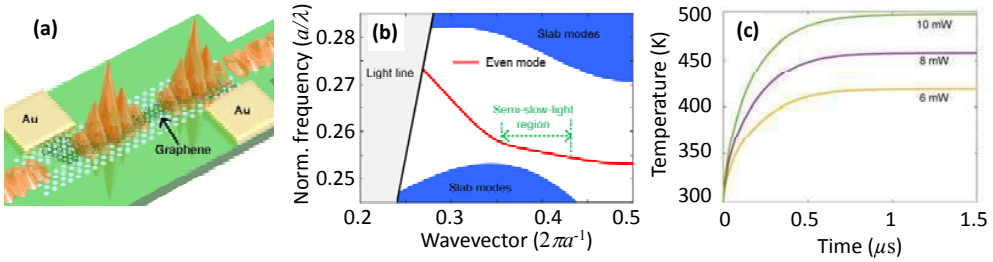

Fig. 1. (a) Schematic of the slow-light-enhanced graphene heater. (b) Band structure of the photonic crystal waveguide. The even guiding mode (red curve) consists of a semi-slow-light region (green dashed line). (c) The temperature response for different heating power.

The tuning efficiency is significantly enhanced owing to the semi-slow light effect that is obtained in the PhCW, which increases the effective interaction length between the heater and the waveguides [5]. By optimizing the positions of the first and second rows of holes adjacent to the line-defect, the band structure with semi-slow light effect is obtained (see Fig. 1(b)). Fig. 1(c) indicates the theoretical response time of the proposed microheater, 420 ns response time is achieved, which is faster than most previous reported microheaters.

The slow-light-enhanced graphene heater was fabricated by CMOS fabrication process and the graphene wet transfer process. The false-color SEM image is shown in Fig. 2(a). In order to test the efficiency, the device is incorporated in a Mach–Zehnder interferometer. By applying external voltage on the device, both the static (see Fig. 2(b)) and the dynamic response (see Fig. 2(c) and 2(d)) of the device are measured. The interference dips shift at 1533.71 nm and 1525.12 nm as functions of the tuning power is represented, and tuning efficiencies of 1.07 nm/mW and 0.65 nm/mW are achieved, respectively. A fast rising and decaying times (between 10% and 90%) are measured to be 750 ns and 525 ns, respectively, as indicated in Fig. 2(d). The corresponding figure of merit of the device [6], i.e. the product of the power consumption per FSR and the average response time, is 2.543 nW·s, which is one order of magnitude better than previous reported results [6].

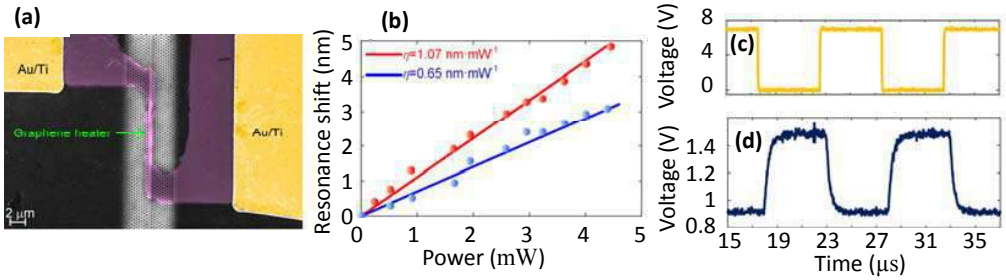

Fig. 2. (a) False-color SEM image of the slow-light-enhanced graphene heater. (b) Measured resonance shifts for the interference dips at 1525.12 nm (blue) and 1533.71 nm (red) as functions of the applied heating power. (c) Driving electrical signal and (d) corresponding temporal response signal.

In summary, we demonstrate an ultra-high efficiency and fast graphene microheater on semi-slow light silicon photonic crystal waveguide. We achieved ultra-high tuning efficiency of 1.07 nm/mW and power consumption per FSR of 3.99 mW. A fast response times (10% to 90%) of only 750 ns and 525 ns is demonstrated.

Abstract-We present the structures and performances of silicon-photonics-based optical phased-arrays (OPAs) to achieve wide beam-forming angles for LiDAR applications. Beam-forming and steering are experimentally demonstrated with 1x16 OPAs in which power splitters, phase shifters, and radiators are integrated on a silicon photonics platform. For wide transversal steering over 45°, two radiator types are examined; the grating- and photonic crystal-based structures. We will compare the detailed performances and tradeoffs for such structures.

The optical phased-array (OPA) has received considerable attention as a compact laser beam scanning/steering device for real-time 3D scene acquisition in the LiDAR (light detection and raging) systems. To attain a wide field of view while maintaining a single-beam characteristic and a high power throughput to the free space, the radiator element in the OPA needs to be carefully designed. In this paper, we present our ongoing works on the integrated OPAs based on the silicon photonics platform with a special emphasis on the radiator structures that can address such issues. Fig. 1(a) shows an example of a 1x16 OPA with 16 tunable phase shifters and 16 grating-based radiators operating near 1550 nm wavelengths.

For wide transversal beam steering in the azimuthal direction, two types of radiator structures were examined, namely a grating radiator structure (Fig. 1(a)) based on the Bragg diffraction and a nano-hole array radiator (Fig. 1(b)) based on the one-dimensional photonic crystal. For longitudinal steering, thermally tunable grating radiators were employed (Fig. 1(c)). The performances of these radiators were compared through 1x16 OPAs in which multi-mode interferometer-based splitters and electro-optic p-i-n phase shifters were integrated with the radiators on the silicon-on-insulator wafer. The radiator pitch was varied in a range of 1.5 μm ~ 2.0 μm.

Both the grating and hole-based radiators showed wide beam-steering ranges above 45° in the transverse direction. Especially, the nano-hole radiators showed a possibility of even wider beam-forming angles with a narrower pitch due to less interference between the neighboring radiators. The thermo-optic tunable grating radiator showed a vertical steering of up to 7° with a current injection of 6 mA into the radiator region. For the examined OPA structures, the overall performances and tradeoffs on the radiation efficiency, beam shapes, power consumption, and phase control speed as well as the steering range will be compared.

Orbital angular momentum (OAM) multiplexing is a promising technology to expand the transmission capacity of either free space optical communication or fiber communication. Previously, we have demonstrated a compact silicon photonic OAM emitter capable of generating single but arbitrary OAM states. The operation principle of the device is based on the coupling of whispering gallery modes (WGMs) in a micro-ring resonator to OAM modes through an angular grating embedded within the micro-resonator. This device is capable of generating any OAM states by simply changing the input wavelength. However, this wavelength dependent approach made it difficult to achieve OAM multiplexing, which is of vital importance for the application of OAM-based optical communications.

Here, we demonstrate a 3D integrated OAM multiplexer, which can be used to combine or multiplexing up to four OAM modes. As shown in Fig. 1, the device consists of two layers of silicon microring resonator with angular grating embedded in the innerwall. The 3D structure is fabricated through a wafer bonding process.

Abstract- We report our recent progress on hybrid silicon photonic devices based on the phase change of GST. The Si-GST hybrid waveguide loss is extracted from the measurement of straight waveguides and ring resonators. A MZI switch enabled by the electrically-driven GST is realized. Experimental results reveal that the GST can undergo repeatable phase change induced by electrical pulses, giving rise to a switching extinction ratio variation of 5 dB.

To make a large-scale photonic integrated circuit, the individual optical components should be as compact as possible to reduce the chip footprint and power consumption. Silicon-on-insulator based photonic devices are extremely attractive due to its compactness and compatibility with microelectronic circuits using the well-developed CMOS technology [1, 2]. The active tuning in silicon is usually realized by the thermo-optic or free-carrier plasma dispersion effects. However, the thermal effect is slow in the order of microsecond [2]. The free-carrier effect, on the other hand, is fast but relatively weak with a refractive index change only in the order of 0.001[1]. Resonant structures, such as ring resonators, disk resonators, Bragg gratings and photonic crystals, can be employed to reduce the device size [3, 4]. However, this is achieved with the sacrifice of the optical bandwidth. The resonant devices are quite sensitive to temperature change, leading to potential stability issue [5]. One solution to overcome the fundamental limitation in today's silicon photonic devices is to use the exotic materials with a much larger refractive index modulation. The phase-change material (PCM) is one of the materials that can serve for this purpose. There exist at least two phases with significantly different optical properties, which can be repeatedly and rapidly cycled. The $Ge_2Sb_2Te_5$ (GST) is a widely-used PCM in which the phase change can be thermally, optically or electrically induced potentially with an ultrahigh speed. The GST possesses the "self-holding" feature, and consequently there is no static power consumption to maintain the states.

We first investigated the phase change of a GST thin film by using thermal stimulus. Crystalline GST turns to amorphous when it is heated beyond the melting point and quenched rapidly. On the contrary, amorphous GST turns to crystalline when it is heated to above the crystallization temperature (but below the melting temperature). The change in the real part of the refractive index leads to phase shift, while the change in the imaginary part leads to attenuation. We measured straight waveguides and micro-ring resonators to extract the relevant parameters of the GST. The silicon waveguide dimension is 500 nm (width) by 220 nm (height). The GST film thickness is 10 nm, covering a part of the silicon waveguide. By comparing the transmission spectra before and after GST phase change, we obtained the loss and phase change of the GST-covered waveguide section. The GST phase change from the amorphous state to the crystalline change was enabled by heating the devices at 200 °C for 3 min on a hot-plate. For the straight waveguides, we extracted the change in attenuation from the measured waveguide loss. It revealed that the waveguide loss increases by around 1.4 dB after phase change

from the amorphous to the crystalline state for every micron length of active waveguide. For the micro-ring resonator, we fitted the measured resonance spectrum with the resonator transfer function. Upon fitting, we obtained the waveguide losses of 1.38 dB/μm and 0.1 dB/μm for the crystalline and amorphous states, respectively. The phase change induced resonance wavelength shift per unit length of GST was measured to be 0.375 nm/um.

We next implemented a Mach-Zehnder interferometer (MZI) optical switch based on the phase change of electrically-driven GST as shown in Fig. 1. One arm waveguide of the MZI is partially covered with a stack of ITO/GST/ITO film. As the GST has a self-holding characteristic, the two switching states can be maintained without any electrical supply. Electrical power is only consumed during the dynamic phase change process, leading to much lower power consumption if the switching frequency is low. We performed the phase change experiment using electrical pulses as stimuli. Preliminary experimental results reveal that the GST can undergo repeatable phase change induced by electrical pulses. The phase change has a significant effect on the optical performance of the MZI switch. The extinction ratio varies by 5 dB. The proof-of-principle experiment proves the possibility of hybrid integration of GST with silicon waveguides for potential ultra-compact photonic integration.

A flat-top bandpass mode order convertor based on two dimensional Bragg gratings

Yuechun Shi*, Rulei Xiang, and Xiangfei Chen
National Laboratory of Solid State Microstructures & Collaborative Innovation Center of Advanced Microstructure & College of Engineering and Applied Sciences, Microwave-Photonics Technology Laboratory, Nanjing University, Nanjing, 210093, China

Abstract- We propose a new scheme for forward mode order conversion in a multimode waveguide based on cascaded two dimensional Bragg gratings. Usually, the waveguide grating structure, i.e. long period grating or Bragg grating with small period, is an important way to realize mode order conversion for its advantages such as bandpass conversion and easy to control wavelength. But for the long period structure, the device length is very long due to the long period in nature and the conversion spectrum is hard to realize flat-top shape. While for the Bragg grating structure, only backward conversion can be realized up to now. In order to overcome these issues, we employ two Bragg reflections along with twice mode conversions to achieve a flat-top bandpass and forward convertor. Thinks to the Bragg grating structure, the device size is much more compact than that based on long period grating. And the wavelength and bandwidth can be easily adjusted by grating parameters. The simulation results show high mode conversion efficiency (nearly 100%) and low inter-modal crosstalk (<-20dB). In addition, the improved convertors can be obtained by carefully designing grating profiles, such as apodizaion structure for rectangle shape conversion spectrum. Therefore, we believe the proposed scheme may provide a new method for high-performance mode order converter in on-chip mode-division multiplexing.

Figure 1(a) shows the schematic of the proposed converter from mode TE_1 to TE_2 as an example. It includes two BGs, i.e., G_{02} (front section) and G_{01} (rear section). Here, G_{01} and G_{02} are used for reflection-type mode conversion between TE_0 and TE_1, and between TE_0 and TE_2, respectively. The waveguide is designed to support the first-three-order transverse electric (TE) modes, which is sandwiched by an upper silicon-dioxide cladding and a buried oxide (BOX) layer. The whole mode conversion process is described in the following. When the mode TE_1 with a specific wavelength is launched and propagates in the waveguide, it first passes through G_{02} without any reflection until gets to G_{01}. Then, TE_1 is reflected along with mode conversion to TE_0. The resulting mode TE_0 backward propagates and gets to G_{02}. Then, the following mode conversion from TE_0 to TE_2 occurs in G_{02} and subsequently the mode TE_2 pass through the G_{01}. Thus the forward mode conversion from TE_1 to TE_2 is achieved. Figure 1(b) shows the corresponding phase match condition. This condition for two arbitrary order mode conversion from mode i to mode j can be expressed as,

$$\beta_j = \beta_i + K_{mj} - K_{im}. \tag{1}$$

where, $\beta_i = 2\pi n_i/\lambda$, $\beta_j = 2\pi n_j/\lambda$, $\beta_m = 2\pi n_m/\lambda$, and $K_{im}=2\pi/\Lambda_{im}$, $K_{mj}=2\pi/\Lambda_{mj}$. n_i, n_j and n_m are the effective refractive indices of i_{th}, j_{th} and m_{th} order mode, respectively. Λ_{im} and Λ_{mj} are the grating periods for mode conversion between the i_{th} and m_{th} order modes, the m_{th} and j_{th} order modes

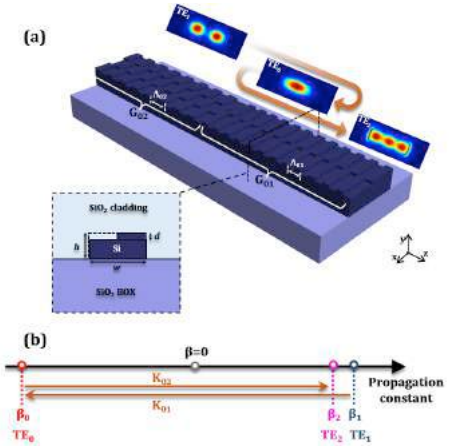

Fig. 1. Schematic of (a) the proposed device structure for conversion from mode TE1 to TE2. The detailed figure shows the cross section of the waveguide. (b) The corresponding phase matching condition.

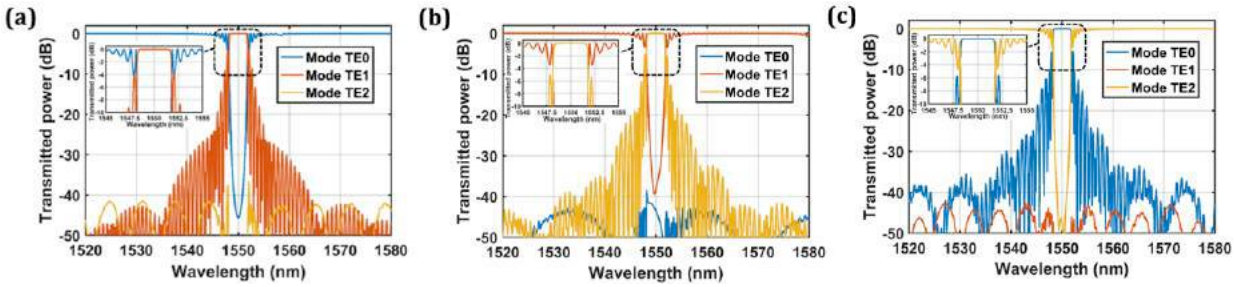

Fig. 2. Transmission spectra for the forward conversions (a) from mode TE_0 to TE_1, (b) from mode TE_1 to TE_2, and (c) from mode TE_2 to TE_0, respectively. The inserted figures show the detailed spectra around the Bragg wavelength.

Arbitrary two gratings from G_{01}, G_{02} and G_{12} are used to achieve one of the three kinds of forward mode conversions. As shown in Fig. 2(a), the mode conversion is wavelength-dependent due to the phase match condition. The designed Bragg wavelengths are both 1550 nm and the bandwidth is ~ 3.7 nm. Within the bandwidth, the mode TE_0 is converted to mode TE_1 with a high conversion efficiency (nearly 100%) and the inter-modal crosstalk is very low (<-20dB). By combining the G_{02} and the G_{01}, we can also obtain the mode conversion from mode TE_1 to TE_2. Simulation results show that the bandwidth is also about 3.7 nm. High conversion efficiency and low inter-modal crosstalk are obtained as shown in Fig. 2(b). Figure 2(c) shows the conversion spectra from mode TE_2 to mode TE_0 with the similar performances. Here, G_{01} and G_{12} are used.

Metasurfaces and 2D Metamaterials in microwave region

Generation of vector beams based on Field Transformation metasurface.

Cheng Wang, Ke Chen, Junming Zhao*, and Yijun Feng
Department of Electronic Engineering, School of Electronic Science and Engineering
Nanjing University, Nanjing,China
*jmzhao@nju.edu.cn

Abstract-The microwave beam whose polarization is radially polarized is called vector beam. Because of its unique properties and potential applications, there has been a rapid increase of the number of publications on vector beams. Different approaches have been proposed to generate vector beams through these studies. Here, for the first time, we use one field transformation(FT)[1] approach to design a metasurface which can generate vector beams. Such vector beam generation metasurface can be easily realized with 3D printer.

Vector beam has great potentialities in various scientific and engineering realms, and it has been extensively explored in helicon inspection and microwave devices. Recently, many types of vector beams have been proposed, such as cylindrical vector beam[2], double-ring-shaped vector beams[3], tractor beams[4] etc. However, most of these vector beam generation methods have limitations that the generation devices are not easy to fabricate. Our previous studies have shown a remarkable degree of fundamental and conceptual advances by applying the FT technique in the design of wave-plates utilizing artificial anisotropic dielectrics[5]. Thus, we utilize the FT theory into designing metasurfaces which can generate vector beam. As Fig 1 shown, the permittivity of the red material is 10, its height d1 is 1mm and the permittivity of the blue material is 1, its height d2 is 1.5mm. We arranged the two materials intersecting along one direction periodically, and gradually rotate 8 different angles, which are -78.75° ,-56.25° ,-33.75° ,-11.25° ,11.25° ,33.75° ,56.25° ,78.75° , respectively. Then we can get 8 different portions that can produce different outgoing polarization directions. The whole metasurface is shown in Fig. 2, whose thickness is 12.5mm, and simulation result at 11.5GHz is shown in Fig 3. We can see that as the whole effect of the combination of the 8 portions, one radially polarized outgoing beam is generated. Besides such metasurface can be easily fabricated through 3D printer. The effective permittivity of each metasurface portion can be achieved based on effective media theory.

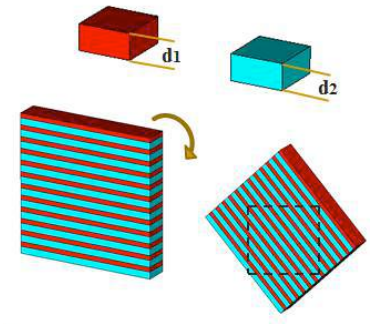

Fig 1. Schematic diagram

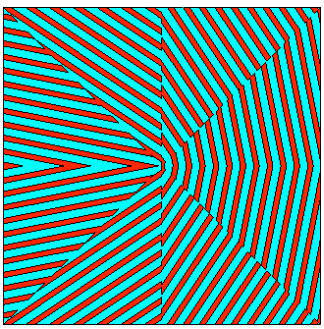

Fig 2. The metasurface to generate vector beam

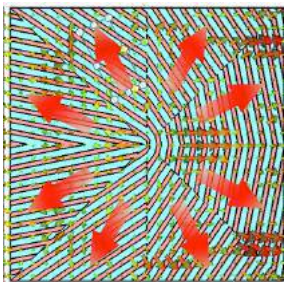

Fig 3. Simulated result

Conclusion

In this paper we propose a new method that utilizing combined metasurfaces through FT theory to generate vector beam, and the metasurface can be easily fabricated by 3D printer.

Omega-bianisotropic metasurfaces: from controlling radiative fields to manipulating evanescent modes

Abstract— Omega-bianisotropic metasurfaces (O-BMSs) have been shown to be able to implement any locally power-conserving field transformation via passive lossless meta-atoms. In previous work, we have utilized this theorem to design O-BMSs realizing reflectionless refraction and beam splitting, and perfect reflection. In this talk, we propose a novel O-BMS waveguide, whose eigenmodes are quadruples of surface waves, allowing manipulation of near-field features.

Metasurfaces, ultrathin planar arrangements of subwavelength polarizable particles (meta-atoms), have been intensively investigated in recent years for a myriad of beam manipulation applications [1]. Examining the fundamnetal problem of engineered refraction, early reports have pointed out that to reduce undesirable reflections, it is required, as per the equivalence principle, to use Huygens' metasurfaces (HMSs), allowing induction of *both* electric and magnetic surface currents [2–4]. Nonetheless, subsequent investigations revealed that to guarantee realistic (passive and lossless) design specifications, the field transformation supported by the HMS should satisfy the local power conservation and local impedance equalization conditions [5]. The latter implies that certain reflections are required to compensate the impedance mismatch between the fields on the HMS facets [4].

More recently, we have shown that this restriction can be alleviated by breaking the HMS meta-atom symmetry, introducing omega-type magnetoelectric coupling [6]. The resultant omega-bianisotropic metasurfaces (O-BMSs) are characterized by their electric surface impedance, magnetic surface admittance, and magnetoelectric coupling coefficient, indicating that applied electric fields excite *both* electric and magnetic surface currents, and analogously for magnetic fields [1]. Harnessing this additional (magnetoelectric) degree of freedom, we have proven that *any* (given) field transformation $\{E_x^< (y,z), H_y^< (y,z)\} \leftrightarrow \{E_x^> (y,z), H_y^> (y,z)\}$ which *locally* conserves the real power, i.e., for which $\Re\{E_x^< (y,z)\, H_y^{<*} (y,z)\}_{z\to 0^-} = \Re\{E_x^> (y,z)\, H_y^{>*} (y,z)\}_{z\to 0^+}$, $\forall y \in \mathbb{R}$, can be implemented via a passive lossless O-BMS situated at $z = 0$, whose constituents are given in [6].

While the theorem can be straightforwardly invoked to design reflectionless *refracting* O-BMS [6] (independently derived in [7]), achieving accurate designs becomes less trivial when reflectionless beam splitting or "perfect" engineered *reflection* are considered [7,8]. In these cases, the interference between the incident and (desirable) scattered modes yields non-trivial power profiles on the O-BMS facets, generally difficult to match. In [9] we have proposed an unconventional approach to tackle this problem, requiring auxiliary surface waves (SWs) to be induced by the O-BMS. While the SWs do not affect the functionality in the far field, they can be used to manipulate the flow of real power via interference with the incident and scattered modes. Indeed, by judicious stipulation of the SW properties, we were able to achieve the required local power conservation, leading to accurate optimal analytical designs of passive lossless O-BMSs for these two functionalities [9].

Specifically, to implement engineered plane-wave reflection, we have utilized two SWs propagating on the top facet, the interference between which requires power to be drawn from the lower half-space in the first half of the interference period, and pushes it back downwards at the other half-period; this power profile exactly matches the one exhibited by the interfering incident and anomalously reflected plane waves on the bottom facet [9]. This solution highlighted the possibility to sustain power circulation across the O-BMS facets, supported by interfering SWs.

Inspired by this result, we propose herein a novel *penetrable* O-BMS SW waveguide (SWG), designed to guide a pair of SWs on each of its facets [four SWs overall, Fig. 1(a)]. The SWs below and above the metasurface can have, in general, different amplitudes, propagation constants, and decay coefficients, and they exchange power via the O-BMS while propagating along it. Interestingly, the eigenmodes of this SWG are quadruples of SWs, the properties of which are tailored by the O-BMS design. To synthesize it, we stipulate the fields above and below the O-BMS to follow

$$E_x^>(y,z) = E_1^+ e^{-\alpha_1^+ z} e^{-jk_{t,1}^+ y} + jE_2^+ e^{-\alpha_2^+ z} e^{-jk_{t,2}^+ y};\;\; E_x^<(y,z) = E_1^- e^{\alpha_1^- z} e^{-jk_{t,1}^- y} + jE_2^- e^{\alpha_2^- z} e^{-jk_{t,2}^- y} \quad (1)$$

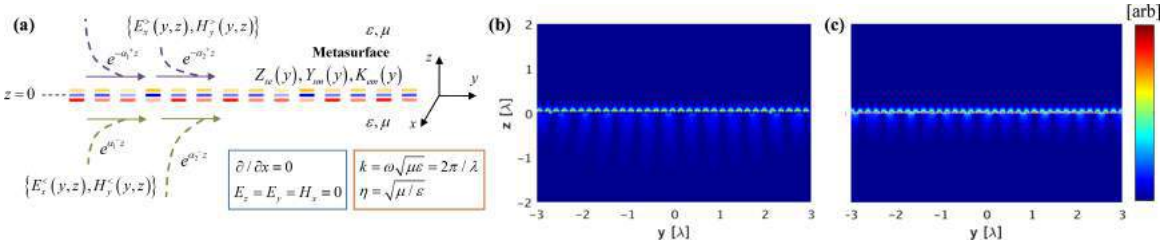

Figure 1: (a) O-BMS SWG configuration. (b) Simulated and (c) analytical field distribution $|\Re\{E_x(y,z)\}|$ of the SWG designed in the text (zoomed in around $y \in [-3\lambda, 3\lambda]$).

with complex amplitude $E_n^{\pm}$, transverse wavenumbers $k_{t,n}^{\pm} > k$, and corresponding decay coefficients $\alpha_n^{\pm} = (k_{t,n}^{\pm 2} - k^2)^{1/2}$. To guarantee local power conservation, the SW parameters must satisfy

$$\left(\alpha_2^+ - \alpha_1^+\right)\left|E_1^+ E_2^+\right| = -\left(\alpha_2^- - \alpha_1^-\right)\left|E_1^- E_2^-\right| \quad \wedge \quad \left(k_{t,2}^+ - k_{t,1}^+\right) = \pm\left(k_{t,2}^+ - k_{t,1}^+\right) \quad \wedge \quad \xi^+ = \pm\xi^-, \qquad (2)$$

where the phase shifts $\xi^{\pm}$ are defined as $E_1^{\pm} E_2^{\pm *} \triangleq \left|E_1^{\pm} E_2^{\pm}\right| e^{j\xi^{\pm}}$. Finally, the SW quadruple of (1), with parameters adhering (2), is substituted into the formulas in [6] to evaluate the O-BMS design.

To verify this new waveguiding concept, we have followed the outlined procedure and designed an O-BMS SWG that simultaneously guides SWs with long ($\alpha_1^+ = \alpha_2^- = 16.78[\lambda^{-1}]$) and short ($\alpha_2^+ = \alpha_1^- = 4.00[\lambda^{-1}]$) evanescent tails, with different balance on each facet ($E_1^+/E_2^+ = 46.3$, $E_2^-/E_1^- = 0.463$). A 25λ-long O-BMS SWG was defined in ANSYS HFSS, using abstract three-layer impedance sheet structures to implement the O-BMS meta-atoms (*cf.* [6,9]), excited by an electric line source at $y = -12.5\lambda$. Comparison between full-wave simulated [Fig. 1(b)] and analytically-predicted [Fig. 1(c)] field distributions reveals good agreement, validating our theoretical concept.

Although extensive research has been conducted on metasurface-based SWGs in the past decade, it was restricted to *impenetrable* structures, and focused on controlling the trajectories of the SWs, or their coupling to leaky-wave radiation [10]. In contrast, the ability to support propagation of "surface wave packets" on the *penetrable* O-BMS holds great potential for generating exotic near-field features by controlling the interference between the guided evanescent waves.

Abstract-We report on the optical properties of metal-less diamond-based planar metamaterials in terahertz (THz) frequency range. A conductive 200 nm-thick graphitized layer was formed on a surface of CVD polycrystalline diamond by excimer KrF-laser. Optical properties of a diamond plate with a graphitized layer were measured and simulated according to the Drude model. A polarizer with a graphitized subwavelength grating as a prototype of metamaterial device was tested in THz range and had shown different loss for orthogonal polarizations.

Recently, significant progress has been achieved in technologies of generation and detection of terahertz (THz) radiation. As the result a new class of high power sources has been appeared – free electron lasers [1]. These high power coherent sources need new elements with high damage threshold to manipulate radiation. Composite materials, consisted of conductive areas on the surface of dielectric, called metamaterials, are the best candidate for this purpose. Among the methods of fabrication of planar metamaterials may be pointed out following: lithography [2], laser printing [3] and laser-induced forward transfer [4]. However all known for today methods propose to cover conductive layer (metal film) on the dielectric substrate, that induce number of limitations on produced composites (adhesion, damage threshold) and on fabrication techniques in turn. In this work another solution for the formation of conductive planar structures on the dielectric substrate is proposed. It is based on laser-induced graphitization of the diamond surface. In this case fabricated metamaterials will be completely carbon, and conductive graphitized structures will be strong bonded with diamond substrate, that will provide high adhesion and thermal contact –so valuable for the use in high power beam. And the diamond plate will serve as cooler and withdraw heat from working metasurface. The aim of this work was to fabricate graphitized structures on the transparent CVD diamond substrates by means of excimer KrF-laser and to investigate their optical properties in THz frequency range.

In the first step the surface area with size of 4200x4000 μm^2 was irradiated with excimer laser at the fluence of 35 J/cm^2, which was significant larger than the threshold of graphitization of polycrystalline diamond. As the result a graphitized layer with thickness of 200 nm was formed on diamond. Transmittance spectra of the pure diamond with thickness of 574μm and formed graphitized layer on a diamond surface were analyzed in the range of 10-1000 cm^{-1} by Fourier spectrometer BRUKER IFS113v. Modeling of transmittance spectra was carried out according to the formulas for transmission coefficient T as a function of conductivity σ for single – or bilayer medium and plane electromagnetic waves [5]. The dielectric properties of the graphitic layer were simulated according to the Drude model. Fitting the values of scattering rate γ and plasma frequency ν_p has provided to minimize the deviation of the calculated transmittance spectrum from the experimental values for a graphitized layer on the diamond substrate. The best result was achieved for following values: γ=5000 cm^{-1} and ν_p=16340 cm^{-1}. Obtained value of the optical conductivity σ_{DC}=890 $Ohm^{-1}cm^{-1}$ of the graphitized layer in THz frequency

range is in good agreement with the value, measured by the four-probe method.

To demonstrate the possibilities of proposed laser method for the fabrication of metamaterials, the periodic grid, consisting of graphitized lines of a width of 15 μm, a length of 4400 μm and a period of 30 μm, was made by the same laser technique on the surface of the diamond. The obtained sample should act as a polarizer for radiation in the THz frequency range. Transmittance spectra of the structured sample were measured on the spectrometer "Epsilon" [6] in the range of 31 – 39 cm^{-1} for parallel (s-) and perpendicular (p-) orientation of polarization of the radiation relative to the graphitized lines on the diamond surface and are presented in figure 1. It is seen from the obtained spectra that the grid is transparent for waves with p-polarization, and is reflective for waves with s-polarization. Thus, the periodic subwavelength grid created by the laser irradiation acts as a metamaterial polarizer for the THz radiation.

Inductively reconfigurable periodic structures for synchronous and wideband tuning

Yih-Dar Chen and Chien-Hao Liu

National Taiwan University, Taipei, Taiwan
r04522545@ntu.edu.tw and cliu82@ntu.edu.tw

Abstract— In this research, we propose a planar reconfigurable periodic structure that its frequency response can be tuned continuously over a wide frequency range. Each element is composed of three metallic strips pinned as a deformable triangle acting as an equivalent series LC resonator illuminated by vertically-polarized normal incident electromagnetic waves. By manipulating the induced surface current path on each element, the resulting variations of the equivalent inductance can shift the resonant frequency. In addition, a linkage mechanism is exploited in this research to synchronously alter each element for large area applications. Two prototypes with the dimension of 15 by 18 unit cells was designed, fabricated, and examined with field tests. It was demonstrated that the resonant frequency of the fabricated structure was shift from 5.6 GHz to 7.5 GHz with a wide range of 1.9 GHz (29 % in terms of fractional bandwidth). The research results are expected to be beneficial for wideband reconfigurable periodic structures and large-area applications.

1. INTRODUCTION

In recent years, various techniques have been exploited for developing reconfigurable periodic structures that their frequency responses can be tuned continuously or switched on/off by manipulating each element. Most periodic structures are composed of equivalent LC resonators for providing band-pass or band-stop responses. Since the resonant frequency is inversely proportional to the square root of inductance and capacitance, the resonant frequency can be shifted by altering the equivalent capacitance such as varactors [1] and liquids. However, these methods have some disadvantages including bulky, complicated manufacturing, and parasite harmonics.

In this research, we propose a planar inductively reconfigurable periodic structure that its frequency response can be tuned continuously by varying the equivalent inductances. Each element of the proposed periodic structure is composed of three metallic strips pinned as a triangle with a gap at one edge shown in Fig. 1. The vertically strips are fixed in free space and the two side strips deformable due to the combinations of the slots and pins. For normal incident electromagnetic (EM) waves with vertically polarizations, the induced capacitive gaps and the surface currents on the strips represent the capacitors and inductors of each unit forming a series LC resonator with a band-stop response. The resonant frequency can be shifted by shrinking (short current pathes) and enlarging (long current pathes) the triangles shown in Fig. 1(a) and (b). For synchronously adjusting each unit cell, all the elements are connected via the mechanical linkages for large-area tuning applications.

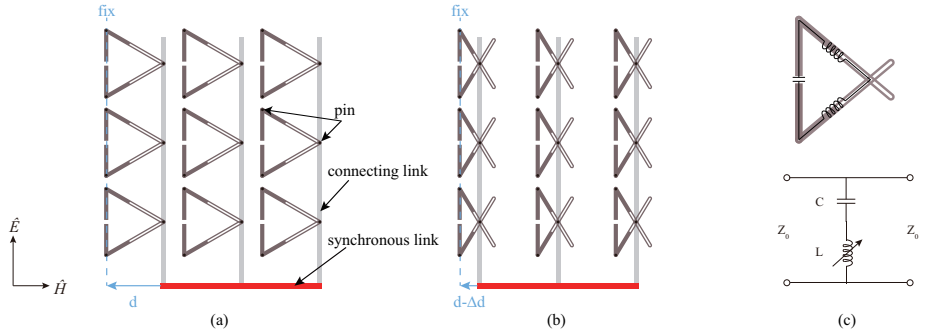

Figure 1: Schematic diagram of the proposed periodic structure under vertically-polarized normal incident EM waves (a) before and (b) after deformations. (c) The equivalent circuit model.

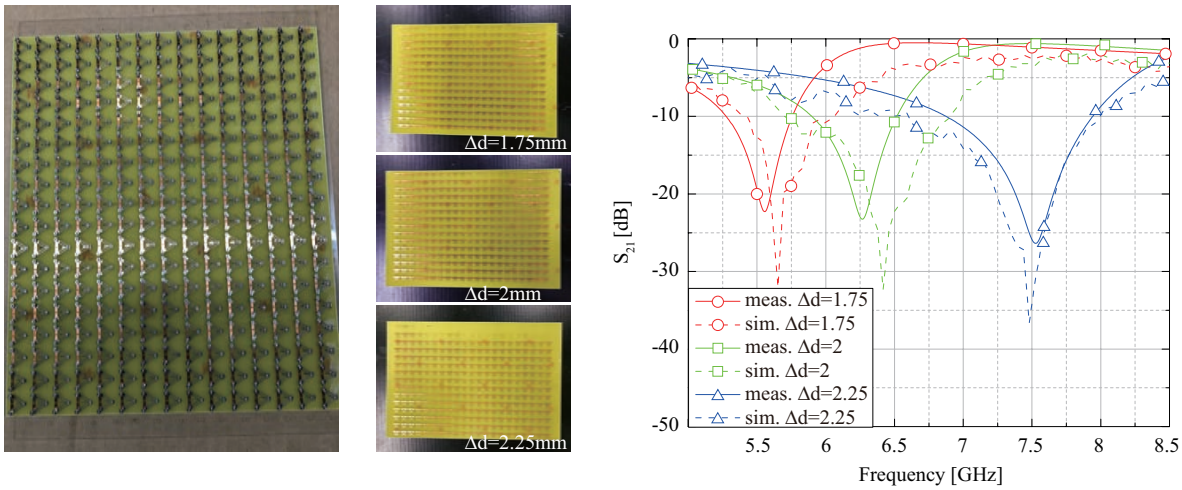
2. DESIGN

Fig. 1(c) shows the equivalent circuit model of the propose triangular element which is composed of a capacitive gap and variable inductor due to the induced surface current on the metallic strips under vertically-polarized EM waves. The resonant frequency was designed at 5.6 GHz before deformations via full-wave EM simulations and circuit simulation tools. As the triangle shrinks, the decrease of the induced current path on the metallic strips results in decrease of the inductance and increase of the resonant frequency shown in Fig. 2(c).

3. FABRICATIONS AND MEASUREMENTS

The proposed triangular periodic structure and the linkage were fabricated via chemical etching and laser cutting shown in Fig. 2(a). However, the linkage did not function correctly due to fabrication errors and tolerance which needed a second fabrication. In stead, three triangles with different sizes corresponding to the three tuning stages of the aforementioned periodic structure with the linkage was fabricated via PCB boards shown in Fig. 2(b). They were examined with the experimental setup reported in [2]. Fig. 2(c) shows the simulated and measured transmission coefficients before and after deformations. As can be seen, the resonant frequency was shifted from 5.6 GHz to 7.5 GHz with a wide range of 1.9 GHz (29 % in terms of fractional bandwidth).



(a) (b) (c)

Figure 2: (a) The fabricated periodic structure with a linkage. (b) Three different triangular periodic structures fabricated on PCB corresponding to the three tuning stages of (a). (c) The simulated and measured transmission coefficients for the three triangles shown in (b).

4. CONCLUSION

In this research, we proposed a relatively large-area reconfigurable periodic structure. By altering the inductive surface current path of each unit cell, its resonant frequency could be shifted from 5.6 GHz to 7.5 GHz with a wide range. The research results are expected to be beneficial for wide-band tunable applications.

Exploiting Linkage Mechanisms for Synchronously Tunable Dual-Band Frequency Selective Surfaces with Large Areas

Yu-Chieh Hung and Chien-Hao Liu

National Taiwan University, Taipei, Taiwan
r04522543@ntu.edu.tw and cliu82@ntu.edu.tw

Abstract— In this research, we propose a double-rocker linkage mechanism for synchronously tuning the frequency responses of the dual-band FSSs with large areas. Each unit cell is composed of a patch and a loop forming a combination of a series and parallel resonators. Since the patches and loops are connected separately with two rocker linkages, their frequency responses can be synchronously tuned by two linear driving actuators. A prototype of the dual-band FSS with the dimensions of 16 by 16 unit cells was design, fabricated, and examined with field tests. By rotating the patches (loops) via the driving linkages, the pass-band (stop-band) was shifted 7.8% (11.4%). The research results are expected to be beneficial for large-area tuning and high-power microwave applications.

1. INTRODUCTION

Tunable frequency selective surfaces (FSSs) have long been used in modern communications and military applications for providing switching or continuous tuning of the frequency responses. Various tuning approaches have been proposed including electronics, liquid, plasma, memory alloy, and optics. However, the main challenge is to synchronously alter the frequency response of each unit cell for creating desired frequency deviations. For large-area FSSs, it may need millions of bias circuits or actuators to change the frequency response of each unit which is impractical. Take the commonly-used electronic approach as an example, an FSS operating at 10 GHz with a dimension of 1 m $\times$ 1 m and 1 period of 5 mm (i.e. 40,000 unit cells), it needs more than thousands of components for actuation. Therefore, in this research, we propose a dual-rocker linkages for mechanically tuning the frequency responses of the dual-band FSS shown in Fig. 1. Each unit cell is compose of a patch and a loop. For normal incident electromagnetic waves, the patch and loop correspond to the pass- and stop- bands of the FSS. In Fig. 1(a), all the patches and loops are connected separately via two linkage and controlled by two linear driving actuators. By rotating the patches via the driving linkage shown in Fig. 1(b), the corresponding pass-band can be tuned synchronously and continuously. In the other hand, the stop-band responses of the FSS can be tuned synchronously by rotating the the loops via the driving linkage shown in Fig. 1(c).

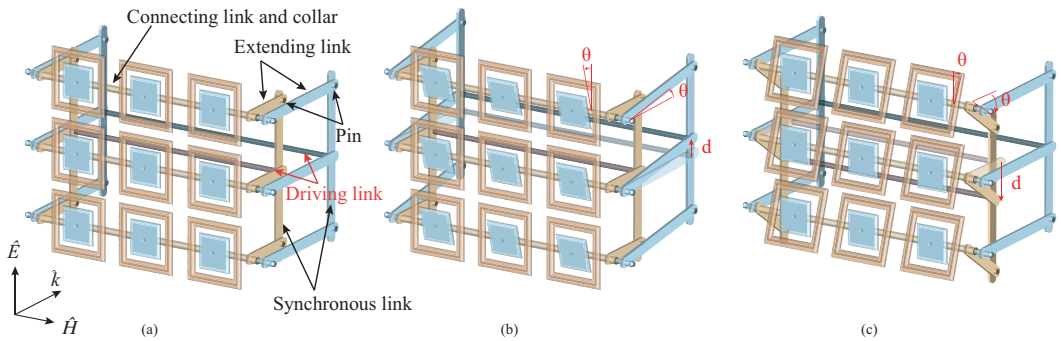

Figure 1: (a) The dual-band FSS composed of patches corresponding to the stop-band and loops corresponding to the pass band for normal incident electromagnetic waves. (b) The pass-band was tuned synchronously by rotating the patches based on the displacement of the driving linkage. (c) The stop-band was tuned synchronously by rotating the loops based on the displacement of the driving linkage.

2. DESIGNS AND FABRICATIONS

The propose dual-band FSS is composed of patches and loops forming a combination of series and parallel resonators illuminated by a normal incident electromagnetic waves shown in Fig. 3(a). The gap between the patch and the loop (loops) acts as an variable capacitor, C_2 (C_1), corresponding to the frequency shift of the pass-band (stop-band). A prototype was fabricated via standard PCB photolithography shown in Fig. 3(b).

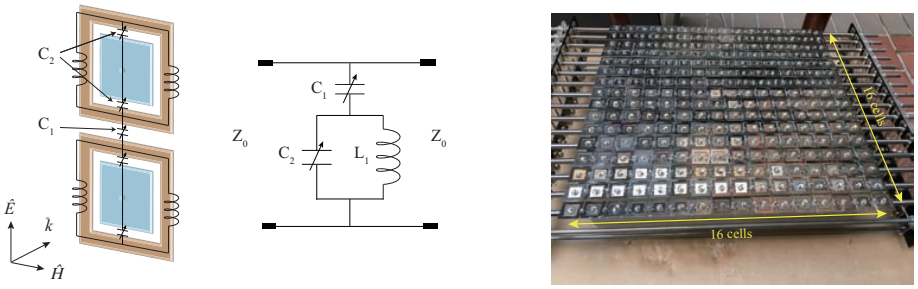

Figure 2: (a)The equivalent circuit model. (b) The photo of the prototype. The patches, loops, collar, and the connecting link were made of stainless metals. The rest components were made of acrylic.

3. MEASUREMENTS

The fabricated prototype was examined with an experiment setup reported in [1]. By synchronously rotating the patches, the pass-band shifted with a 7.8%. Similarly, by rotating the loops, the stop-band shifted with a 11.4%. It was demonstrated that by controlling the driving links separatively, the pass- and stop- bands of the dual-band FSS could be adjusted individually. The measured results (solid lines) deviated from the simulated results (dashed lines) due to fabrication errors.

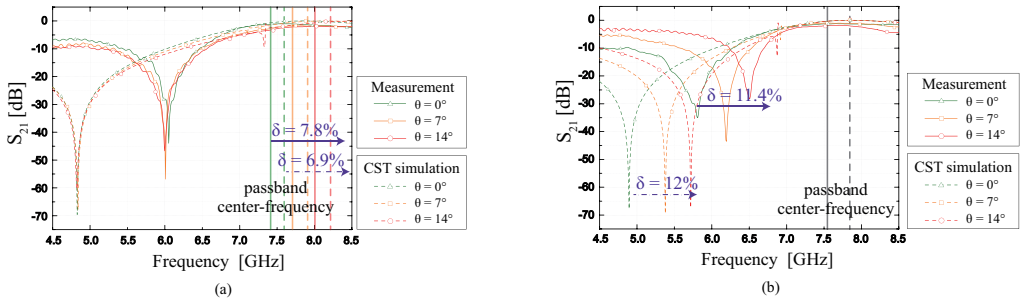

Figure 3: (a) Rotating the patches resulting in shifting of pass-band. (b)Rotating the loops resulting in shifting of stop-band.

4. CONCLUSION

In this research, we proposed a linkage-mechanism based tunable dual-band frequency selective surface with a large area of 16 by 16 unit cells (total: 256 unit cells). By individually recreating the displacements of the two driving linkages, the pass- and stop- bands could be continuously tuned with 7.8% and 11.4%, respectively. The research results are expected to be helpful for large scale tuning applications.

Abstract-A planar active metasurface composed of meta-atoms incorporating voltage-controlled varactor diodes, is used as reflector for microwave antenna applications. The dispersion responses of the cells are individually tailored for reconfigurability mechanisms. The phase characteristics of a several reflectors is engineered by judiciously controlling the bias voltage of the varactor diodes on the planar metasurface.

Metasurfaces have been proposed to manipulate light propagation [1]. They present the main advantage of having reduced profile and therefore reduced losses. By controlling the reflection and/or transmission characteristics of metasurfaces, they have been successfully implemented in planar lens antennas [2-4], cavity antennas [5-6], and leaky-wave antennas [7] to achieve high directivity.

In this study, we propose a planar reflecting metasurface as an interesting alternative to classical reflectors. Passive metasurfaces in most cases operate for a single functionality and at a single frequency or on a very narrow frequency band and therefore present limitations in terms of bandwidth due to the intrinsic characteristics of resonant cells. An active metasurface allows integrating multiple functionalities into a single metasurface, and paves the way to new possibilities in controlling the path of electromagnetic waves. In this context, a reconfigurable metasurface composed of resonant meta-atoms is designed, fabricated and tested. Each individual meta-atom incorporates a varactor diode that can be controlled by an external direct current (DC) voltage. Such an active metasurface allows to tailor individual properties from the resonant cells and particularly to control the reflectivity so as to overcome the unique response limitations of passive ones. As such, we show that the proposed metasurface is able to mimic both a corner reflector and a parabolic reflector. The corresponding phase profile can be engineered and can be electronically modified to mimic the corner and parabolic reflector designs, as illustrated by the schematic in Fig. 1.

Abstract-A wideband metamaterial structure (MMS) using frequency selective surface (FSS) loaded with lumped resistor has been designed in the range of 2 to 18 GHz. The MMS consists of a resistor loaded FSS, a dielectric sheet and a metallic ground. The results show that the MMA covers the wide frequency range of 5.5 GHz with reflection loss of -31.7 dB at normal incidence. The broadband absorption is mainly resulted from the strong electromagnetic (EM) resonance. The obtained result reflects the potential of lumped resistor based MMSs for distinct EM applications.

MMSs are getting significant interest of researchers in the field of electromagnetics due to their diverse practical applications [1]-[5]. But it is still a very challenging task to obtain good absorption with wide bandwidth. However, the requirement of broadband frequency response can be fulfilled by adopting advanced electromagnetic (EM) structures like FSSs [6]. It is well known that the FSS geometry, its dimensions, inter-element spacing, and substrate greatly affects the EM performance of MMSs. A very good pioneer work on MMSs has been reported by the researchers, but still there is a need to introduce the strategies which can further improve the absorption characteristics of the MMSs. Therefore, in this study an effort has been made to critically analyze the effect of the patch and aperture FSS geometries over the performance of MMSs. Further, the bandwidth of MMS has been enhanced by incorporating lumped resistive circuit elements.

The proposed MMS unit cell of size 10 × 10 mm consists of a square patch and square aperture geometries impacted dielectric layer of FR4 material (with thickness- 3.0 mm, dielectric constant 4.3 and loss tangent tan δ=0.025) backed with a perfect electric conductor designed using the CST microwave studio as depicted in the Fig. 1 (a). The Floquet theorem has been utilized in order to develop periodic structures followed by periodic boundary conditions (PBCs). Figs. 1(b) and 1 (c) sketches the square patch and square aperture geometries and corresponding design variables, where grey region represents the conductive surface of the copper.

(a) (b)

Figure 2. RL characteristics of MMSs (a) square patch and square aperture geometries based MMSs and (b). Resistive element loaded FSS based MMS.

The RL values for square patch and square aperture geometries based MMSs is shown in the Figure 2 (a). It has been observed that the peak RL value of the square patch (a=b= 4.0 mm) is -11.543 dB at 12.3 GHz. While, the square aperture (a =8.0 mm, b=1.0 mm) based MMS possess a peak RL value of -6.1 dB at 17.3 GHz. The RL characteristics of patch geometry are comparatively better than aperture geometries, however the results are not as per the expectations as far as the wide bandwidth is considered. The resistive lumped circuit elements play an active role in order to provide good absorption [3]. Based on analysis reported by Ghosh et al. [3], the lumped resistive elements have been incorporated with FSSs to improve the bandwidth of aperture square based MMS. Figure 2 (b) depicts a square aperture FSS geometry loaded with resistive circuit elements and corresponding RL characteristics. The optimal design variables are p=12.5 mm, d= 8.0 mm, w= 1.25 mm, R_c =100 Ω, g= 1.2 mm. A critical analysis has been carried out to examine the effect of dielectric thickness and resistance value over absorption properties of MMS. An optimal MMS has been found to provide a peak RL value of -31.7 dB at 9.4 GHz in the range of 2.0 to 18 GHz. Most importantly, the MMS has been found to possess a wide absorption bandwidth of 5.5 GHz in the range of 10.6 GHz to 5.1 GHz. The obtained results clearly reflect the effectiveness of designed MMS for distinct commercial applications.

Abstract

A new tri-band perfect meta-surface absorber based on square shaped metallic resonator, where the circular rings are in the middle of the resonator is investigated in this paper. The proposed absorber structure shows a wide bandwidth and applicable for C-, X- and Ku-band application. Due to the effective medium ratio 6.48 absorber structure compact in size and shows three absorption peaks are 82%, 67%, and 93% respectively in 6.22, 8.76, and 13.05 GHz. In addition, the lumped element model based equivalent circuit has been designed, where for calculation the resonance point, total inductance and capacitance formulas are also developed. In the circuit model the inductance is formed by the metal strips and gaps or splits are induced the capacitance. Besides, the proposed meta-surface absorber structure also exhibits left handed characteristics from 9.10 to 11.34 GHz and the surface impedance is -443.14-158.06j.

1. Introduction

Electromagnetic meta-surfaces are composed of artificial atoms, whose electric and magnetic response could be flexibly tailored to meet desired macroscopic properties. Benefiting from these novel properties, meta-surface absorbers have produced many exotic effects, such as negative refraction, negative permeability, sub-wavelength imaging super-lens, antenna performance enhancing, SAR reduction, and invisible cloaking. The development of the perfect meta-surface absorber utilizes the intrinsic loss of the system, with the help of structural design, to obtain near unity or perfect absorption at a certain frequency. Because of many advantages over the conventional ones, such as ultra-thin dielectric layer thickness, high absorption coefficient, and simple unit design, the research on meta-surface absorbers is in full swing. Perfect meta-surface absorbers have been broad applications in the fields of microwave, terahertz, infrared, and optical frequencies. In spite of high absorption of meta-surface absorbers, the absorption bandwidth of meta-surface absorber is often narrow, i.e., typically no larger than 10% with respect to the central frequency. Few reviewed on the meta-surface and meta-surface absorber have been reported in this paper. In 1996, Pendry et al. anticipated the negative permittivity from thin wire configuration and in 1999 negative permeability from split ring resonator [1]. In 2000, Smith et al. introduced a material that shown simultaneously negative permittivity and permeability with some exceptional properties at microwave frequency [2]. In 2008, N. I. Landy and a group of scientists from Boston College first demonstrated a microwave metamaterial absorber by using a classic sandwiched structure composed of a split ring resonator, a dielectric substrate, and a metallic cut wire. They generate electric and magnetic resonances that were independently manipulated for effective permittivity and permeability, respectively and the absorption of 88% at 11.50 GHz [3]. In 2016, Hasan et al. proposed a z-shaped double negative metamaterial for wide band applications. The 10×10 mm^2 structure metamaterial unit cell was applicable for C- and X-band operations [4]. In 2016, a compact square split z-shape metamaterial with left handed meta-atom for S-, C-, X- and Ku-band application and had 5.67 GHz wide bandwidth. The compact meta-atom had effective medium ratio of 9.10 and exhibited left handed characteristics in 8.50 GHz [5]. A wearable metamaterial microwave absorber (WMMA) for indoor radar clear applications was proposed for dual resonances in 9.0 and 9.8 GHz. The proposed WMMA was composed of two square ring resonators with different sizes, a backing ground plane, and a felt substrate with a 1.0 mm thickness. The grid array of different square ring resonators provided two broad absorptivity peaks greater than 90% due to the polarization angle of the electromagnetic waves and deformation effect as well as a full width at half maximum (FWHM) of 18.9% in 9.48 GHz [6]. In [7] a multi band split S-shape metamaterial was suggested for absorption analyses, which shown resonances in S-, X- and Ku-band in microwave frequency. The absorption spectra for the proposed absorber was 45% achieved at S-band. Moreover, after reducing the coupling capacitance in the z-axis absorption was reached up to 55% but in the y-axis absorption was extended up to 47%. Besides the absorption the proposed metamaterial could be used for various applications like, near zero refractive index, epsilon negative, mu negative, and double negative application. An ultra-thin polarisation-insensitive metamaterial structure has variable absorption bandwidth, which composed of three different cross-dipole-shaped metallic patches and each of which is printed on a very thin dielectric substrate where the ground was metal plane. The designed absorber displayed high absorptions (<80%) up to 45° incident angle for both TE and TM polarisation [8]. A microwave metamaterial absorber was designed that resonance at C-, X- and Ku-band with double negative characteristics as well as the absorption peaks were respectively, 82%, 67%, and 93% at 6.22, 8.76, and 13.05

GHz in [9]. An infrared dual-band metamaterial absorber consisted of a cross resonator ringed by four split-ring resonators spaced a distance above a gold ground plane with a dielectric layer of SiO_2 and exhibited two absorption peaks of 90.3% and 88.4% respectively at 4.17 μm and 4.86 μm [10]. An octave bandwidth metamaterial absorber structure consisted of geometrical patches placed diagonally on the top surface of the structure. The structure had a large bandwidth from 6.86 to 15.16 GHz, covering the entire X-band with absorptivity <90%. In addition, the peak absorptivity of 97.4%, 99.9%, and 97.8% had been observed respectively in 7.24, 10.18, and 14.32 GHz. Moreover, the structure was sensitive to polarisation of the incident field exhibiting maximum absorption at 0° and 90° with no absorption taking place at 45° angle of polarisation [11]. A graphene based terahertz absorber consisted of a single layer periodically arranged grapheme electric resonant and the ground plane was spaced out by SiO_2 dielectric layer. The designed graphene based structure displayed absorption of 99% at 35 μm and 97% at 59 μm [12]. In [13] frequency selective surface metamaterial absorber structures based on resonators like, omega, plus, cross shapes with and without a rectangular frame printed on the dielectric materials were presented and investigated for both microwave and terahertz frequency. In case of structure 1, in 4.0 and 5.60 GHz the simulated and measured absorptions were respectively 99%, 84% and 99%, 79%. Structure 2 displayed simulation absorption of 99.69% around 10 GHz in microwave frequency range. In addition, structure 3 exhibited maximum absorption of 99.78% and 98.80% respectively at 10.66 and 11.23 GHz for the simulation. Further, three different resonances occur at around 8.82, 9.95, and 10.91 GHz and the absorption in those resonance peaks were respectively 74.86%, 99.34%, and 88.86% for the structure 4. Moreover, for terahertz range lowest absorption was around 0.83 THz as 97.14% for 120° and the highest absorption almost 0.88 THz as 99.98% for 60° for structure 5. Besides, structure 6 shown lowest absorption in 1.05 THz as 46.95% for 60° and highest absorption in 0.99 THz as 99.98% for 90°. Besides, it had seen that the structure 6 provided good absorption for 0°, 120°, and 150° with the absorptions of 88.11%, 98.07%, and 87.22% respectively.

A left handed meta-surface absorber is presented in this paper, which consists of square ring resonator with the inner circular ring. The finite integration technique based CST microwave studio electromagnetic simulator has been used for achieving the reflection and transmission parameters. The measured and simulated results are well compiled together, where the measured transmittance resonance are in5.14 GHz (C-band), 7.29 GHz (C-band), 11.83 GHz (X-band), and 16.34 GHz (Ku-band) and the simulated resonance are in 5.35 GHz (C-band), 7.29 GHz (C-band), 11.85 GHz (X-band), and 16.45 GHz (Ku-band). The designed meta-surface compact in size, where the effective medium ratio is 6.48 and the absorption in 6.22 GHz is 82%, 8.76 GHz is 67%, and 13.05 GHz is 93%. Besides, left handed characteristics are shown from 9.10 to 11.34 GHz for any frequency points in that frequency range.

2. Meta-surface Absorber Design

Meta-surface structure operates like a lumped resonant circuit, which can be formed by incorporating inductive and capacitive effect by using the magnetic structures. This inductive and capacitive effect can be produced by adopting printed metallic stripe and gap between the stripes. The length of the metal strip is responsible for creating inductive effect and the spilt between the stripes is responsible for capacitive effect. By increasing the length of the metal line, inductance can be increased and by varying the gap, capacitance can be controlled. Consequently, by increasing the inductance, the effective medium ratio can be improved and this can be achieved as well by lowering the gap between the stripes. These lumped resonant elements has various advantages compared to the traditional microwave absorbers such as supplementary miniaturization, wider adaptability and increased effectiveness. The proposed absorber structure is consisting of a square shaped metallic resonator, where the circular rings are in the middle of the resonator. Meta-surface is usually designed on dielectric substrate material. The thickness and dielectric constant has effects on the properties of meta-surface. Thickness is more important when resonators are etched at the both side of the dielectric slab. Substrate material with high thickness cause low dielectric constant. Similarly, Substrate materials with low dielectric constant produce low bandwidth at higher frequency region. The metallic structure of the proposed meta-surface is designed on a FR-4 dielectric material, which has dielectric constant of 4.50, tangent loss of 0.002 and the thickness of 1.60 mm shown in figure 1(a) and the fabricated array structure in figure 1(b). Copper is used as a resonator on the dielectric substrate with an electrical conductivity of $\sigma=5\times8$ s/m. Moreover, the optimized geometry dimension parameters of the proposed absorber single unit cell are given in table 1 with the detail specifications.

Table 1: Specification of the tri-band meta-surface absorber.

Design parameters	Size (mm)	Design parameters	Size (mm)
Length of the substrate, A	9.0	Radius of outer circle, r1	3.0
Width of the substrate, B	9.0	Radius of inner circle, r2	2.25
Length of the outer RR, L1	8.5	Length of inner metal line, P	3.0
Width of the outer RR, W1	8.5	Length of inner metal line, q	3.0
Length of the inner RR, L2	7.5	Width of the metal strip, d	0.5
Width of the inner RR, W2	7.5	Gap between the rings, g	0.25

3. Methodology and Measurement Set-up

Electromagnetic simulation helps evaluating the fundamental field quantities from Maxwell's equation adopting some numerical technique. In this research, finite integration technique is adopted for numerical analysis. This is a spatial discretization method to solve electromagnetic field problems numerically in frequency domain. The technique provides high flexibility in complex geometric structure modelling as well as boundary handling. Periodic boundary conditions are applied for simulation. Moreover, two converse boundaries are connected here with a perceptible phase shift in such a way that the simulation process is forwarded periodically in the relevant direction. The PEMC boundary condition is the generalization of perfect electric and perfect magnetic boundary. Perfect electrical boundary condition is applied along the *x*-axis, and a perfect magnetic boundary is applied along *y*-axis as well as electromagnetic waves are excited the absorber along the z-axis. However, the permittivity, permeability and refractive index are retrieval by the following procedure [14],

$$S_{11} \approx \left\{ \frac{R_1\left(1-e^{j2nk_0d}\right)}{1-R_1^2e^{j2nk_0d}} \right\} and, S_{21} \approx \left\{ \frac{\left(1-R_1^2\right)e^{j2nk_0d}}{1-R_1^2e^{j2nk_0d}} \right\} \quad 1$$

$$e^{j2nk_0d} \approx T \pm j\sqrt{(1-T^2)}, T = \left\{ \frac{1-S_{11}^2+S_{21}^2}{2S_{21}} \right\} \quad 2$$

$$k_0 \approx \frac{2\pi f}{c} and, Z \approx \pm\sqrt{\frac{\left(1+S_{11}\right)^2+S_{21}^2}{\left(1-S_{11}\right)^2+S_{21}^2}} \quad 3$$

$$Refractive\ index,\ \eta_r \approx \frac{2}{jkd}\sqrt{\left\{ \frac{\left(S_{21}-1\right)^2-S_{11}^2}{\left(S_{21}+1\right)^2-S_{11}^2} \right\}} \quad 4$$

$$Permittivity, \varepsilon_r \approx \left(n_r \middle/ Z \right) \quad 5$$

$$Permeability, \mu_r \approx \left(n_r \times Z \right) \quad 6$$

In the equivalent lumped circuit based on the combination of inductors and capacitors both in parallel is shown in figure 2. In the circuit model inductors are included for the metal strips and a capacitor for the strip gaps or splits. The capacitors located in the circuit maintained the raise of total inductance, similarly inductors are minimized the raise of total capacitance in the circuit for fixing the resonance peaks. However, with the change of geometric structure of the proposed structure the inductance and capacitance will be varied and change the resonance peaks but the resonance band will be similar like before changing structure [5, 15]. So, the total inductance and capacitance of the designed structure can be figure out by the developed equation (7-9),

$$L_T \approx \mu_0 t^2 \left\{ \frac{\left(L_2+g-q\right)^2}{\left(2t^2+\pi d^2\right)} + \frac{\sqrt{A^2+B^2-L_1^2}}{\sqrt{r_1^2+r_2^2-P^2}} \right\} \quad 7$$

$$C_T \approx \varepsilon_0 \left[\frac{\pi\left(L_1+W_1-P\right)}{2\left(P+q+t\right)} \ln\left(\frac{L_2+W_2-d}{r_1+r_2} \right) \right] \quad 8$$

$$f_r = \frac{1}{2\pi\sqrt{L_TC_T}} \quad 9$$

$$Equivalent\ Impedance,\ Z_{eq} \approx \left(\frac{1}{C_{eq} + 1 \middle/ L_{eq}} \right) \quad 10$$

where '*d*' is the thickness of the substrate, '*Z*' is the normalize impedance, 'k_0' is the wave vector, '*c*' is the velocity of light. In addition, the free-space permeability is $4\pi\times10^{-7}$ H/m and the permittivity is 8.85×10^{-12} F/m. The EM-waves incident on the meta-surface absorber and the absorption response of the meta-surface structure described by transmittance $T(\omega)$ and reflectance $R(\omega)$ which are frequency dependent quantities can be calculated from,

$$Absorption, A(\omega) \approx \left[1-R(\omega)-T(\omega)\right] \quad 11$$

Reflectance and transmittance rate on the other hand depend on the scattering parameters, $R(\omega)= S_{11}^2$ and $T(\omega)= S_{21}^2$ which are given at bottom,

$$S_{11} = \frac{\sqrt{Reflected\ Power}}{\sqrt{Incident\ Power}} \text{ and } S_{21} = \frac{\sqrt{Transmitted\ Power}}{\sqrt{Incident\ Power}}$$

In order to optimize the absorptivity of the proposed structure reflection and transmission coefficients must be minimized to obtain minimum feasible values. However, the absorption of the designed mwta0surface absorber is obtained by,

$$Absorption, A(\omega) \approx \left[1 - |S_{11}|^2 - |S_{21}|^2\right] \quad 12$$

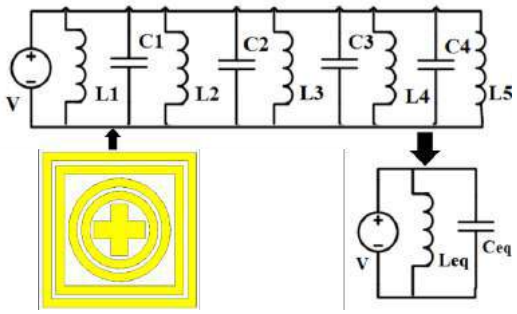

Figure 2. Equvalent lumped circuit model of the proposed meta-surface absorber.

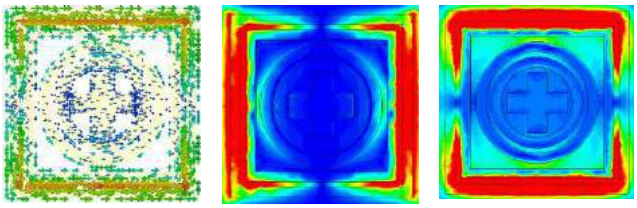
In order to check the accuracy of the simulations, experimental study is also performed. The free space measurements are obtained by using two horn antennas. Antennas are placed far enough from each other to provide far-field conditions. Since the backward side of the structure is covered by a metal, there will be no transmission. Therefore, only the reflection measurements are carried out to evaluate the absorption coefficient. To verify the results, the simulation and measurement results of the absorption coefficient are plotted on the same graph as shown in figure 4(d) to compare them with each other. The measurements are carried out without connecting resistive loads by using an Agilent N5227A vector network analyser and two linearly polarized microwave horn antennas. The VNA supplies frequency range from 2.0 to 18.0 GHz and used to obtain the reflection (S_{11}) and transmission (S_{21}) coefficients to calculate the effective medium parameters.

4. Result Analysis of the Meta-Surface Absorber

The design absorber shows left handed characteristics with high absorption peak due to the electric and magnetic resonance by the inductive and capacitive element. This phenomenon can be explained with the help of surface current density, electric field and magnetic field pattern shown in the figure 3 (a-c). Electric field distribution shows charge accumulation on the oppositely facing strips and indicates capacitive effect. When external magnetic field is applied along the axis of the ring under the effect of the magnetic induction the current to flow in each half of the ring. This current lags with respect to the external magnetic field thereby giving a strong magnetic response. Besides, the flow of current at opposite direction causes the stop band and the colour and arrows indicates the intensity and direction of current flow.



(a) (b) (c)

Figure 3. (a) Surface current distribution, (b) Electric field, (c) Magnetic field, of the proposed meta-surface absorber single unit cell in 5.14 GHz.

The absorber shows tri-band resonance, where the measured exhibited good arrangement with the simulated results in figure 4(a). The figure shows the simulated resonance in 5.35 GHz (C-band), 7.29 GHz (C-band), 11.85 GHz (X-band), and 16.45 GHz (Ku-band), whereas the measured resonances in 5.14 GHz (C-band), 7.29 GHz (C-band), 11.83 GHz (X-band), and 16.34 GHz (Ku-band). The measured resonance peaks in 5.14 GHz, 7.29 GHz, 11.83 GHz, and 16.34 GHz are slightly shifted from the simulated results due to the fabrication tolerance and environmental inferences. In figure 4(b), the effective medium parameters represent the left handed characteristics. The permittivity shows the real value of negative portion from 3.39 to 5.97 GHz, 6.37 to 7.76 GHz, and 8.75 to 11.34 GHz, which covers the bandwidth of 2.58 GHz, 1.39 GHz, and 2.59 GHz. In addition, in case of permeability negative curve from 9.10 to 18.0 GHz. Moreover, it shows that there is variation between the curves of permittivity and permeability due to the polarization effect of the interior construction of the materials. However, the refractive index shows negative real regime from 2.94 to 5.04 GHz, 9.20 to 13.91 GHz, and 16.30 to 18.0 GHz. As we know, when the both real part of permeability and permittivity go to the frequency area with negative value, which indicates the properties of left handed or double negative. From figure 4(b), the negative regime from 9.10 to 11.34 GHz, the effective medium parameters, i.e. permittivity, permeability and refractive index all are negative. As a result, the proposed perfect meta-surface absorber structure can be characterised as left handed for any frequency point from 9.10 to 11.34 GHz frequency range. Such as, in 9.26 GHz the real values of the permittivity, permeability and refractive index are respectively, -10.70, -194.79, and -45.65. From figurer 4(c) the reactance or surface impedance is -443.14-158.06j in 9.15 GHz. The absorption of the designed absorber is figure out from the equation (11). The absorption the proposed absorber at reflection (S_{11}) resonance point are 82% at 6.22 GHz, 67%8.76 GHz, and 93% at 13.05 GHz shown in figure 4(d). The absorption value is obtained from the reflection value by using the absorption equation. It should also be stated that the frequency range is high enough to be affected by small quality. Therefore, the proposed meta-surface absorber based having a high absorption level and a wide bandwidth

nature can be a good candidate for absorbing and future energy harvesting applications in communication bands.

5. Conclusion

In summary, the absorption characteristics of a novel multi band meta-surface absorber based harvester has been designed, investigated, fabricated, and experimentally verified in this paper. Both numerically and experimentally results are well complied. Measured results show three absorption peaks and the absorption is greater than 93%. Distributions of the electric and magnetic fields are investigated to gain a better understanding of the resonance mechanism. Moreover, the lumped circuit model has been designed to calculate the resonance peaks by the developed total inductance and capacitance formulas. However, compared with the previous studies, the proposed meta-surface absorber has some significant advantages: such as compact unit size, resonance mechanism, and high absorption. Finally, due to the above advantages the proposed absorber structure makes it a good candidate in absorption, detection, sensing, imaging, and so on.

Singularity Points in Acoustic Metamaterials: Physics and Applications

Acoustic Energy Harvesting Based on Metamaterials and Metasurfaces

Abstract-Acoustic energy harvesting based on acoustic metamaterials and metasurfaces are proposed and investigated. The proposed concepts are based on the idea of using plate-type metamaterial and multilateral metasurface to confine the acoustic energy, and subsequently convert it into the electrical one by a structured piezoelectric material connecting with optimized circuits. The properties of proposed acoustic energy harvesters will be presented and discussed.

As a kind of clean, ubiquitous and renewable form of energy, sound/noise may act as a promising sustainable power source for energy production and micro autonomous devices, such as wireless sensors, mobile electronics and so forth. Due to low power densities in ordinary surroundings, sound/noise generally needs to be focused or confined through effective conversion media for better acoustic energy harvesting (AEH). Intuitively, classical Helmholtz and other chamber resonators could be used to enhance the acoustic confinement and subsequently realize AEH. In general, the strategy based on the resonators suffers from defect of the bulky structures and uncontrolled wave field, thus hampering the applicable energy harvesting. In a different context, the recent emergence of the artificially engineered acoustic metamaterials and metasurfaces has significantly broadened the horizon of acoustic wave and wavefront manipulations. They possess a variety of advantageous and anomalous properties and capabilities.

In this research, we theoretically and numerically report on innovative and practical acoustic energy harvesters based on acoustic metamaterials and metasurfaces [1, 2]. The ideas of AEH and acoustic confinement with the acoustic metamaterials metasurfaces will be demonstrated and analyzed. More specifically, we will present here some recent works and advances on acoustic energy harvesting making use of a defected plate-type metamaterial and a multilateral metasurface based on the coiling up space geometry. Different concepts and designs of the AEH will be presented and discussed as well as and their physical and electrical properties.

Abstract-Here, we report a novel soft acoustic metamaterial with tunable topological phase by applied mechanical deformation. Harnessing deformation Dirac point in our acoustic system can be switched on and off, resulting in energy band inversion. Our finding offers a new approach to generate an interface state at topological domain wall. Besides, the frequency of interface state can also be tuned continuously. Importantly, we provide a general topological phase diagram to design desired tunable topological state by deforming soft acoustic metamaterials.

Acoustic metamaterials are useful in controlling sound waves in the way that does not exhibit in nature, with practical applications in noise reduction and wave guiding technologies. Particularly, recent study on phononic periodic system in view of topological order has drawn increased attention such as phononic analogue of quantum spin Hall effect(QSHE)[1]. Elastic wave, also known as small elastic oscillation in solid, is that motion occurs in a deformed body. It has special advantages in information carrying, seismic detection and geologic prospecting[3]. Due to the nature of low frequency elastic waves, which attenuate more slowly and propagate more stable than high frequency ones, long-wavelength elastic waves play a significant role in information processing. Thanks to the development of advanced fabrication technique, elastically anisotropic and isotropic materials, elastic properties varying from direction, can be fabricated successfully. Nonetheless, a common feature of most such materials is having a fixed geometry, resulting in fixed properties of a system. Thus, soft materials and structures associated with mechanics capable of configuring its global and partial geometry are introduced to tune the functionality of a system[2]. Here, we achieve a dynamically tunable topological elastic metamaterial realized by soft materials. By harnessing deformation, the topological property of our elastic system can be switched. And the interface state can be generated at the boundary separating two elastic metamaterials that are placed at different geometry states respectively, corresponding to opposite style of symmetry in reciprocal space. Finally, we offer a general topological phase diagram to design desired interface state. This strategy gives us possibility to realize and then control topological interface state both statically and dynamically. Note that in our study we only focus on unit cell of millimeter scale, the proposed design can be more complex and has various scales depending on the phonon frequency. The ability to dynamically control interface state in soft materials may be used in other smaller or larger phononic system such as thermal management and help to develop flexible acoustic devices. The interesting phenomenon of robust topological sound wave propagation in soft

materials, which is tuned by mechanical deformation, may have potential applications in military and communication field.

Abstract. Acoustic metamaterial is extremely attractive due to its unprecedented manipulating properties of acoustic wave. Here we proposed a fiber-beads metamembrane that can cause π phase shift and maintain a 0.9 transmittance with 1/250 lambda thickness at low frequency range. Based on this, we construct a binary metalens with different arrangement modes, which can manipulate the diversity of sound and realize focusing. Meanwhile, our work lay the foundation for the following research about transformation acoustics and so on.

Advanced materials with deep-subwavelength thickness as well as unprecedented controls of propagation of acoustic wave have been vigorously pursued for broad applications such as negative refraction[1]. Popular approach is to manipulate the characteristics of the materials and further adjust the reflection or transmission phase. In this context, emerging acoustic metamaterials are fabricated artificially to achieve some novel properties that don't exist in natural constitutive materials[2]. Common acoustic metamaterial has been designed based on local resonance theory[3]. However, most LC resonant devices even like DMR[4] are not thin enough so as to limiting their application in more scenarios. Here, we report an ultrathin fiber-beads membrane that causes a π phase shift with 90% transmittance at low frequency range. It's worth mentioning that the thickness of membrane reaches to a deep subwavelength scale, as thin as 1/250 λ of the feature size, which is a significant advance compared with previous work[4,5]. Our fiber-beads membrane is inspired by a conventional spring-mass resonator principle: soft polymer fiber embedded with hard beads forms 3-dimensional network membrane. On this basis, unprecedented controls of acoustic wave can be achieved just by manipulating the amplitude and phase of acoustic wavelets at every point in the plane that is perpendicular to incident direction. Moreover, we build a metalens with our membranes to manipulate the directivity of sound and then shift the energy of incident wave to the surrounding, which can be used to reduce far-filed sound intensity or applied to other field requiring specific diversity of sound.

Abstract-We report novel strategies to study topologically protected states in nanophononic systems working at frequencies around 300 GHz. We theoretically predict the existence of such modes in multilayer GaAs/AlAs structures. High resolution Raman scattering unveils features related to the maxima in the phononic local density of states associated to topologically protected states.

A nanophononic cavity shapes the local phononic density of states and can dramatically modify the interactions between mechanical vibrations and other excitations in solids.[1,2] It usually consists of two distributed Bragg reflectors (DBR) enclosing an acoustic spacer. A DBR inherits the topological properties of the associated infinite periodic structure -symmetries and characteristic energies- determining the confinement properties of an acoustic cavity. Despite the obvious relation between the acoustic bandgap structure and the performance of the DBRs, the study of topological states in nanophononic systems remained unexplored.

In this work, we report two novel design strategies for the study of topological states of longitudinal acoustic phonons with frequencies around 300 GHz. In the first approach we concatenate two GaAs/AlAs DBRs presenting inverted band structures for a given gap to create an interface state.[3,4] We study the influence of the choice of unit cell and different interface configurations on the confinement characteristics of these states. In the second approach we mimic the SSH model of polyacetylene[5] by means of a nanophononic multilayered system. We demonstrate the existence of topologically protected nanophononic states. We also discuss the potential application of these novel design strategies into 3D structures.

We have fabricated nanocavities allowing the confinement of phonons based on the aforementioned ideas. We performed high resolution Raman scattering measurements at room temperature.[6] Clear features related to the maxima of the acoustic density of states were measured and reproduced by photoelastic model calculations. The presented results open a new playground in the control of acoustic vibrations in solids, providing new tools not only to confine and control the dynamics of ultra-high frequency phonons but also a new platform to study topological and general localization effects.

Topological Distinction of Single Negative Metamaterials: from Phononics to Acoustics

Weiwei Zhu[1],Shanshan Hou,[1] Hong Chen,[1]and Jie Ren[1,2]

[1] School of Physics Science and Engineering, Tongji University, 200092 Shanghai, P. R. China
[2] Center for Phononics and Thermal Energy Science, The Institute for Advanced Study, Tongji University, 200092 Shanghai, P. R. China

Topological insulators are new class of states, which are insulating in the bulk but conducting on their surface, protected from the disorder. Similar effects are extended to photonic/micro-wave systems, and so on. In this work, we use a simple circuit model unifies all the different physics of different systems, beyond electronics, ranging from phononics to acoustics, even to microwave photonics. We confirm from the topological band theory and further from continuous Dirac equation method that the single negative metamaterials are topologically distinct, eg., the ENG is topologically different from the MNG. We also analytically study and experimentally measure the reflection phase that is related to the Zak phase through bulk-boundary relation. We observe the field distribution of the interface state, the same as the relativistic Jackiw-Rebby topological solution. The analytical result of the circuit model has a good agreement with the experimental results based on microwave photonics, which however is universal to phononics and acoustics.

Singularity point applications of acoustic vortices

Abstract-Single singularity point in water has been yielded by integer-order acoustic vortices, which can be used to trap, move and rotate a single particle or particle cluster. Multiple singularity points in water have been created by generating fractional-order acoustic vortices or superposing two or more first-order acoustic vortices, which can be used to manipulate two or more particles at the same time. Moreover, singularity points of acoustic vortices in air are able to levitate and rotate diverse objects.

Abstract— We demonstrate a laser-written photonic lattice exhibiting topologically-protected Weyl point degeneracies in its three-dimensional band structure. Probing the lattice at various wavelengths, we observe topological surface modes and conical diffraction characteristic of an anisotropic "type-II" Weyl point. This constitutes the first realization of a photonic Weyl point at optical frequencies, allowing further study of their novel properties in a wide class of linear and nonlinear photonic systems.

In three dimensional band structures Weyl points are degeneracies that form monopoles of Berry curvature protected by a quantized topological charge. This charge results in novel properties such as arcs of robust surface modes and chiral anomalies [1, 2]. Two different types of Weyl points can occur, depending on the anisotropy of the system. At a "type-I" Weyl point the density of states vanishes, whereas the "type-II" Weyl point illustrated in Fig. 1(a) has a strongly anisotropic conical dispersion with a nonzero density of states at all frequencies [3, 4]. The former has been observed in photonics in microwave photonic crystals [5], however scaling to the important optical wavelength regime is a challenging task requiring the fabrication of complicated 3D structures with high refractive index contrast.

Here we report the observation of "type-II" Weyl points using the three-dimensional photonic lattice of evanescently coupled helical optical waveguides shown in Fig. 1(b). The waveguides are written in borosilicate glass using a femtosecond laser. Monochromatic light propagation along the waveguide axis z is governed by the paraxial equation

$$i\partial_z\psi = -\frac{1}{2k_0}\nabla_\perp^2\psi - \frac{k_0\delta n(x,y,z)}{n_0}\psi, \tag{1}$$

where ψ is the beam envelope slowly varying in z, $k_0 = 2\pi n_0/\lambda$ is the wavenumber, n_0 is the ambient refractive index, λ is the input wavelength, and δn is the refractive index modulation of the waveguides. The three dimensional photonic band structure associated with our periodic index modulation $\delta n(x, y, z)$ hosts a type-II Weyl point at a critical wavelength [6].

We probe the lattice at various wavelengths (1450–1650nm) and observe that the protected surface modes only exist above the Weyl point wavelength, i.e. they form arcs terminating at the Weyl point. Meanwhile, bulk propagation at the Weyl point generates a conical diffraction pattern characteristic of a type-II Weyl point's conical isofrequency surface, see Fig. 1(c). These experimental observations are the first demonstration of a Weyl point at optical wavelengths, and the first realization of a type-II Weyl point in photonics. In future it would be interesting to explore other linear, nonlinear, and quantum propagation dynamics in this class of lattices [7].

Abstract-Topological insulators have inspired analogues in acoustics, in which one-way gapless edge/surface states, featured with absence of scatterings, have been widely achieved via synthetic magnetic field or pseudo-spins. Varied mechanisms to realize topologically protected sound transportation have been realized, as characterized by Chern number, Z2 number as well as winding number. We present that topological phases can be tuned into trivial phases by distorting the geometry of 1D Helmholtz resonator chain or breaking the inherent symmetry of 2D resonator/cylinder array.

Abstract- We demonstrate that generalized Weyl points can exist in a parameter space and we report the first observation of such nodal points in one-dimensional photonic crystals in the optical range. The reflection phase inside the band gap of a truncated photonic crystal exhibits vortexes in the parameter space where the Weyl points are defined and they share the same topological charges as the Weyl points.

Great efforts have been devoted to investigating the intriguing phenomena associated with Weyl points[1-3], such as the Fermi arc surface states[4,5] and the chiral anomaly[2] associated with electronic systems. Besides electronic systems, Weyl points have also been found in photonic [6-9], and plasmonic[10] systems. Up to now, Weyl points have mostly been identified as momentum space magnetic monopoles, i.e. sources or sinks of Berry curvature defined in the momentum space. As such, Weyl points are usually perceived as topological nodal points in the 3D momentum space defined by Bloch momentum coordinates. We show that topological nodal points can in fact also be meaningfully defined in a generalized phase space in which some of the dimensions are not Bloch momentum, and yet their topological characteristics make them analogues of Fermi-arc-like interface states in much the same way that ordinary Weyl points are defined in the 3D k-space. We use photonic crystals (PCs) to realize the idea of generalized Weyl points experimentally in the optical frequency regime.

To illustrate the idea of synthetic Weyl points in a generalized parameter space, we consider a 1D PC consisting of four layers per unit cell, as shown in the inset in Fig. 1a. In our experiments, the first and third layers (blue) are made of H_fO_2 with refractive index n_a=2.00, and the second and fourth layers (red) are made of S_iO_2 with refractive index n_b=1.45. where p and q both fall within [-1,1]. The total optical length L inside the unit cell is a constant $2(n_a d_a + n_b d_b)$ for the whole p-q space. As illustrated in Fig. 1a, the structural parameters p and q, together with one Bloch wave vector k, form a 3D parameter space in which Weyl physics can be studied. The band dispersion is plotted in Fig. 1b in red. Fig. 1c shows the band dispersions in the p-q space with $k = 0.5k_0$, where $k_0 = \pi/(d_a + d_b)$. To characterize this degenerate point, we derive an effective Hamiltonian for parameters around it:

$$H = pv_{pz}\sigma_z + qv_{qy}\sigma_y + \xi_k v_{kx}\sigma_x \quad (1)$$

where $\xi_k = (k - 0.5k_0)/k_0$, $v_{pz} = 0.1073$, $v_{qy} = -0.0946$ and $v_{kx} = -1.985$ for our system. This Hamiltonian possesses a standard Weyl Hamiltonian form and with the Weyl node located at $(p,q,k) = (0,0,0.5k_0)$ carrying a "charge" of -1 according to the usual definition. If we consider the Weyl points on the fourth and fifth bands. There are a total of eight Weyl points: six with charge -1 and the remaining two with charge +1. We then set the working frequency to the frequency of the Weyl point with a positive charge (303THz) and truncate the PCs at the center of the first layer. In Fig. 4a, we show the reflection phase in the parameter space, where gray areas within black dashed lines mark the regions of the bulk band. The reflection phase of the silver film coated is measured to be $(-0.95 \pm 0.0471)\pi$ at 303THz. White dashed lines in Fig. 2a show the trajectories of interface states. In addition to

interface states connecting Weyl points with different charges, there are also trajectories of interface states terminating at the boundary of our parameter space. We emphasize here that the existence of interface states is "robust" to the property of the reflecting substrates: we can always find trajectories of interface states that link the two Weyl points with opposite charges no matter what the reflecting substrate is.

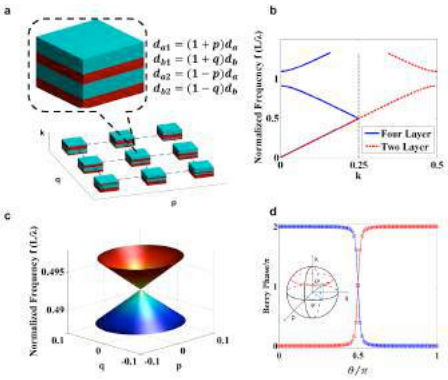

Fig. 1 **(a)** Photonic crystals (PCs) with different p, q values. (b) The band dispersion of PCs with different unit cells. **(c)** The dispersion of PCs in the p-q space with $k = 0.5k_0$. Here two bands form a conical intersection. **(d)** Berry phases defined on the spherical surface with a fixed θ (see the inset).

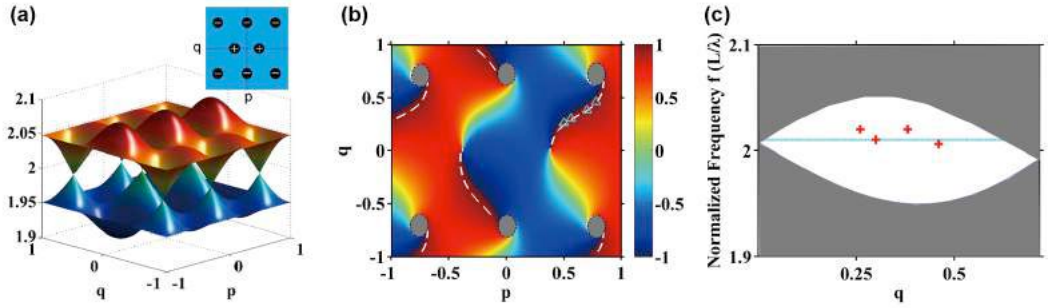

Fig. 2 (a) The band dispersions of band 4 and band 5 in the parameter space; (b) The reflection phase of the PCs at the frequency of Weyl points with charge +1. These interface state trajectories are analogues of Fermi arc states. The triangles mark the and values of the four samples in the experiment. (c) The cyan line indicates the working frequency used in a, and the red crosses label the experimental results.

Abstract-The intriguing concept of topological insulators has been transposed from condensed matter to optics/acoustics. However, these photonic/phononic topological insulators are inherently physically wavelength scaled. Here, we explain how structural modifications of locally resonant metamaterials, although deep-subwavelength scaled, also induce a topological phase transition. This experimental and numerical demonstration allows to envision applications benefiting the compactness of metamaterials and the amazing potential of topological insulators.

In this talk, we will show how going beyond the usual description of locally resonant metamaterials in terms of effective parameters allows to induce topological properties on a subwavelength scale[1]. Without any loss of generality, we take the particular case of quarter-wavelength-resonators in the microwave domain. First we show numerically that, thanks to multiple scattering[2], it is possible to engineer the band structure of a subwavelength scaled lattice of such resonators in order to obtain Dirac cones.

Then, following the previous work of Wu and Hu[3], we operate adiabatic subwavelength structural changes within the metamaterial. We show that these modifications lead to a phenomenon of band inversion which, added to the computation of the topological invariant, is a proof of the topological nature of the metamaterial crystals we designed. This band inversion is demonstrated both numerically and experimentally comparing the symmetries of the measured modes within the samples. This phenomenon is completely explained from a polaritonic point of view.

Moreover, the interface between media which present different topological behavior supports topological edge modes. Therefore we will show that this phenomenon occurs in the case of our subwavelength microwave topological insulator. We measure experimentally, and corroborate numerically, the propagation of subwavelength topological edge modes along the interface between two topologically different samples. This demonstrate the guiding of microwave on a subwavelength scale. We finally show that this work can be directly transposed to the acoustic domain[4].

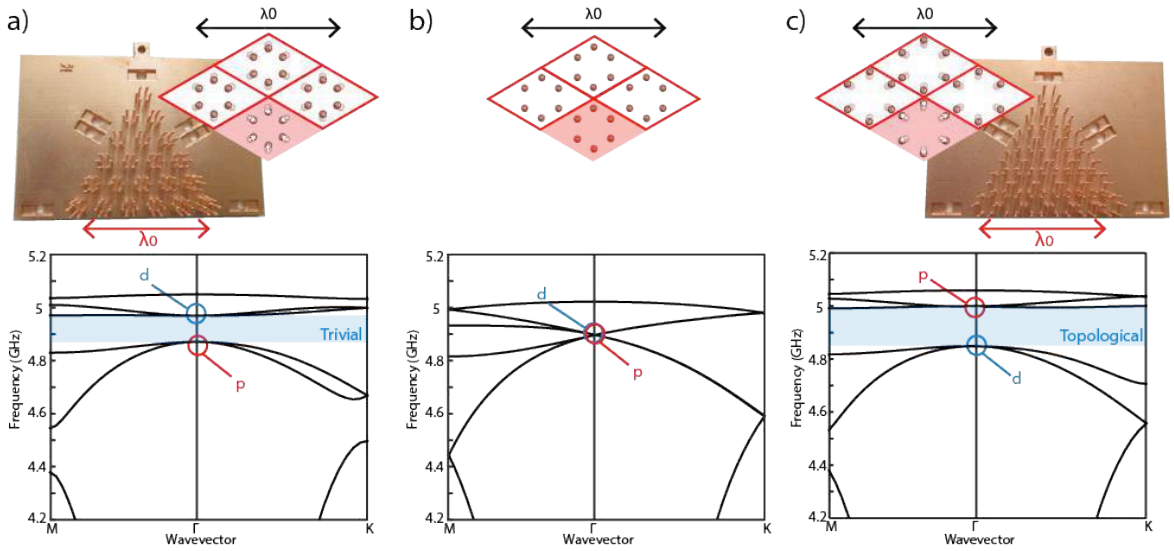

Fig. 1. Tailoring the deep-subwavelength structure of a honeycomb lattice of wires (b), we demonstrate that we can induce a topologically trivial (a) or non-trivial (c) bandgap.

Abstract-Photonic band topology in a dimerized chain is defined with the winding of pseudo spin along the Brillouin zone. However, no experiment has measured the winding process in any photonic system so far. Here we present the direct measurement of pseudo-spin winding in a dimerized designer-surface-plasmon chain.

Recently, many efforts are devoted to the measurement of photonic band topology in one-dimensional (1D) dimerized chain which relates to the winding of pseudo spin in the Brillouin zone [1, 2]. However, photonic pseudo spins, which can be represented by the in-phase and out-of-phase hybridized wavefunctions in a unit cell, are not easy to characterize in photonic structures [2]. Furthermore, sweeping the pseudo spin across the whole Brillouin zone, which requires physical realizations of tuning wavevectors k, is also difficult to implement in photonic structures. Therefore, it is very challenging to measure the winding of pseudo spins.

Designer-surface-plasmon structures, in which field patterns with phase information can be easily captured, shows promising potentiality to demonstrate the winding of photonic pseudo spins [3, 4, 5]. Based on this platform, tuning k is also feasible. Here, we present the direct measurement of windings of pseudo spins in a 1D designer-surface-plasmon dimer chain.

Abstract- The introduction of topology unravels a new chapter of physics, where photonic systems can also benefit from. Engineering locally in real space a honeycomb photonic crystal (PC) with double Dirac cone in its photonic dispersion, topology transition in photonic band structure is induced and a pseudospin unidirectional photonic channel is created and demonstrated by the backscattering immune electromagnetic transportation.

In electronic system, the intrinsically Kramers pair associated with electronic spin states is crucial for the helical edge states in quantum spin Hall effect with time-reversal symmetry (TRS). In order to realize topology protected electromagnetic propagations, a direction mapping of Kramers pair in photonic system is needed.

In this paper, the experimental demonstration of a unidirectional electromagnetic waveguide is conducted using dielectric PCs as previously theoretically schemed.[1] Hexagonal clusters of six neighboring dielectric rods are arranged in a triangular lattice (Fig. 1a). Two competing lengths exist in such a composite lattice (Fig. 1c & d): the intra couple distance h_1 defined as the distance between neighboring rods within the same cluster and the inter couple distance h_2 defined as the distance between the nearest rods in neighboring clusters. By tuning the ratio between h_1 and h_2, the original double Dirac cone photonic dispersion (Fig. 1b) can be engineered and PCs with inversed bulk band properties can be created.

Unidirectional backscattering immune photonic pathway forms at the interface between two PCs with inversed bulk bands and its wave propagation properties is characterized with proof-of-principle microwave experiments using dielectric materials. An antenna array is designed as the source of electromagnetic wave to mimic Kramers pairs in this photonic system with TRS. Direct experimental visualization of the unidirectional waveguide is achieved even in the frequency bands where the topological edge state is buried in bulk photonic band edges. As only dielectric materials with reasonable permittivity are adopted, the structure can be readily available at near-infrared or even optical wavelengths and the present design of topological PC will contribute to future optical communication technology.

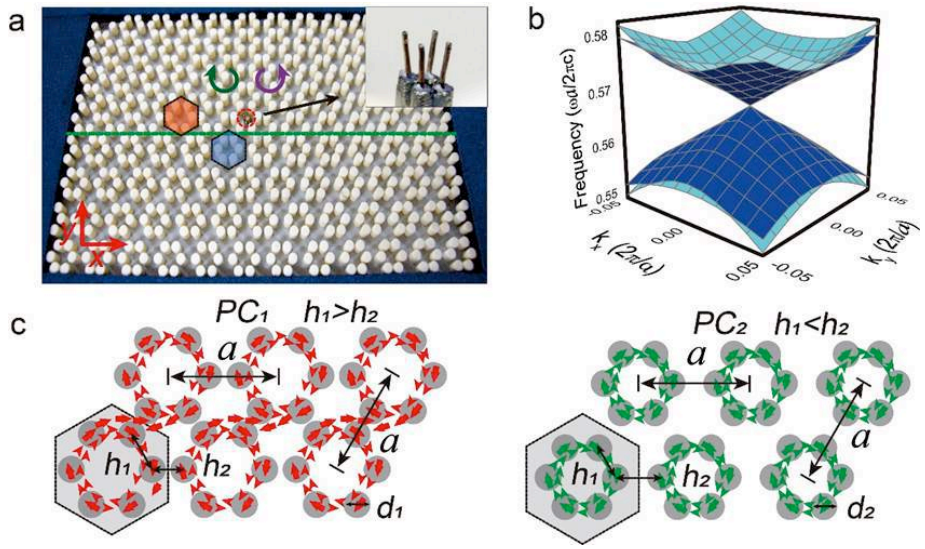

Fig. 1: (a) Experimental setup of dielectric PCs to realize unidirectional microwave propagation. (b) Double degenerate Dirac cone appears at the Brillion zone center of a honeycomb PC. (c) and (d): By tuning the ratio between intra couple distance h_1 and inter couple distance h_2, PCs with topological/trivial band diagrams can be created and unidirectional electromagnetic waveguide can thus be created at the interface between a topological PC and a trivial one.

Building Photonic Topological Insulators with Reconfigurable Multipost Re-Entrant Meta-Cavities

M. Goryachev[1*]**, and M. E. Tobar**[1]

Abstract-The concept of multiple post re-entrant metastructures scaling from a double post cavity to a lattice with nontrivial topological properties is considered. We demonstrate reconfigurable photonic analogues of topological insulators on a regular lattice of tunable posts in a re-entrant 3D lumped element type system. High post tunability allows dynamical in-situ change of media chirality and other properties via alteration of the same parameter for all posts. This provides great flexibility in choice of bulk/edge configurations. Also, one way photon transport without an external magnetic field is demonstrated.Applications in quantum hybrid systems and fundamental physics tests are be discussed.

Being a universal probe of the electromagnetic field, microwave cavities are important tools used in many areas of physics and engineering. In particular, they are employed in many experiments of Quantum Electrodynamics (QED) enhancing field-matter interaction and searches for fundamental particles, forces and symmetries such as Lorentz violating interactions and dark matter particles. The success in many of these areas is related to the ability to produce cavity-like structures with the given field geometries at given frequencies and possibility of *in-situ* reconfigurability. An interesting method to approach the cavity design problem comes from the field of photonic metamaterials. In particular, we will consider photonic meta-cavities built of multiple re-entrant posts.

A single post re-entrant resonator is a well known closed electromagnetic cavity that is widely used in accelerators and some other areas. It may be understood as a 3D version of a split-ring resonator with the rotation symmetry around the post centre. The post is characterized inductance around itself and capacitance in the gap underneath. Due to the high concentration of the electric field in the gap, the resonant frequency of the structure is highly turnable. A natural generalisation of the concept is introduction of several posts in the same closed cavity[1]. In such a case, a number of resonances equals a number of posts, and mutual orientation of post currents for every resonances gives a full control over the distribution of magnetic field inside the cavity. This idea was used to achieve strong and superstrong coupling with spins in solids for QED applications [2-4]. For system with a relatively large number of posts in such a meat-cavity, one can speak of mode bands of different polarisation with possible bandgaps between them that have been demonstrated both in one and two dimensions[1,5]. Moreover, it is possible to control these bands and having control over the gaps under the structure posts. Thus, it makes possible to introduce a concept of programable cavity arrays similar in spirit to the widely used programable gate arrays (FPGAs), where one my control frequencies and mode shapes over a large number of regular posts[5].

The post gaps and thus electromagnetic properties of re-entrant post meta-cavities can be controlled either mechanically or electronically. In the first case, the gap is changed by a piezoelectric actuator that is attached to the post or the opposite cavity wall. In the second case, a varactor diode is introduced between the post and the opposite wall and the equivalent electrical distance in the gap is controlled via the DC between them.

After demonstrating the band properties in closed multiple post meta-cavities, the further important step is to achieve topologically nontrivial phenomena. Unfortunately, each straight re-entrant post is a trivial object that os lumped in the cavity plane. On the other hand, instead of having a lattice of single posts, one may introduce an array of a group of closely positioned posts. Such a group may be understood as a ‘meta-molecule’ constituting the lattice and have non-trivial shapes in the cavity plane[6]. In particular, it is possible to introduce chirality for such an object, for example, through varying the post gaps in the clockwise or counter-clockwise direction across the molecule. Such method has an advantage of being reconfigurable *in-situ* through gap modification. Thus, it is possible to design a meta-cavity with reconfigurable chiral post objects that may compose a lattice with nontrivial topological properties.

To demonstrate nontrivial topological properties of multiple-post arrays, we consider a lattice of four post square molecules where the gap size changes clock-wise or counter-clockwise. Moreover, in order to make the

entire lattice as regular as possible, the inter-molecule spacing is set equal to the square size. This constitutes a regular array of posts where the molecules are distinguished only by gap variations. The system is modelled using both Hamiltonian eigenmode approach and full 3D electromagnetic modelling. We show that the system exhibits band gaps and edge modes in both 2D and 1D arrays. These modes arise on the boundary between lattices with different chirality. Additionally, one way photon transport without an external magnetic field is demonstrated. The ability to change configuration of the system in any spot gives an advantage of changing the system topology 'on the fly'. High localisation of edge modes together with its reconfigurability may be exploited to address certain areas of the system coupling to some small objects 'on-demand'. This is a vital property in the scope of QED where magnetic crystals or qubits should be strongly coupled to condition to some other signals. In other words, the concept implements multi-purpose random access systems, e.g. memories. The other possible applications inspired by the reconfigurability property is topological signal processing and sensing.

Towards copolymer self-assembly of photonic Weyl metamaterials

M. Fruchart and **V. Vitelli**

Leiden University, The Netherlands
fruchart (at) lorentz.leidenuniv.nl

Abstract— Block copolymers are soft materials made of different types of monomers glued together by covalent bonds. They self-assemble into highly structured phases which can replicate at the mesoscopic scale the symmetry of atomic crystals. Here, we present a bottom-up approach based on copolymer-self assembly to engineer photonic crystals with topologically protected Weyl points. These photonic metamaterials exhibit a frequency and angle selective optical response, lack of Anderson localization and chiral edge states, even in the absence of time-reversal symmetry breaking.

Dynamic long-range couplings in low-symmetry topological photonic systems

Kin Hung Fung*

The Hong Kong Polytechnic University, China
khfung@polyu.edu.hk

Abstract— Non-Hermitian and Lorentz non-reciprocal photonic resonators have attracted intense attention due to their complexities which are strongly dependent on their spatial and temporal structures. Recently, it has been found that arrays of these resonators could also form interesting topological bands and edge modes, which has provided alternatives for realizations of new topological states. Classical photonic systems are different from electronic systems in that the fields near photonic resonators are usually not very localized. However, many traditional theories for the topological bands and edge modes were based on oscillator models with nearest neighbor couplings, ignoring many interesting effects. We try to understand the roles of radiative long range couplings on topological bands and edge modes. In this talk, we will discuss the dynamic radiative effects on the bands and edge modes in these low-symmetry topological photonic systems. Arrays of plasmonic nanoparticles and gyromagnetic resonators will be used as examples to illustrate the effects. The roles of various symmetries including Lorentz reciprocity, time-reversal symmetries, and other spatial-temporal symmetries will also be discussed.

Topological and noreciprocal sound and light in quantum well structures

A. V. Poshakinskiy[1], **and A. N. Poddubny**[1,2*]

[1] Ioffe Institute, 194021 St. Petersburg, Russia
[2] ITMO University, 199034 St. Petersburg, Russia
corresponding author: poddubny@coherent.ioffe.ru

Abstract— We study optomechanical effects in the laser-pumped periodic multiple-quantum-well structures. The light-sound interaction is strongly enhanced at the exciton resonance of the quantum wells and the hybrid exciton-light-phonon quasiparticles, termed as phonoritons, are formed. The phonoritons exhibit pumping-induced synthetic magnetic field in the artificial "coordinate-energy" space that makes transmission of left- and right- going waves different. The transmission nonreciprocity allows to use such phonoritonic crystals with realistic parameters as optically controlled nanoscale acoustic diodes and one-way lasers.

In layered multiple quantum well structures the photoelastic interaction is enhanced by several orders of magnitude at the exciton resonance [1], boosting the optomechanical effects. So far the optomechanics of such structures has been analyzed only in the weak exciton-light coupling regime [2]. Here, we study the laser-pumped quantum well structures depending on the relative strength of exciton-photon and exciton-sound interaction. We consider the strong exciton-light coupling and add a new dimension to the phase diagram of coupled light and matter [3], see Fig. 1. In the regime, when both these interactions are strong the eigenmodes are phonoritons, i.e., a hybrid of phonons, photons, and excitons.

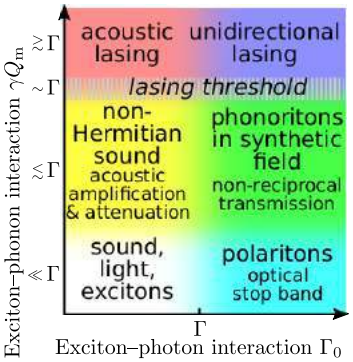

Figure 1: Effects in laser-pumped quantum wells, depending on the exciton-photon and exciton-phonon interactions.

We demonstrate that the propagation of phonoritons through the 1D structure is equivalent to the quantum walk on a stripe of a 2D lattice in the virtual "coordinate–energy" space. Finite pump laser wave vector induces synthetic magnetic field on the lattice, making the wave transport nonreciprocal. The structure can controllably amplify phonons transmitted in one direction while attenuating those transmitted in the opposite direction, enabling construction of an acoustic diode and and unidirectional laser. The proposed devices are can be realized using the mature planar growth technology, are easily integrable with existing optoelectronic platforms and might be promising for phononic computing.

Abstract – We study the effect of topology on quantum walks using on-chip generated correlated photon pairs in an array of silicon waveguides. By using single-photon measurements and simulations we demonstrate the transition between the characteristic path entanglement in random quantum walks and topological localization of the quantum states. Further, we show the robustness of that topological localization to disorder.

Quantum walks are one of many fascinating aspects in quantum information, which are receiving increasing interest since it was shown that they can efficiently perform tasks that are computationally hard in a classical computer [1]. The intrinsically low decoherence of photons, combined with the capability of easily engineered optical platforms, make photonic systems ideal to study different phenomena in quantum walks [2]. In particular, the study of topological phenomena in quantum walks is interesting since it provides a route to robust transport of multiphoton states [3].

We recently demonstrated topological localization of light in an array of silicon waveguides [4], in close analogy with the SSH model [5]. Here, by single-photon measurements and simulations, we demonstrate that a similar platform can be used to study the effect of topology in quantum walks. In particular, we take advantage of the high nonlinearity of silicon waveguides that leads to the generation of correlated photon pairs via four-wave mixing (FWM). In a purely random quantum walk scenario, with equidistant waveguides, the correlated photon pairs spread across the lattice (Fig. 1a). This yields the path entanglement shown in the correlation map at the output of the lattice (Fig. 1b) and the measured correlation counts in the nine center waveguides shown in Fig. 1c.

Next we introduce non-trivial topology in the array by alternating the distances between waveguides and creating long-long defects [4,6]. When exciting the center waveguide of the long-long defect we observe topological localization of the photon pairs (Fig. 1c) giving rise to an output correlation map (Fig 1d) in which the initially spread path entanglement collapses into the center waveguide waveguides. This is further evidenced by the correlation counts measured at the output, shown in Fig. 1f.

The most striking effects of topology in quantum walks are observed when the system is subject to disorder. In this particular implementation, we introduce disorder in the position of the waveguides (the width of the waveguides remains unchanged). Introducing disorder in the purely random quantum walk leads to strong disturbances of the propagation of the photon pairs, which lead to a correlation map strongly affected by disorder (Fig. 1g). When the same level of disorder is introduced in the array with nontrivial topology the propagation of the photon pairs and the correlation map at the output (Fig. 1h) remain unaffected. This robustness is due to the existence of a topological phase that is preserved as long as the chiral symmetry of the structure is conserved.

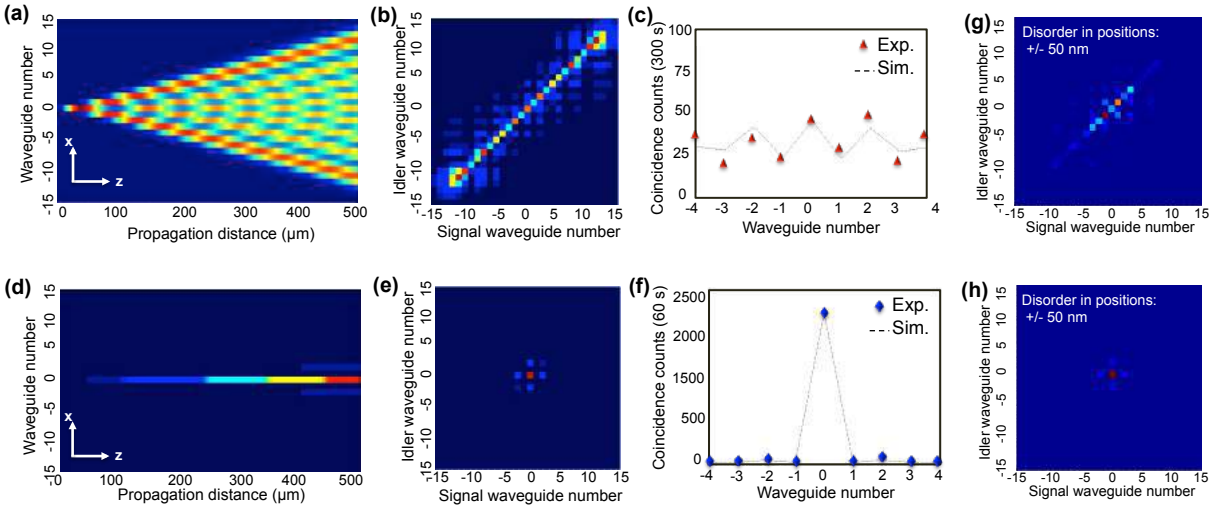

Figure 1. Comparison between random quantum walk and topological quantum walk: (a) Simulated photon pair propagation, (b) simulated output correlation map, and (c) measured correlation counts at the output of the random quantum walk; (d-f) Similar for the topological quantum walk; (g) Correlation map at the output of the random quantum walk and (h) the topological quantum walk when disorder in the position of the waveguides is introduced.

Abstract-We demonstrate that a symmetry protected topological (SPT) state can be engineered in a three-dimensional (3D) all-dielectric metacrystal where the electromagnetic duality between electric and magnetic fields is ensured by the meta-atoms design. Magneto-electric coupling results in a complete topological photonic bandgap and an emergence of spin-polarized surface states with conical Dirac dispersion on 2D topological domain walls.

Following the footsteps of condensed matter topological systems, a significant progress has been recently made in understanding and realizing topological states of light [1]. Here demonstrate that that topological state protected by the electromagnetic duality can be engineered in a 3D metacrystal. The duality, which is reflected in the symmetry of the Maxwell equations with respect to electric and magnetic field components, responsible for the SPT phase of the electromagnetic eigenmodes, otherwise broken by materials response [2,3], is restored by careful design of building blocks of the 3D photonic lattice – meta-atoms. We demonstrate a 3D photonic metacrystal based on the all-dielectric metamaterial platform, which is thus free of very restrictive requirement earlier concepts, including time-reversal violating systems, where magnets or temporal modulation are required, and SPT approaches utilizing lossy metallic/metamaterial components [2,3]. The suggested design can therefore be readily implemented across entire electromagnetic spectrum from microwave to visible.

The topological photonic metacrystal introduced here is schematically shown in Fig. 1a. It represents a 3D hexagonal lattice of dielectric disks with the permittivity ϵ_d=81 embedded into a matrix of permittivity ϵ_b=3. The dielectric disks - meta-atoms - and their 3D periodic arrangement are designed in a way that the photonic band structure exhibits two overlaid 3D Dirac points near the K-point in the Brillouin zone as in Fig. 1b. Each of the observed Dirac bands originates from the electric and magnetic dipolar modes of the disks with their dipole moments aligned in the *xy* plane, perpendicular to their axes. It is important that the very possibility to emulate a true 3D Dirac point found for relativistic massless spin-½ fermions described by the Dirac equation, i.e. the four linear bands which are overlaid in a pairwise manner, is enabled by the duality symmetry. The presence of these two independent sets of modes, the magnetic-dipole and electric-dipole degrees can also be understood as the result of inversion symmetry in the z-direction, present in the case of gapes structure Fig.1b, as the electric (magnetic) modes are odd (even) with respect to the σ_z ($z\rightarrow -z$) transformation. Any reduction of the σ_z symmetry results in the coupling of the in-plane electric and magnetic orbitals and opening of a band gap in the place of Dirac points. This magneto-electric coupling, also referred to as bianisotropy, has an effect equivalent to the spin-orbital interaction in condensed matter [2,3].

An example of the metacrystal with σ_z symmetry broken by removing part of the dielectric cylinder is shown in Fig. 1a, right panel, with its band structure in Fig. 1(c), which reveals a full 3D bandgap. The modes of such gapped structure no longer represent pure electric and magnetic modes, but are mixed states with the phases between their electric and magnetic components being locked. The dipolar electric and magnetic moments of these modes always appear to be tilted by 90 deg and -90 deg with respect to each other, thus constituting two sets of eigenmodes $\psi^{\uparrow}$ and $\psi^{\downarrow}$, where the superscript indicates up (↑) or down (↓) pseudo-spin value, both for lower and upper bands.

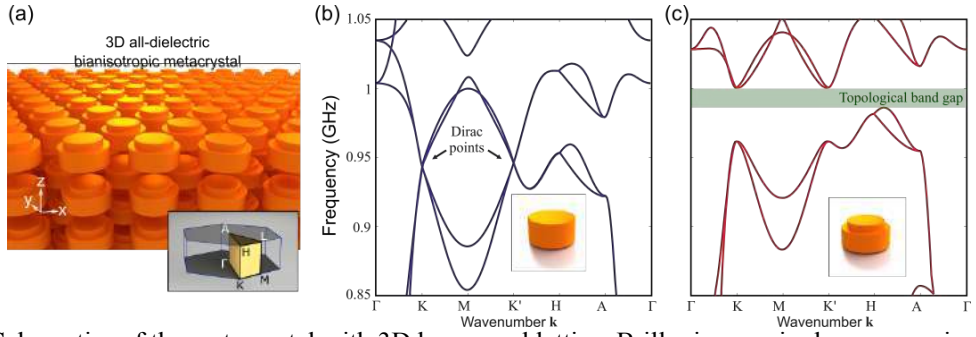

Fig 1. (a) Schematics of the metacrystal with 3D hexagonal lattice. Brillouin zone is shown as an inset. (b,c) Photonic band structures calculated along the high symmetry directions for crystals without and with bianisotropy.

One of the most important consequences of topological order is the emergence of gapless surface states, which may occur either on the external interfaces with topologically trivial system or at the domain walls separating topological systems of distinct classification. Here we consider the topological domain wall along the *yz*-cut which represents an interface between two topological crystals inverted with respect to each other along the z-direction, which results in the reversal of bianisotropy. The corresponding structure is shown in Fig. 2a with the photonic band structure in Fig. 2(b,c). The left and central panels in Fig. 2(b) show two cuts of two-dimensional band structure $\omega(k_y,k_z)$ and reveal two pairs of surface states. The surface states appear within the band gap region interconnecting lower and upper bulk bands. The 3D band diagram shown in Fig. 2(c) exposes one of the Dirac cones corresponding to the surface states near K-point. As in the case of 3D electronic topological insulators, the surface states in our system also have a property of spin-locking which endows them with topological robustness.

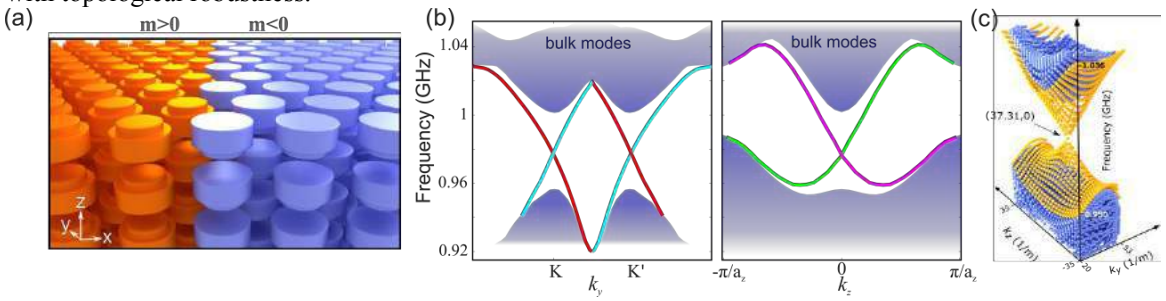

Fig 1. (a) The schematics of the domain wall formed by the reversal of the mass term induced by the bianisotropy in the middle of the metacrystal. (b) Band diagrams of topological surface states supported by the domain wall. (c) The conical Dirac-like dispersion of the surface states.

In summary, we propose an all-dielectric photonic platform which can be used for implementation of topologically robust 3D photonic circuitry in entire electromagnetic spectrum from microwave frequencies to optical domain. The proposed all-dielectric metacrystals may allow avoiding undesirable effects of Ohmic loss unavoidable in metallic structures, and, in addition, facilitates topological order in photonics-compatible dielectric and semiconductor materials, thus avoiding technical difficulties associated with the use of magnetic materials and external magnets required to induce topological order in systems with broken TR symmetry.

Abstract- Photonic topological insulators are an interesting class of materials whose photonic band structure can have a band gap in the bulk while supporting topologically protected unidirectional edge modes. Recent studies on bianisotropic metamaterials that emulate the electronic quantum spin Hall effect using its electromagnetic analog are examples of such systems with a relatively simple and elegant design. In this presentation, we present a rotating magnetic dipole antenna, composed of two perpendicularly oriented coils, that can efficiently excite the unidirectional topologically protected surface waves in the bianisotropic metawaveguide (BMW) structure recently realized by T. Ma *et al.* [Phys. Rev. Lett. **114**, 127401 (2015)] despite the fact that the BMW medium does not break time-reversal invariance. In addition to achieving a high directivity, the antenna can be tuned continuously to excite reflectionless edge modes in the two opposite directions at various amplitude ratios. We demonstrate its performance through experiments and compare to simulation results. For details, see Phys. Rev. B **94**, 195427 (2016).

Transformation Optics concept and applications

Detecting the spatial chirp signals by fractional Fourier lens with transformation materials

J. Chen and J. Hu*
School of Information and Electronics, Beijing Institute of Technology, China
*corresponding author: bithj@bit.edu.cn

Abstract- Detecting the rate of frequency change or chirp rate (CR) of a spatial chirp signal is important in some optical applications. With the help of transformation optics, the improved fractional Fourier lens can be designed to adjust the CR as well as the focusing location of the given input chirp signals. In consequence the CR detection precision can be improved and the range of the input signals can be extended. The numerical simulations verified the design.

Transformation optics (TO) provides an intuitive and direct way to control electromagnetic wave propagation by designing appropriate materials [1]. Lu et al. [2] utilized TO to widen the input spatial frequency bandwidth of the graded index (GRIN) lens by isotropic transformation media and pointed out its potential in fractional Fourier transform (FrFT). In this study, we explore the application of the FrFT lens proposed by Lu et al. [2] in detecting the CR of a spatial chirp signal with enhanced precision and range. Detecting the CR of a spatial chirp signal is important in some optical application. For example, the Newton's rings are two dimensional (2D) chirps and their CRs are important in optical measurements.

It is known that if $f(x)$ is a chirp signal and the FrFT has proper order corresponding to the CR, the FrFT result of $f(x)$ is an impulse [3]. In view of this, the FrFT lens can be used to detect the CR of an input chirp. The chirp will focus at the location within the lens where the corresponding FrFT order can be found [4], in turn the CR can be calculated [3]. The higher the CR is, the smaller the FrFT order will be, and the closer the impulse will locate to the input facet. As the traditional GRIN lens is work under the paraxial approximation, the short propagate distance of high CR signal will lead to considerable error. The proposed lens compress the input facet and maintain the output facet length [2], as a result, although the input signal is the same, it can be viewed as a compressed chirp and is equivalent to a uncompressed chirp in the original space according to TO principle. That is, the proposed lens can reduce the input CR. Compared to the signal with higher CR, the one with lower CR can focus farther in the lens and makes the paraxial approximation satisfied better, thus the detection precision can be improved, which also means the range of the input chirp signals can be extended for the given error.

The 2D numerical simulations results are shown in Fig. 1 and Tab. 1. The compression factor of the input facet is 2.3819 and the input test chirps are transverse electric (TE) waves, with wavelength= 0.09m. One should note that the proposed lens has different method from the traditional GRIN lens in obtaining the FrFT order [2]. It is clear that with the help of the proposed FrFT lens, the detection precision of the CR can be greatly improved. The proposed device may boost the applications of optical FrFT, and the idea proposed here also implies that TO has broad prospects in the field of spatial signal processing.

Designing transformation optics devices for wave vectors manipulation

Mircea Giloan*, **Robert Gutt**, **and Gavril Saplacan**

Company for Applied Informatics, Cluj-Napoca, Romania,
*corresponding author: mircea_giloan@cianet.ro

Abstract— The devices designed using a transformation optics approach are mainly accomplishing their functionality by inducing specific manipulations of the wave paths through coordinate transformations. In this study we analyze how the wave vectors can be manipulated as the waves propagate in transformation media derived from a specific class of coordinate transformations. We provide a powerful method for designing electromagnetic devices able to accomplish different functions by inducing proper manipulations of the wave vectors generated by appropriate coordinate transformations.

An electromagnetic device alters the wave path and/or the wave vector of an incident wave according to the desired functionality. So far, the concept of transformation optics was used to design different devices, mainly by focusing on the manipulation of the wave path of the electromagnetic waves [1]-[3].

In this study we present the design of a flat device consisting of a medium delimited by two parallel planes. The required functionality of the device is a proper manipulation of the wave vector in order to provide a specific wave vector distribution at the output plane of the device. The wave vector distribution at the output plane will determine the propagation path of the wave into the homogeneous medium which surrounds the device. This theoretical study shows a general method to retrieve the proper coordinate transformation, and consequently the corresponding permittivity and permeability of the transformed medium, which will generate the desired wave vector distribution at the output plane of the device [4].

Figure 1 shows the main geometrical characteristics of the designed device, the trajectories of the wave paths inside the device and after leaving the device, and the components of the wave vectors of the incident and emergent waves. The device consists in a medium delimited by two planes perpendicular on $z-$axis. The wave path of a normally incident wave is constrained to a parallel line to $z-$axis. In order to manipulate the wave vector inside the device the following coordinate transformation of the original space was used:

$$\left\{ \begin{array}{l} x' = x \\ y' = y \\ z' = zf(x,y) \end{array} \right\} \tag{1}$$

where $f(x,y)$ is a function of two variables which transforms the z coordinate with respect to x and y coordinates.

Considering that the original space is the free space the relative electric permittivity ε and magnetic permeability μ of the anisotropic medium, having an identical electromagnetic behavior as the transformed space described by equations (1), are given by the same symmetric tensor, denoted by n:

$$n = \frac{1}{f(x,y)} \begin{bmatrix} 1 & 0 & \frac{z\partial_x f(x,y)}{f(x,y)} \\ 0 & 1 & \frac{z\partial_y f(x,y)}{f(x,y)} \\ \frac{z\partial_x f(x,y)}{f(x,y)} & \frac{z\partial_y f(x,y)}{f(x,y)} & \frac{z^2((\partial_x f(x,y))^2 + (\partial_y f(x,y))^2)}{f^2(x,y)} + f^2(x,y) \end{bmatrix} \tag{2}$$

where $\partial_x f$ and $\partial_y f$ denote the partial derivatives of the f function with respect to x and y variables,respectively. Note that, tensor n described by equation (2) is expressed in terms of x', y', and z' coordinates of the transformed space where, for simplicity, the primes have been dropped.

After performing some mathematical computations we proved that at normal incidence (i.e. the wave vector of the incident wave has the form $\mathbf{k}_i^T = (0, 0, k_{zi})$, where the superscript $(\cdot)^T$ denotes

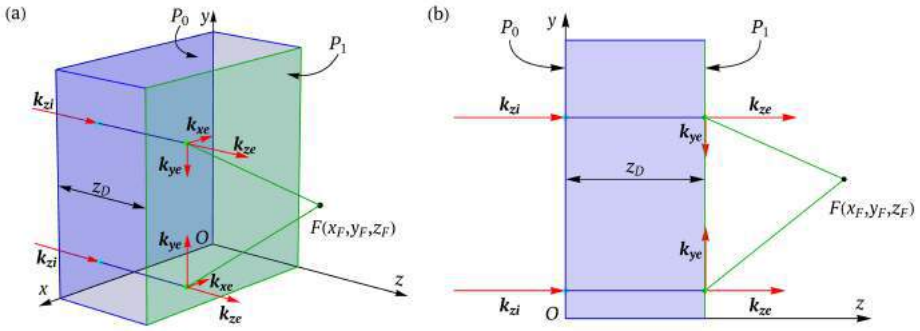

Figure 1: **(a)** 3D view and **(b)** yz plane view, of a reduce area of the device. The device is delimited by the input ($P0$) and output ($P1$) planes perpendicular on $z-$axis and displaced by z_D. The wave paths are depicted inside and outside the device by blue and green lines, respectively. The incident and emergent wave vector components are depicted by red arrows. F denotes an arbitrary point of convergence for the emergent wave vectors (i.e. a focal point) in the particular case of a converging flat lens design.

the transpose operator) the transverse components of the wave vector k_x and k_y are changing linearly with respect to z coordinate so that the $x-$ and $y-$axis components of the emergent wave vector $\mathbf{k}_e^T = (k_{xe}, k_{ye}, k_{ze})$ are described by the following equations:

$$k_{xe} = \frac{\partial h}{\partial x} z_D, \quad k_{ye} = \frac{\partial h}{\partial y} z_D \tag{3}$$

where z_D is the thickness of the device and $h(x, y) = 1/f(x, y)$ (see Fig. 1 and ref. [4]). Since the emergent wave propagates in the free space the components of the wave vector are satisfying also the relation:

$$k_{xe}^2 + k_{ye}^2 + k_{ze}^2 = 1. \tag{4}$$

Equations (3) are the most important result of our theoretical study. In completion with equation (4) these equations allow us to retrieve the function $f(x, y)$ which describes the transformation media able to produce at the output interface of the device the wave vector distribution required by the functionality of the device. Once this function is found the material parameters of the device are easily found from equation (2).

In our presentation we will show through numerical simulations using Finite-Difference Time-Domain (FDTD) algorithms how this theoretical result, which enables a flexible manipulation of the wave vectors, can be applied to design optical devices for the following fields:

- generation of Bessel and angular momentum beams;
- optical information processing;
- super-resolution imaging;
- optical cloaking.

Abstract-We apply transformation optics to the field of thermal radiation where fluctuational electrodynamics is shown to be invariant under transformation optics. We show that thermal camouflage/cloaking can be possibly realized using the proposed theory.

In this paper, we extend transformation optics theory [1-2] to thermal radiation physics [3] in order to control thermally radiated signatures emitted from an arbitrary object. Applications concern countermeasure effects in a way similar to other thermal camouflage techniques [4-8].

Starting with fluctuation dissipation theorem [4-6] where thermally fluctuating current sources are related to radiative losses, we show that it is possible for objects residing in virtual and physical space to have the same spectral thermal signature. To reach this goal the complex permittivities and permeabilities should be related by the typical transformation optics such that the fluctuation electrodynamics problem [7] is invariant under transformation. Furthermore the thermal current sources are transformed in a way similar to that of coherent sources according to source transformation [14]. These two properties are the basis for the invariance of fluctuation electrodynamics and allow the illusion procedure in thermal radiation.

We illustrate the concept using the cloaking/illusion paradigm in the two dimensional space [15], where an object is coated with a transformation optics designed cylindrical coat in order to mimic [16] the emitted thermal signature of two other different objects, one for its Transverse Electric polarization and the other for its Transverse Magnetic polarization. Finally we discuss possible extensions to other transformations and physical limitations of their realizations.

Practical Realization of a Transformation Optics based Dielectric Superstrate for Patch Antenna using 3D printing

C. Joshi[1], A.C. Lepage[1], X. Begaud[1] and G.P. Piau[2]
[1]LTCI, Télécom ParisTech, Université Paris-Saclay, France

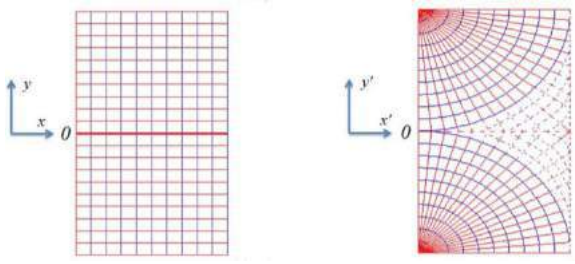
Abstract- Transformation Optics (TO) based superstrates allow modifying radiation patterns of antennas but generally required anisotropic magnetic and dielectric materials or metamaterials. Previously, we presented a TO-based all dielectric solution which allows achieving in-plane radiation from planar antennas. In this paper, we will present the approach to design the superstrate prototype using 3D printing process and the performances achieved.

First introduced in seminal work of Pendry [1], Transformation Optics (TO) is a great tool for electromagnetic design that offers new perspective to long studied electromagnetic problems. One such problem is achieving in plane radiation from planar antennas. Traditionally such radiation can be achieved with leaky wave antennas or end-fire arrays. In [2], design of a dielectric superstrate was proposed that allows reorienting the broadside radiation pattern of a patch antenna in its azimuthal plane. Using TO and optimization techniques, permittivity values are found to interpret the transformation of a rectangular Cartesian space according to a virtual space comprised of 2 opposed quarter ellipses (Figure 1). When placed over a patch antenna, superstrate allows achieving an antipodal radiation pattern with two opposite radiation lobes in the azimuth, and a null in the broadside. Furthermore, a 3D solution is also discussed with a profile comprised of 48 pixels arranged in 3 layers with 16 pixels each, and with permittivity values ranging between 1 and 14. Such a superstrate is shown to provide the desired reorientation behavior for a patch antenna designed to function at 1.25 GHz. The profile is shown in Figure 2.



a) b)

Figure 1 (a) Physical space, (b) Virtual Space

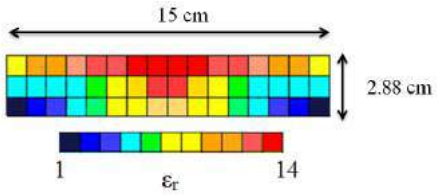


Figure 2 Dielectric TO profile with 48 pixels

While permittivity gradients can be designed by drilling holes of variable radii in a single dielectric medium, implementing the dielectric profile of [2], presented in Figure 2, is very complex using only one material due to the wide-varying permittivity profile. Indeed, materials with high-ε_r values are difficult to find and particularly to

machine. Alternatively, multiple materials can be used. For example, a three material dielectric magnifying lens has been presented in [3], where the high permittivity regions are interpreted using a single high permittivity material (F4B).

In the present work, we adopt a similar approach to address the concern of high permittivity values. Alumina ($\varepsilon_{r\text{-}high} = 9.9$) is used to interpret high permittivity region i.e. all pixels with permittivity value higher than that of alumina. Remaining values are interpreted by a single permittivity value ($\varepsilon_{r\text{-}low}$), corresponding to the permittivity of a 3D printer material. For $\varepsilon_{r\text{-}low}$ realization, two different materials were considered: Objet-FullCure photo curable resin ($\varepsilon_r = 2.8$) and PLA Thermoplastic ($\varepsilon_r = 2.56$, $\tan\delta = 0.031$). In practice, this leads to a two materials design, as shown in Figure 3. Plexiglas sheet is screwed on top face of the receptacle to secure alumina slabs.

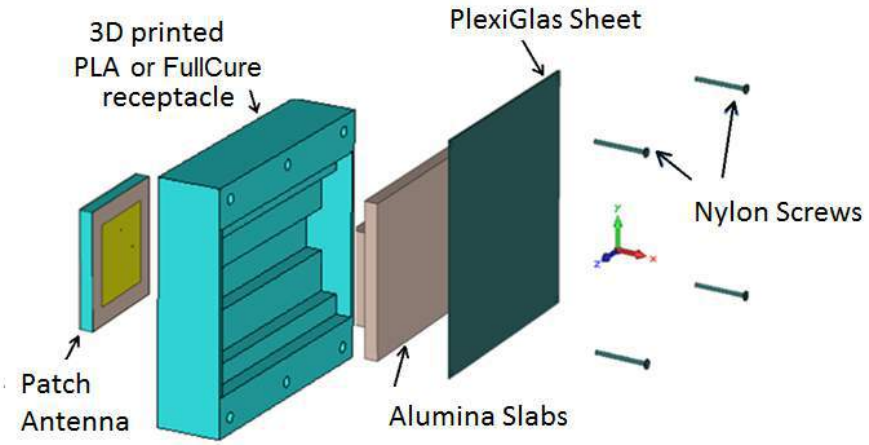

Figure 3 Representative image of the fabricated prototype

The performance achieved with these two different configurations of the superstrate placed over a classical patch antenna will be presented during the conference.

Abstract-As an effective approach for manipulating propagation of waves, transformation optics has inspired many novel applications in past decades. In this paper, our recent efforts in metamaterial devices for manipulation of waves in microwave region are reviewed with emphasis on (1) multifunctional device with three different kinds of electromagnetic properties, (2) homogeneous illusion device exhibiting transformed and shifted scattering effect and (3) wave bending devices with homogeneous complementary material.

Transformation optics has attracted great attentions of scientists in optics and magnetic since proposed [1]. Based on theory of optical transformation, novel applications in manipulation of waves were proposed and analyzed in theory, including cloaks, illusion device, to name a few [2-4]. In this paper, we briefly review our recent work on metamaterial device for manipulation of waves based on transformation optics. Multifunctional device with three electromagnetic properties, homogeneous illusion device exhibiting transformed and shifted scattering effect and wave bending device with homogeneous complementary material will be introduced.

First, a multifunctional device with invisible, transparent and illusion electromagnetic properties is proposed. This device can be used as complementary cloak, as shown in Fig.1a and 1b. Scattering fields of the circular object in Fig. 1a is cancelled by corresponding anti-object, as shown in Fig.1b. Meanwhile, this device can be used as transparent device, as shown in Fig.1c and 1d. It can be seen that the field distributions of the device of horn antenna in free space are is same as with that of a horn antenna in proposed device free space. Second, a kind of homogenous illusion device exhibiting shifted and transformed scattering effect is proposed. Fig. 2a, 2c and 2e show the electrical field distributions of different PECs in shifting device with linearly minified, magnified and reshaped properties, respectively. Compared electrical field distributions of practical PEC with that of equivalent PEC (shown in Fig. 2b, 2d and 2f), we can see that the field distributions of two PECs are same although they have different size and locate in different location. Third, we adopt homogeneous complementary material to manipulate the propagation property of waves. Fig. 3a and 3b show the wave deflects with a given angle moving through the refractor and splitter. Fig. 3c and 3d show electric field distributions and the time average power outflow of waveguide bend respectively. It is clear that the guiding mode pattern is not distorted and the nearly all the energies are transmitted.

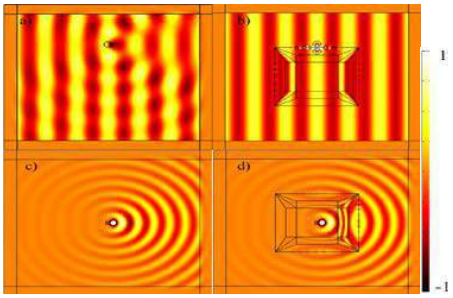

Fig. 1 Electrical field distributions of (a) circular object in free space, (b) circular object in the device, (c) horn antenna in free space and (d) horn antenna in the device.

Abstract-A 3D lens calculated by spatial light transformation method for electromagnetic field shaping is proposed. The lens is capable of transforming cylindrical wavefronts into planar ones, and therefore generating a directive emission. Such manipulation is simulated and analyzed by solving the Laplace's equation. A potential 3D realization with all-dielectric gradient refractive index metamaterials is presented.

Transformation Optics (TO) concept [1,2], known as a powerful and effective method to simultaneously control electromagnetic (EM) fields, has been widely used to design new classes of optical and electromagnetic devices. The best known design by TO approach is the invisibility cloak [3]. Moreover, quasi-conformal transformation optics (QCTO) provides the possibility to design arbitrary shapes and avoid singularities in material parameter value. Thus it has been widely applied to design arbitrary broadband devices such as the carpet cloak [4] and functional lenses [5] with all-dielectric materials. In this study, we propose the design of a 3D lens with a mushroom shape that can significantly enhance the directivity of a conical horn antenna. Such a 3D lens is based on a former 2D one that is capable of restoring in-phase emissions from a conformal array of antennas so as to obtain performances similar to a linear one [6].

The designed model is based on quasi-conformal transformation optics (QCTO) and achieved by solving Laplace's equation. For fields' equivalence at the outer boundaries with the virtual space, Neumann and Dirichlet sliding boundary conditions are set at the edges of the cap lens:

$$\begin{aligned} &x\big|_{B'C',C'D',D'A'} = x', \quad \hat{n}\cdot\nabla x\big|_{A'B'} = 0 \\ &y\big|_{A'B'} = 0, \quad y\big|_{B'C',C'D'} = y', \quad \hat{n}\cdot\nabla y\big|_{D'A'} = 0 \end{aligned} \tag{1}$$

The range of ε_{zz} is related to the deformation between the physical space and the virtual space. We consider the initial parameters as t = 4 cm, r = 14.5 cm and θ = 0.761 rad (Fig. 1). In this case, the permittivity distribution ranges from 0 to 2.8. To refrain from using resonant metamaterials and to support a potential all-dielectric realization process, we have to consider ε_{zz} values below 1 as unity. The discrete lens is designed from dielectric-hole structures for broadband performances, as illustrated in Fig. 2.

Keywords: Metasurfaces, boundary optics, optical antenna.

Abrupt modifications of the fields across an interface can be engineered by depositing an array of sub-wavelength resonators specifically tailored to address local amplitude, phase and polarization changes [1]. Physically, ultrathin nanostructure arrays ($\delta \ll \lambda$), also called ''optical metasurfaces'', control light by engineering artificial boundary conditions of Maxwell's equations. Metasurfaces have been implemented to obtain various sorts of optical functionalities, ranging from the basic control of the transmission and reflection of light[1-2], to the control of the radiation patterns for comprehensive wavefront engineering and holography[3]. In the introduction, we will review the recent works in this field and we will explain the physical mechanisms required for the design of efficient planar optical components.
In this presentation, we will discuss recent works on free standing visible (GaN based) and mid-infrared (Si-based) metasurfaces [4]. We will explain which physical mechanisms are utilized for the design of efficient ultrathin planar optical components and show that these conditions are connected with the well-known Kerker conditions already proposed for isolated scatterers.

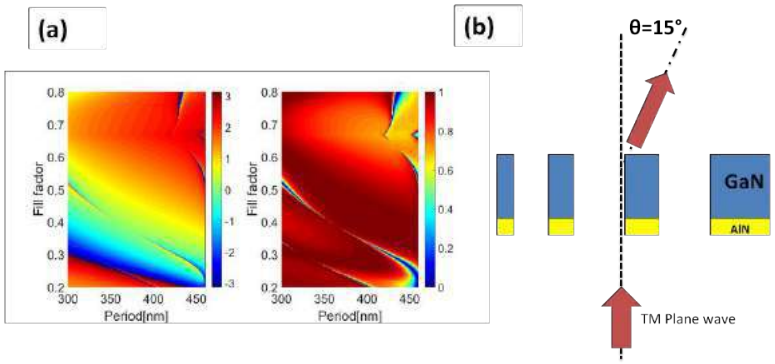

Figure 1 : (a) Phase introduce by the gratings as a function of the fill factor and the period (right) Contour of the transmission versus the fill factor and the period of the grating (b) Schematic diagram of the grating.

Beam deflectors are designed and optimised through sequential particle swarm and gradient descent optimisation in order to maximise transmission efficiency and reduce unwanted grating lobes. We have designed and optimised freestanding silicon nanohole array beam deflector for the visible and the mid-IR. Our metasurfaces, made of GaN for visible and Si for mid-infrared, are fabrication friendly and have high transmission due to the lack of substrate and the fulfillment of Kerker's conditions (fig1 and 2).

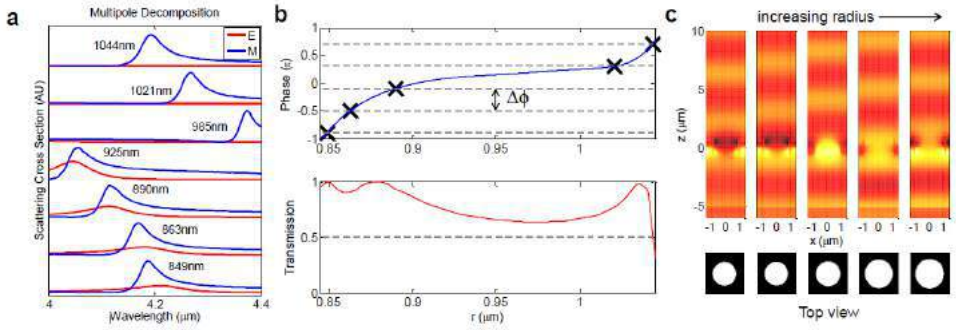

Figure 2. (a) Electric and magnetic dipolar contributions at several selected hole radii. (b) Crosses mark the chosen hole radii for the metasurface beam deflector, showing the constant phase shift difference Df and corresponding high transmission. (c) Field amplitudes before and after incidence on nanohole arrays with different radii, showing the linear phase gradient.

Similar principles can be used to design various other optical metasurfaces, e.g. flat lenses, phase plates, waveplates, helical wavefront generators, and holograms. Rectangular, elliptical, or other asymmetrical hole shapes can be used to impart birefringence to different light polarisations, as required in waveplates or polarisation beam splitters. We will conclude our presentation with a discussion on the concept of **conformal boundary optics**: an analytical method based on novel, first-principle derivations that allows us to engineer transmission and reflection at will for any interface geometry and any given incident wave[5].

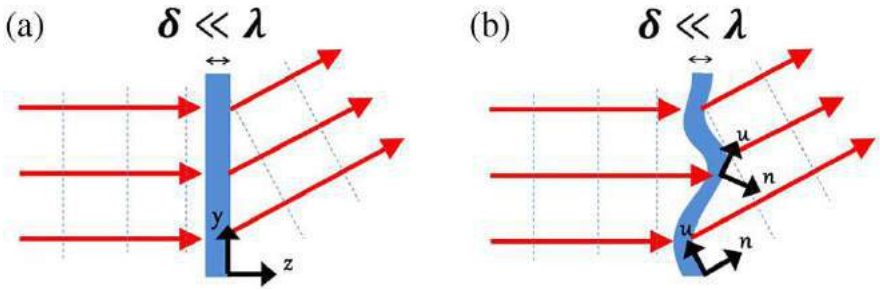

Fig. 1: 2D planar metasurface of subwavelength thickness. For planar interfaces, generalized sheet boundary conditions readily apply, and the surface susceptibility tensors can be calculated. (b) The local coordinate system of the surface follows its local curvature, changing with the position along the interface. Boundary conditions of the fields are obtained in the coordinate system of the interface and are therefore position dependent. To produce an effect equivalent to that in (a), the surface susceptibilities of the optical interface have to be engineered to account for the effect of the physical distortion. The dashed blue lines denote the equiphase fronts of the electromagnetic fields.

Advanced passive and active metasurfaces

Passive, Active, and Nonlinear Chiral Metasurfaces

Wenshan Cai
School of Electrical and Computer Engineering, Georgia Institute of Technology, USA
corresponding author: wcai@gatech.edu

Abstract- Metasurfaces can be designed to exhibit extraordinarily strong chiral responses, commonly described in terms of the circular dichroism and polarization rotation. Here we present a set of photonic metasurfaces that possess pronounced chiroptical features in both the linear and the nonlinear regimes. These structures are further exploited for chiral-selective two-photon luminescence from quantum emitters and a photon-drag effect with helicity-sensitive generation of photocurrent. Finally, we report a noticeable shift in the chiroptical responses under a modest level of excitation power.

The past few years have witnessed an explosive development of chiral photonic nanostructures that exhibit circular dichroism and optical rotation orders of magnitude larger than conventional materials. Though chirality is most commonly applied in linear optical regime, opposing circularly polarized waves can also display parity as a property of higher order optics. In this talk, we present a set of photonic metasurfaces that possess pronounced chiroptical features in both the linear and the nonlinear regimes.

In addition to gigantic linear chiroptical responses, including the circular dichroism and optical activity that are many times stronger than those found in naturally occurring media, the metasurfaces demonstrates a 20x contrast between second harmonic responses from the two circular polarizations. Linear and nonlinear response images probed with circularly polarized lights show strongly defined contrast, and the second-harmonic circular-dichroism images are produced to reveal the chiral characteristics of a metasurface pattern consisting of opposite meta-enantiomers.

The chiral hotspots created at the center of the chiral meta-atoms can be made accessible to nanoscale probes. By both exposing the resonant near field of the chiral nanostructure via plasma etching and inserting quantum dots as indicators of localized chiral hotspots, we observed substantially enhanced and chiral-selective two-photon luminescence from the hybrid meta-system. The giant chiral response in the metasurface facilitates circular dichroic manipulation of the far-field intensity of locally emitted nonlinear signals, and the strength of the two-photon signal is directly correlated to the chiral resonance in the linear regime.

In the end, we report a chiral metasurface based on topologically continuous metallic layers, which supports a photon-drag effect with helicity-sensitive generation of photocurrent. The structure is further exploited under varying illumination intensity, with which we observe an intensity-dependent modulation of optically active signals, including the circular dichroism and polarization rotation, under a modest level of excitation power..

Abstract- For practical applications of orbital angular momentum (OAM) states, a simple approach is highly desirable for the generation of OAM beams and the manipulation of their superpositions in multiple channels. We propose and experimentally demonstrate a facile metasurface approach to realize polarization-controllable multichannel superpositions of OAM states at will. Four OAM beams in separate channels are observed for an incident Gaussian beam with circular polarization. By manipulating the polarization state of the incident light, arbitrary control of the superpositions of various OAM states in multiple channels is realized using a single plasmonic metasurface.

Light possessing OAM (namely optical vortex) has a helical phase structure described by $\exp(il\theta)$, where θ is the azimuthal angle, l is the topological charge of optical vortex corresponding to an orbital angular momentum of $l\hbar$ per photon. Recently, the OAM of light has attracted considerable attention due to its promising applications, including optical tweezers, quantum memories, and metrology. Specially, a superposition of OAM states is of importance in classical physics and quantum sciences. Despite the diverse applications of OAM ranging from metrology to quantum entanglements, there are fundamental or technical challenges for current techniques to efficiently generate and manipulate multi-OAM-state of light.

Metasurfaces, the two-dimensional analog of conventional metamaterials, have drawn considerable attention in the scientific community due to their exotic electromagnetic properties and potential breakthroughs for light manipulation [1, 2]. In this paper, we propose and experimentally demonstrate an efficient approach to generate multiple OAM states and arbitrarily control their superpositions [3]. Figure 1 shows the superposition of OAM states with topological charges of same absolute values but opposite signs in four output channels. Under the illumination of RCP light, two pairs of off-axis OAM beams are generated, i.e., $|R,\ l_i\rangle$ (denoted by black dots along the horizontal direction) and $|R,\ l_j\rangle$ (yellow dots along the vertical direction), respectively (see Fig. 1a (i)). Here l_i, l_j are the topological charges. By changing the helicity of the incident light from RCP to LCP, the signs of all the topological charges of output OAM states are flipped (see Fig. 1a (ii)), and the positions of the beams are changed to the corresponding centrosymmetric positions with respect to the center, accordingly. A linearly polarized (LP) incident light can be decomposed into two equal-weighted RCP and LCP components with a phase difference, the states of the output beams generated by the metasurface are $e^{i\vartheta}|R,\ l_i\rangle + e^{-i\vartheta}|L,\ -l_i\rangle$ and $e^{i\vartheta}|R,\ l_j\rangle + e^{-i\vartheta}|L,\ -l_j\rangle$, respectively. Consequently, the superpositions of OAM states are realized. The combination of multichannel OAM generation, polarization-controlled OAM superposition, subwavelength resolution, broad spectral band, and compactness

renders this technology very attractive for diverse applications in both classical physics and quantum sciences.

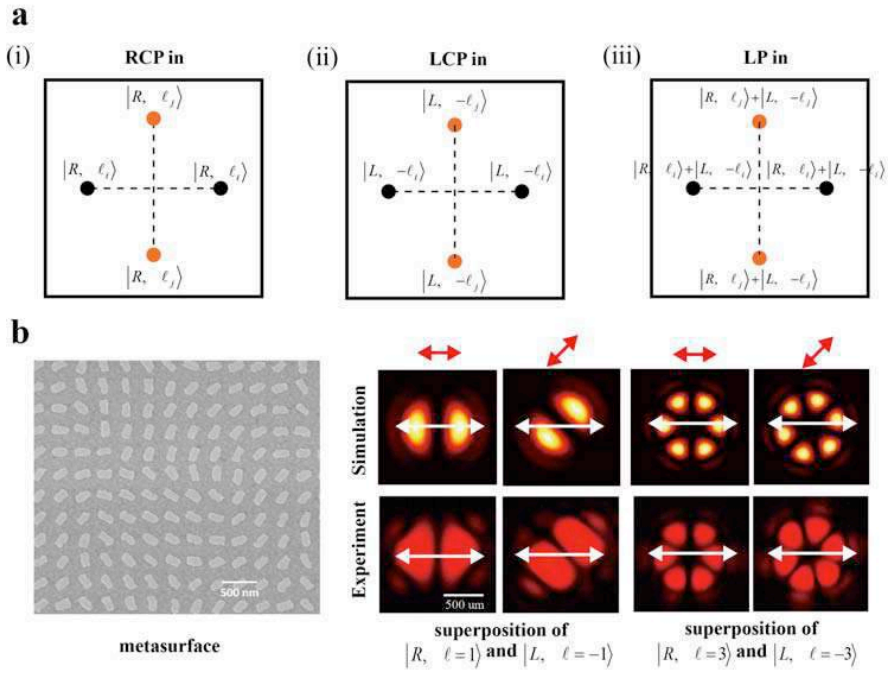

Figure 1 Schematic of the four-channel OAM superpositions, SEM images of metasurfaces, and numerically calculated and experimentally observed superpositions of OAM states. a, The generation of two kinds of OAM modes and their superpositions in four channels. (i) Upon the illumination of RCP input light, two pairs of off-axis OAM beams are generated, i.e., $|R,\ l_i\rangle$(denoted by black dots) and $|R,\ l_j\rangle$(denoted by yellow dots), respectively. (ii) The positions of OAM states and their signs are changed for LCP input light. (iii) Equal-weighted OAM states superpositions occur under the illumination of linearly polarized (LP) input light. b**,** SEM image and numerically calculated and experimentally observed superpositions of OAM states. This metasurface produces two kinds of superpositions, one for OAM states with $l = 1$ and $l = -1$, and another one for OAM states with $l = 3$ and $l = -3$. The polarization angle of incident linearly polarized light and the direction of the polarizer's transmission axis in front of the CCD camera are respectively denoted by the red double-headed arrows and the white double-headed arrows.

Abstract- Recently, Pancharatnam–Berry (PB) metasurfaces exhibit strong abilities to control spin-polarized light. However, low frequency issue becomes a great challenge in their realistic applications. Here, we propose theoretical criterions of high-efficiency PB devices, that guide us realizing several novel effects in microwave regime. These findings can inspire the high efficiency spin-dependent wave-front manipulations in other frequency domains

Pancharatnam–Berry (PB) metasurfaces exhibit strong abilities to control spin-polarized light, leading to fascinating effects such as photonic spin-Hall effect (PSHE), optic-vortex generation and spin-dependent surface plasmon excitations. However, many previous works related to PB devices suffered from the low frequency issues [1-3]. To solve these issues, we have proposed the theoretical criterions for the design of high-efficiency PB devices and performed two different effects to demonstrate our idea.

First, we propose a new scheme to design high efficiency chirality-modulated surface plasmon meta-coupler. It solve the two key issues limiting the performances of previous related devices, that are direct reflections at the coupler surface and the mode mismatch between the coupler and the guiding-out plasmonic structure. We designed and fabricated a realistic device working in the microwave regime, and demonstrate experimentally that it can achieve an spoof SPP conversion efficiency ~78%. Full-wave simulations are in good agreement with experiments, showing that the efficiency can be further pushed to 92% with optimized designs [4]. Second, we demonstrate theoretically that 100%-efficiency PSHE can be realized in PB metasurfaces exhibiting both electric and magnetic responses satisfying certain criterions. Such criterions help us design a microwave transmissive PB metasurface with ultra-thin thickness, yet exhibiting a maximum PSHE efficiency ~91% experimentally. These findings can stimulate many high-performance PB meta-devices with diversified functionalities. As an example, we fabricate several vortex-beam generators with ultra-high working efficiencies [5].

Acknowledgment- This work is supported by National Natural Science Foundation China and Shanghai Science and Technology Committee.

Abstract*:* It is fundamental to achieve negative refraction of highly squeezed polaritons, such as plasmon polaritons in graphene and phonon polaritons in BN with their wavelengths squeezed by a factor over 100, because this could enable many unique nanoscale applications. However, this still remains challenging. We reveal that graphene-BN heterostructures provide a versatile platform to flexibly tune the sign of the group velocity of hybrid plasmon-phonon-polaritons, enabling negative refraction between graphene plasmons, BN's phonon polaritons and their hybrid polaritons.

Polaritons with extreme spatial confinement [1] are crucial for the control over the propagation of light at the nanoscale. A fundamental building block in nano-photonics and plasmonics is the ability to achieve negative refraction of polaritons, because it can offer a novel way of controlling the flow of light and can enable the demonstration of many exotic phenomena and unique applications such as deep-subwavelength imaging, superlens, and novel guiding. However, to do this for highly squeezed polaritons, such as plasmon polaritons in graphene and phonon polaritons in boron nitride (BN) with their wavelengths being able to be squeezed by a factor over 100, requires an ability to flip the sign of their group velocities, which has not been observed nor predicted so far. Therefore, demonstrating negative refraction of highly squeezed polaritons remains an open challenge that is highly sought after due to its importance for the manipulation of light at the extreme nanoscale.

In this work, we predict that utilizing the strong coupling between graphene plasmons and BN's phonon polaritons in graphene-BN heterostructures can flip both signs of their group velocities. This enables us to predict the all-angle negative refraction phenomena between graphene's plasmons and BN's phonon polaritons, and even more surprisingly, between two kinds of graphene plasmons, or between two kinds of BN's phonon polaritons, where the polaritonic wavelengths are all squeezed by a factor over 100. Moreover, unlike

conventional all-angle negative refraction of metal plasmons that are restricted to work at a given fixed frequency, the working frequency of all-angle polaritonic negative refraction demonstrated here can be flexibly tunable within BN's first reststrahlen band, thanks to the tunability of the chemical potential in graphene.

Due to the combined advantages of tunability, low loss, and ultra-confinement provided by these polaritons on the platform of graphene-BN heterostructures, we believe that the negative polaritonic refraction presented in this work will have fundamental and far-reaching impacts. Even more important is the ability to flip the sign of group velocities of highly squeezed graphene plasmons and BN's phonon polaritons. Graphene-BN heterostructures thus provide new fundamental tools to explore other novel actively-tunable polaritonic effects and to design advanced polaritonic devices such as metasurfaces and superlens.

Ultrathin metasurfaces for wide-angle spectrum splitting

Z. Li, Z. Liu, F. Callewaert, S. Butun, and K. Aydin*

[1]Department of Electrical Engineering and Computer Science, Northwestern University, Evanston IL, USA

Abstract-We present flat metasurfaces and metamaterials that enable broadband spectrum splitting and anomalous light reflection and transmission. We will also describe a phase-transition material based dynamic metasurface for beam steering.

Spectrum-splitting, directing different wavelength components of a broadband light source to different directions, has wide range of applications including imaging, spectroscopy, astronomy and solar energy. Conventional optical devices such as lenses, prisms and gratings offer limited control of photon flow due to design constraints and material dispersion. Recently, metasurfaces have emerged as potential and reliable candidates for replacing conventional optical devices. Metasurfaces with desired optical properties can be designed at will by controlling the size, shape, position, and arrangement of metallic and/or dielectric nanostructures enabling extreme manipulation of light-matter interactions at the subwavelength scale[1].

We will present the design and realization of spectrum-splitting ultrathin, flat metasurfaces with unparalleled optical properties that cannot be offered by conventional optical devices. One metasurface design is composed of trapezoid nanoresonator arrays operating in the reflection mode and enabling broadband, highly efficient anomalous reflection at the visible frequency range. We will also demonstrate a novel spectrum splitter capable of directing different wavelengths of light to opposite directions resulting in an ultra-wide ($> 90°$) angular splitting[3]. Utilizing two different size of silver nano-trapezoid resonators as a building block, we engineer the phase gradients imparted by the metasurface beyond the monotonic trend to exhibit frequency-selective characteristics. Spectrum splitting for different visible-frequency component light (blue, green and red light) to completely different or even contrary directions have been demonstrated theoretically and experimentally. When white light is incident normally on a flat metasurface, the red light is reflected at an off-normal, positive angle while green light is reflected at a negative angle. To the best of our knowledge, such counterintuitive, directional wide-angle spectrum splitting and asymmetric light steering cannot be realized by any existing conventional optical devices with a single light-matter interaction.

Such unconventional metasurface building blocks when arranged using a mirror-symmetry at the center, enable the design of a multi-functional optical meta-devices that can behave as a convex, a concave or a planar mirror for different colors of visible light[3]. We believe the first theoretical and experimental demonstration of wide-angle, directional spectrum splitting, asymmetric light steering and multi-functional mirror functionalities based on versatility of the metasurfaces is of significant interest to the broad optics and photonics field[4].

Abstract-We propose new kinds of tunable metasurfaces based on multilayers of gold quantum well. By changing the laser intensity, the tunability is implemented through the ultrahigh Kerr nonlinearity of gold quantum well that we experimentally demonstrated recently.

Metasurface uses the fact that the phase of light can be changed by interaction with sub-wavelength optical scatters, such as metallic or dielectric nanoparticles [1]. Unlike the bulky conventional optical devices that modify the properties of light through the propagation phase which requires device sizes of wavelength scale, metasurface can accomplish the same functionalities within a much shorter length scale. Therefore, metasurface is promising for integrated on-chip optics. Over the past few years, metasurfaces with specific functionalities have been demonstrated using ultrathin layered structures. Examples of such planar devices include optical lens [2], beam redirector [3], wave plate [4], and optical filter [5]. Most of these metasurfaces are designed on linear optics and can only function passively. It is highly desirable to have active metasurfaces to enable tunable functionality, such as through optical nonlinearity. However, since the strength of the nonlinearity of the existing optical scatters is limited, it is extremely challenging to generate strong nonlinear interaction within ultrathin metasurface.

Recently, we found that the optical properties of ultrathin gold films (thickness <3nm) are drastically different from the bulk values due to the quantum size effect [6-7]. More importantly, findings of the optical Kerr nonlinearity of such quantum-sized gold film show a 4 order enhancement as compared to that of bulk gold [7]. Such giant Kerr response indicates that these ultrathin gold film can be used to achieve strong nonlinear interaction over much shorter length than conventional nonlinear materials. Based on this, we propose a new kind of quantum metasurface made of multilayer structures of quantum sized gold film. In the low power region where the nonlinearity is negligibly small, the quantum metasurface is similar to the existing metasurfaces. In the high power region, material properties can be modified considerably by light through optical Kerr effect. More specifically, the phase of the reemitted light of each scatter depends on the light intensity and functionality of the quantum metasurface can be tuned through light intensity. In the presentation, we will talk about our recent work on such tunable quantum metasurface.

Exceptional points in PT-symmetric metasurfaces

Jie Luo[1], Jensen Li[2], and Yun Lai[1*]

[1]College of Physics, Optoelectronics and Energy & Collaborative Innovation Center of Suzhou Nano Science and Technology, Soochow University, Suzhou 215006, China

[2]School of Physics and Astronomy, University of Birmingham, Birmingham B15 2TT, United Kingdom

Abstract-We investigate the systems consisting of a pair of PT-symmetric metasurfaces sandwiching a slab made of metamaterials. We observe two types of exceptional points in such unique systems, at which unidirectional impedance matching is established. By using an epsilon-near-zero slab, a robust one-way cloaking phenomenon is established.

We consider wave incident from dielectric medium with relative permittivity of ε_1 into dielectric medium with relative permittivity of ε_2. An ultrathin metasurface can function as an anti-reflection coating (ARC) for the two dielectric media. Under normal incidence, we find that the relative permittivity of the metasurface ($\mu = 1$) is required to be,

$$\varepsilon = i\frac{\sqrt{\varepsilon_1} - \sqrt{\varepsilon_2}}{k_0 d}. \qquad (1)$$

Equation (1) indicates that the required permittivity is pure imaginary. Both lossy and gain media can operate as the antireflection coatings [1, 2].

For a slab of dielectric or metamaterial, we can sandwich it by a pair of PT-symmetric metasurfaces. In such a system, two types of exceptional points are observed at which unidirectional propagation is established, where the PT-symmetric metasurfaces function as either a CPA-Laser pair [3], or an ARC-ARC pair. Here CPA indicates coherent perfect absorber. By changing the slab to be an epsilon-near-zero slab, an interesting robust one-way cloaking phenomenon can be established, where the cloaking effect is unidirectional.

Nonlinear optics at the nanoscale with metallic, dielectric, and hybrid nanostructures

S. A. Maier[1]

[1] Imperial College London, London SW7 2AZ, UK

Abstract – We discuss a number of schemes for the enhancement of nonlinear processes such as second and third harmonic generation, as well as four wave mixing, focusing on plasmonic, dielectric, and hybrid materials systems. For dielectric systems, anapole modes in Ge disks are shown to allow for maximizing electric field concentration in the material, leading to highly enhanced conversion efficiencies. GaP nanopillars enable localization throughout the visible regime under low-loss conditions, and hybrid structures consisting of both Au and Si elements combine "the best of both worlds" from plasmonics and semiconductor nanophotonics.

Plasmonic nanoantennas with nanoscale gaps act as efficient transducers of electromagnetic energy from the far to the near field at optical frequencies, creating hot spots of field energy utilized extensively in surface-enhanced spectroscopy and sensing. We will review applications of such nanoantennas for nonlinear light conversion on the nanoscale, and then compare with new results obtained on dielectric and hybrid plasmonic/dielectric systems. While not breaking the diffraction limit, dielectric nanoantennas can sustain Mie resonances under low-loss conditions, and we will show that this can be beneficially exploited for applications in nanoscale nonlinear optics. In particular, we will show that anapole modes in germanium disks maximize electric field concentration within the structure itself, hence leading to record nonlinear conversion efficiencies [1]. Wide-bandgap semiconductors such as GaP further enable low-loss operation throughout the visible regime [2].

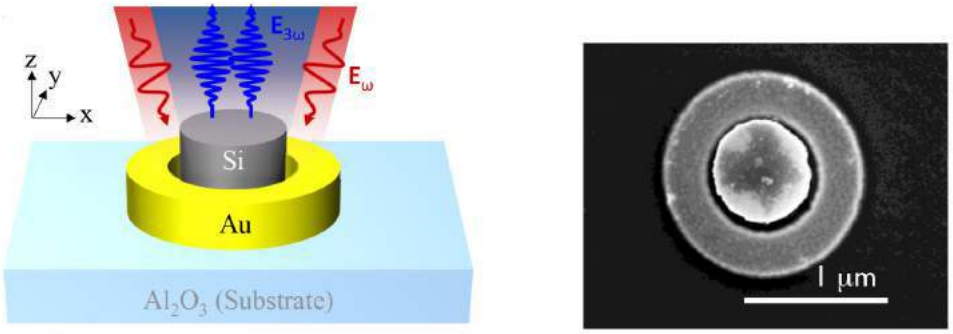

Fig. 1. A hybrid Au/Si nanoantenna structure examined for its performance as a highly efficient generator of third-harmonic radiation at the nanoscale.

We will also present as yet unpublished results on hybrid systems (Figure 1), where higher order plasmon modes of a metallic ring hybridize with modes in a concentric dielectric nanodisk, leading to a boost in conversion efficiencies via both plasmonic light localization and re-radiation, as well as concentration of energy within the dielectric material itself.

Manipulating the Polarization State of Smith-Purcell Emission by Metasurfaces

Abstract- Smith-Purcell emission is far-field radiation of light from swift electrons when electrons move closely above a periodic structure. Here we show that designer metasurfaces composed of C-aperture resonators can control the polarization state of Smith-Purcell emission on demand with high efficiency, which is very difficult to achieve via traditional gratings. These findings open up new opportunities to manipulate electron-beam-induced emission, and to develop compact, tunable and efficient light sources and particle detectors.

The sophisticated interactions between electrons and materials lay the foundation for advanced electron microscopy including electron energy-loss spectroscopy, and cathodoluminescence emission including transition radiation, Cherenkov radiation and diffraction radiation [1]. The recent advances of artificially engineered materials provide new approaches to tailoring electron-matter interactions [2]. For instance, reversed Cherenkov radiation has been theoretically proposed [3] and experimentally observed [4] in left-handed metamaterials. Swift electrons traveling above a metallic film can excite surface plasmon polaritons, which can be thereafter transformed into Cherenkov radiation with enhanced intensity [5]. In addition, researchers have reported the manipulation of Cherenkov emission by photonic crystals [6] and anisotropic metamaterials [7,8].

Here we show that the polarization state of Smith-Purcell emission, a well-known example of diffraction radiation excited by swift electrons, can be effectively controlled by metasurfaces consisting of C-aperture resonators [9]. When the speed of electrons is smaller than the speed of light in the surrounding medium, the fields associated with the electrons are non-radiative. Traditionally we can place a periodic grating close to electrons to couple the near-field energy to the far-field, leading to Smith-Purcell emission. However, the resulting wave is transverse magnetic polarized only. To overcome this limitation, we have designed C-aperture Babinet metasurfaces resonant at terahertz frequencies to control the polarization of the far-field wave, by coupling the non-radiative energy of moving electrons to the inherent electric dipole and magnetic dipole of the C-aperture resonator. Numerical simulations demonstrate that the polarization angle of the radiated light is determined by the orientation of the C-aperture resonators. We have also employed Stokes parameters to characterize the polarization state of the Smith-Purcell emission. Moreover, the efficiency of the Smith-Purcell emission from the metasurfaces is remarkably increased by 84% in comparison with the case of conventional gratings, indicating that the resonant nature of metasurfaces can significantly enhance the radiation efficiency. These results provide a new strategy to develop a compact, tunable and high power terahertz source based on the Smith-Purcell emission, polarization-sensitive detectors and other novel photonic devices.

Abstract In the present work, we demonstrate large angle, optical beam bending using dielectric metasurfaces based on asymmetric, silicon nano-structures. The largest bending angle exceeds 82 degrees. Based on the bending results we design and demonstrate an ultra-high numerical aperture (NA) flat lens, which has a NA around 0.99 at the working wavelength of 720 nm.

Dielectric metasurfaces, two dimensional arrays of resonant dielectric nanostructures, attracts increasing attention and represents a rapidly developing research direction in nanophotonics due to its low intrinsic losses [1] and fascinating functionalities, stemming from their capability to control the amplitude, polarization and phase of light in subwavelength scales. A gradient metasurface, inducing a linear phase shift in the wavefront, is one of these devices, with applications in beam bending [2]. However, in the gradient metasurface one needs several (> 2) elements for a correct phase mapping, which typically means that the so called super-cell (mapping the 0-2π linear phase) will be relatively large if the metasurface inclusions are not deeply sub-wavelength. When the super-cell is larger than the working wavelength, the bending angle cannot be close to 90 degree because of the generalized Snell's law [3]. The limited bending angle will directly connect to the maximum acceptance angle of a dielectric metasurface based flat lens, thus limiting its numerical aperture.

Here, we propose a new dielectric nanoantenna based metasurfaces to cover the large angle bending region. In these metasurfaces, each nanoantenna is tailored to scatter the incoming light into a certain desired diffraction order and to suppress energy channeling into all the other orders, thus causing light bending. The design rule here is to realize asymmetric, directional scattering into the right direction through interference of the different Mie-resonances supported by the antennas. This, in turn, can be achieved by manipulation of their geometrical parameters. Numerical results show that a carefully designed asymmetric silicon dimer can serve this purpose.

Based on this new concept, in combination with the standard gradient metasurfaces [2], we design a flat lens with sub-wavelength thickness and a NA around 0.99 at the operating wavelength (~720 nm). The maximum acceptance angle of the designed lens exceeds 82 degrees and the size of focus spot approaches the diffraction limit.

In the experimental demonstration, the silicon flat lens has a diameter of 599 μm and a focal length around 44 μm (i.e. NA ~ 0.989) at operating wavelength of 720 nm and the measured focal spot size is around 400 nm.

Abstract-We propose a novel method for energy redistribution between diffraction orders in diffractive arrays of dielectric nanoantennas and demonstrate its application for visible light beam bending using subwavelength-size TiO_2 nanoantenna elements. We prove this concept numerically and experimentally for medium (~45°) and extra-high-angle (~80°) beam bending. The designed systems show highly efficient, broadband operation for green and blue frequencies, significantly surpassing the commonly used discrete phase mapping approach.

Phase control in metasurfaces is commonly realized via discrete mapping of the desired phase with a finite number of nanoantenna elements. In particular, beam bending functionality requires a linear phase profile [1]. However, in the case of a low number of elements, corresponding to high bending angles, the efficiency dramatically drops, imposing limitations to the applicability of this method. In this work, we suggest a novel approach for large angle beam bending, exploiting a combination of nanoantenna and grating concepts. By engineering the radiation pattern of the elements/nanoantennas constituting the grating, the energy between the supported diffraction orders is redistributed; hence, the different orders can be enhanced or suppressed at will. By suppression of all reflection and undesired transmission orders all the energy can be channeled into a single transmission order, with an angle defined by the grating period and corresponding to the desired bending angle.

For the experimental demonstration, we choose dielectric nanoantenna arrays due to their lower losses, compared to plasmonics, and broader design flexibility, resulting from the interaction between the electric and magnetic multipole resonances [2]. We design TiO_2 nanostructures and experimentally confirmed high efficiency at different bending angles, spanning from medium (~45°) to very large (>80°) angles. All proposed designs show broadband operation in the green and blue regions of the visible spectrum. Moreover, the proposed concept is general and the structures can be redesigned to work at any desired wavelength, polarization and angle (with a suitable choice of materials) both in transmission and reflection configurations. Possible applications include polarization beam splitters and high numerical aperture (NA) lenses. The largest efficient bending angle obtained in our experiments is 75.5°, with around 50% transmission efficiency into the designed order, which corresponds to the numerical aperture NA~0.97 exceeding most of the commercially available objective lenses and previously reported flat lenses [3,4].

Flat and conformal optics with dielectric metasurfaces

Andrei Faraon, Amir Arbabi, Ehsan Arbabi, Seyedeh Mahsa Kamali, Yu Horie
T.J. Watson Laboratory of Applied Physics, California Institute of Technology, Pasadena, CA, USA

Abstract- In this talk I will give an overview of our progress towards design and fabrication of flat or conformal dielectric metasurface devices with multiple functionalities

Flat optical devices based on lithographically patterned sub-wavelength dielectric nano-structures provide precise control over optical wavefronts, and thus promise to revolutionize the field of free-space optics. I discuss our work on high contrast transmitarrays and reflectarrays composed of silicon nano-posts located on top of low index substrates like silica glass or transparent polymers. Complete control of both phase and polarization is achieved at the level of single nano-post, which enables control of the optical wavefront with sub-wavelength spatial resolution. Using this nano-post platform, we demonstrate lenses, waveplates, polarizers, arbitrary beam splitters and holograms. Devices that provide multiple functionalities, like simultaneous polarization beam splitting and focusing are implemented. By embedding the metasurfaces in flexible substrates, conformal optical devices that decouple the geometrical shape and optical function are shown. Multiple flat optical elements are integrated in optical systems such as planar retro-reflectors and Fourier lens systems with applications in ultra-compact imaging systems. Applications in microscopy and the prospects for tunable devices are discussed.

Low-Loss and Tunable Huygens-Source Optical Metasurfaces

A. Ollanik[1], Y. Ji[1], D. Bar-Or[1], N. Kurtz[1], and M.D. Escarra[1,*]
[1]Tulane University, New Orleans, LA, USA
[*]corresponding author: escarra@tulane.edu

Abstract- This work reports on the development of low-loss (>90% efficient), dynamically tunable (e.g. >85% modulation of transmission) Huygens-source optical metasurfaces composed of arrays of elliptical nanoantennas patterned into dielectric and phase-change materials.

Fundamental new materials insights are required to manipulate the phase and amplitude of light at the nanoscale through optical metasurfaces that are both low-loss and easily tunable. Successful platforms may serve as a key building block for a range of applications, such as high speed encoding of orbital angular momentum for optical communications. In this work, we report on advances towards low loss and dynamically tunable optical metasurfaces. These metasurfaces are composed of elliptical nanoscale antennas that are highly resonant with both the electric and magnetic field of incident light. Numerical analysis shows that these antennas can produce anomalous refraction from the UV (e.g. 378 nm) into the infrared (e.g. 1340 nm) with ~80-90% of incident light deflected into the desired direction [1]. We show bandwidth of 6% and incident angle tolerance of 30°. Experimental verification of our designs is performed using amorphous silicon antennas embedded in a SiO_2/PDMS matrix.

Due to the highly resonant nature of these metasurfaces, their optical response is easily tuned by changes in either metasurface geometry or constituent material properties. We analyze the potential of metasurfaces composed of a wide range of tunable materials, with a particular focus on vanadium dioxide, a material with a strong metal-insulator transition at relatively low temperature (~70°C). Models show that VO_2 metasurfaces may be tuned to provide >85% modulation of transmission (or reflection) and >180° modulation in phase shift within the first 10% of the VO_2 metal-insulator transition. We synthesize VO_2 via pulsed laser deposition and characterize its electronic and optical properties vs. external stimuli (e.g. temperature tuning). A clear metal-insulator transition is attained, providing a large change in the optical properties of the material. The VO_2 is then patterned into Huygens-source optical metasurfaces. The tunability of performance is experimentally measured in several ways, including direct measurement of the phase shift in the material and mapping of the metasurface's ability to guide and redirect incident light vs. external stimuli.

Future directions for this effort include the fabrication of multi-layer metasurfaces, and initial designs will be reported, including 4-way spectrum splitters. Spatially addressable, pixelated tunable metasurfaces and applications of these materials will also be discussed.

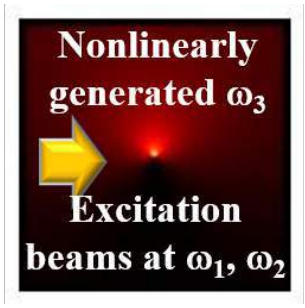
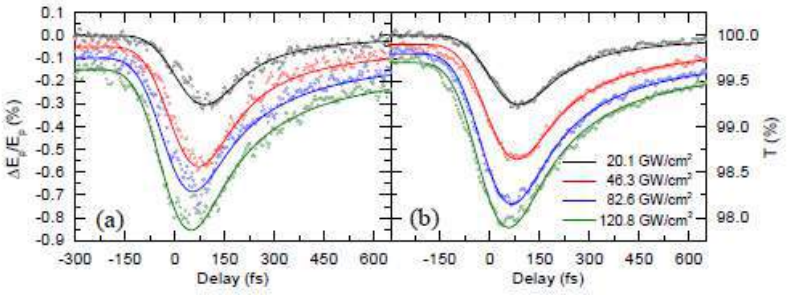
Nonlinear Scattering and Time Resolved Nonlinear Properties of Metasurfaces and Plasmonic Materials

A.M. Urbas
Air Force Research Lab, Dayton, Ohio
augustine.urbas@gmail.com

Metamaterials provide the ability to design materials properties to meet the unique needs of applications beyond what is possible with conventional materials. From spatially tailored dielectrics to tunable, dynamic material properties and unique nonlinear behavior, these systems offer tremendous flexibility to application engineers. In this presentation, we focus on studying the nonlinear properties of plasmonic and metamaterial systems where the careful balance of multipolar components allows for control of linear and nonlinear scattering cross sections and directionality. Ultimately, this will lead to tailored nonlinear response from metasurfaces. This work drives detailed studies on characterizing the nonlinearities of component materials to be used in metasurfaces. Nonlinearity in the component materials can enable controllable nonlinear excitation of multipoles leading to enhancement, suppression, directional control of nonlinear generation (as diagramed to the left), and nonreciprocal response. The overall system response is dictated by the design of the plasmonic dimer, i.e. the thicknesses and size of metallic and spacer components, and the design process is enabled by tools we have developed to retrieve dimer polarizabilities. These effects arise due to the nonlinear response of the component materials and we are actively pursuing novel materials systems and growth procedures to produce structures with controlled response. A significant part of this work focuses on the characterization of time resolved nonlinear response in plasmonic and dielectric materials. We employ the beam deflection method to measure the nonlinear refraction and absorption of thin films. Beam deflection is a pump probe technique which offers extreme sensitivity to nonlinear response in materials. This allows us to measure the response of films at the dimensions relevant to our dimer designs deposited using the same techniques and reveal thickness and process dependent changes in the properties of nonlinear materials. An example material is graphene.



Graphene is a challenging material to measure and is among the materials of interest due to its unique properties such as high thermal conductivity, damage threshold, optical nonlinearity, and broadband saturable absorption. These characteristics are useful in designing nonlinear response from structured materials. The understanding of the time dynamics of the mechanisms is relevant to the design process and of interest to the community. In this work we present nonlinear refraction, $nn2$, and nonlinear absorption, $\alpha\alpha 2$, measurements taken by the Beam Deflection (BD) technique of several plasmonic and dielectric materials, including Graphene shown above, in order to determine the response mechanisms and their associated parameters and the impact on their potential use in nonlinear plasmonics.



Topological Line Wave based on Impedance Surfaces

Dia'aaldin J. Bisharat[1,2*] and Daniel F. Sievenpiper[2]

Abstract-Analogous to surface wave formation at the interface of two semi-infinite spaces, we show a one-dimensional electromagnetic mode at the line interface of two semi-infinite planes that are characterized by complementary surface impedances. The proposed mode possesses singular field enhancement, tunable spatial confinement, extensive bandwidth, and robust wavevector-locked propagation, which may advance topological photonics applications. Here, we specify criteria for the line wave existence and present implementations using metasurfaces and graphene that are suitable for microwave, terahertz and optical applications.*n*

The ability to manipulate fields and energy flow of electromagnetic (EM) waves, such as light, is fundamental to modern sensing and communication technologies, as well as quantum information processing schemes. Due to their peak field property at the planar interfaces of dissimilar media, surface waves have been researched for over a century and have recently been exploited to realize topological photonic insulators (TPIs) exhibiting reflection-free unidirectional propagation [1]. However, current designs rely on magnetic field effects or nonplanar structures, which are not suitable for optical applications, and are limited in bandwidth due to band gaps and band inversion requirements. Here, we introduce a new EM mode that has intrinsic topological properties and other unique features, which surpass the limitations of earlier TPI concepts.

The proposed mode is analogous to surface waves, which can propagate without the need for any enclosing structure but is rather confined to a one-dimensional line at the interface between two planar surfaces. The two surfaces are characterized by complementary isotropic surface impedances, Z_{TE} and Z_{TM} which support surface modes of equal phase velocities but opposite polarizations, transverse magnetic (TM) and transverse electric (TE), respectively as follows [2],

$$Z_{TM} = \eta_0 \sqrt{1-(\frac{k_z}{k_0})^2} = j\eta_0 / \zeta \quad , \quad Z_{TE} = \eta_0 / \sqrt{1-(\frac{k_z}{k_0})^2} = -j\eta_0 \times \zeta \tag{1}$$

When interfacing the two surfaces, a new localized hybrid mode appears at the interface, as shown in Fig. 1(a). Due to the open boundary configuration and the fact that neither TM nor TE surface mode could exist at the opposite side, the line mode has a singular field concentration and decays away from the interface as shown in Fig. 1(b). In the case where ζ, a real number, tends to infinity, the TM (TE) surface becomes a perfect electric (magnetic) conductor. PEC and PMC boundaries, as ε-negative and μ-negative materials, possess different topological orders as they have opposite effects on the electric and magnetic fields components [3]. Clearly, both surfaces support evanescent waves but possess opposite signs of imaginary impedance. However, when the two boundaries are joined, EM duality, which is otherwise broken, is restored; hence new modes emerge that are a combination of magnetic and electric modes with specific phase relationships, i.e. conserved pseudo-spin values [4]. Moreover, since the pseudo-spin configuration is uniquely defined by the direction of the mode wavevector (k_z), the interface constitutes a spin-filtered channel as depicted in Fig 1(c).

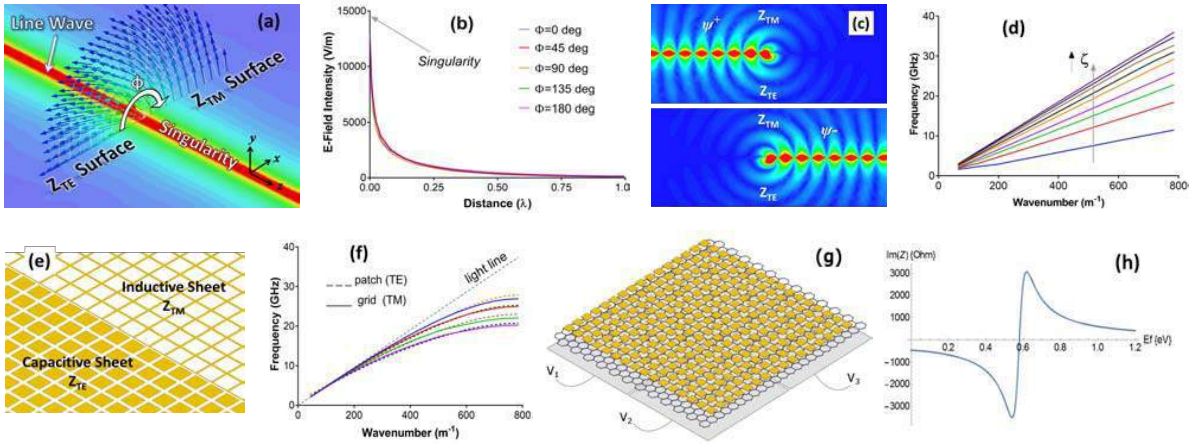

Figure 1. (a) Surface distribution and vector plot of the electric field across the interface of the line wave, (b) decay curves of the electric field at different directions around the interface, (c) pseudo-spin states excited by electric and magnetic hertzian dipoles in phase (above) and out of phase (below), (d) dispersion curves of the line mode at different ζ values, (e) implementation based on complementary FSS cells, (f) dispersion curves of TM and TE FSS cells of different sizes, (g) implementation based on graphene as a reconfigurable platform, and (h) effective impedance of the graphene metasurface at 6 THz at different chemical potentials.

This paradigm applies in general to interfacing complementary impedance surfaces, i.e. inductive/capacitive surfaces with identical ζ value. This enables stronger cross coupling between TM and TE modes and control over the line wave confinement as shown Fig. 1(d). An example of line wave implementation is shown in Fig. 1(e) based on simple frequency-selective surfaces (FSS). Fig. 1(f) shows that the respective surface modes of the complementary FSSs have dispersion curves (phase velocities) that overlap over a wide frequency band, thus giving rise to a line wave at their interface. This is clearly advantageous compared to the typical TPIs based on photonic crystals, which are limited in bandwidth [1]. Furthermore, our effective medium approach based on surface impedance allows for line waves with reconfigurable pathways through electrostatic biasing in graphene as shown in Fig. 1(g). Here, while the patch metasurface has a capacitive effect, tuning the inductive impedance of graphene sheet enables variable net impedance as shown in Fig 1(h).

This is the first demonstration of an entirely planar photonic system with wavevector-locked states that is suitable for both microwave and optical regimes. This makes the line wave an attractive candidate for robust integrated photonic circuits while being potentially the smallest waveguide possible. The exhibited strong mode confinement is a prerequisite for enhanced light-matter interactions, while the field singularity and having an air channel makes the line wave ideal for sensing applications and vacuum based electronic devices. In addition, the tuning capability can be exploited for reconfigurable systems as well as switching and modulation applications. Moreover, our approach provides a flexible and simple platform for investigating and manipulating topological states with subwavelength resolution.

[3]Tokyo Institute of Technology, Japan
[*]corresponding author: t-tanaka@riken.jp

Abstract-Recent progresses on metamaterials absorber will be presented. As an application of IR metamaterial absorbers, high sensitive molecular detection technique using resonant coupling between metamaterial and molecule is proposed and attomole level sensitivity is demonstrated. As an application of absorption engineering by metamaterial in the visible range, ink-free full color printing with controllable color attributes like hue, brightness and saturation is also demonstrated.

Recent advances in plasmonic metamaterials enable us to create unprecedented optical materials, and perfect absorptive material surfaces within a certain frequency range were demonstrated. Since the metamaterial absorber offers a unique surface condition with tailored absorption properties, a wide variety of potential applications have been proposed, such as high-efficiency thermal emitter and high-sensitive bio-chemical sensing. As an application of metamaterial absorber in IR region, we demonstrate high sensitive background-suppressed surface enhanced IR absorption (SEIRA) of molecules adsorbed on the metamaterial.

Figure 1(a) shows a unit cell cross-section of a metamaterial IR absorber, consisting of a 50-nm Au micro-ribbon on a thick Au film separated by a 30-nm MgF_2 gap layer [1]. The width (w) and unit cell dimension (Λ) were 1.5 μm and 3 μm, respectively. The surface structure was designed to exhibit an anomalous IR absorption at ~ 3000 cm^{-1}, which spectrally overlapped with symmetric/anti-symmetric C-H stretching vibrational modes. Fig. 1(b) shows a photograph of the fabricated metamaterial absorber and its SEM image.

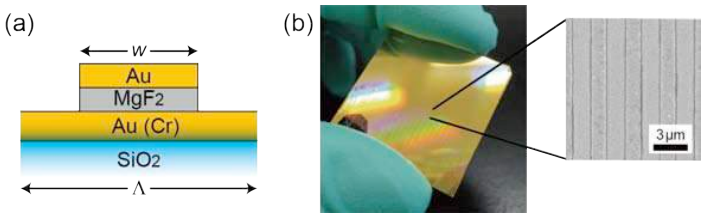

Figure 1 Metamterial IR absorber

Since the metamaterial absorber offers not only strong plasmonic enhancement but also significant background suppression, this unique surface environment improves the sensitivity of the conventional SIERA. In our experiment, 16-Mercaptohexadecanoic acid was used as a target molecule, exhibiting symmetric/ anti-symmetric C-H stretching vibrational modes at ~2855/2920 cm^{-1}. A 21.5-Å thick self-assembled monolayer (SAM) of the 16-MHDA was formed with their thiol head-group chemisorbed on the Au surface. For the reference, a bare Au sample was also prepared by the same process.

Figure 2(a) shows the measured reflection spectrum of the 16-MHDA SAM on a bare Au surface at incident angle of 80º and Fig. 2(b) shows the spectrum from the metamaterial absorber at the incident angle of θ = 40º.

For the bare Au case, the spectrum was suffered from extremely low signal quality, thus the respective absorption dips are undetectable. Moreover, it is notable that the bias of the spectral signal is more than 98% in reflectance. The metamaterial, on the other hand, exhibited a broad plasmonic absorption at 2921.9 cm^{-1}. When the molecules were in the vicinity of the surface structure, their vibrational modes resonantly coupled with the plasmonic modes of the metamaterial. This in turn produced distinct Fano-like anti-resonant peaks within a broad absorption of the metamaterial. Using the SAM packing density of 21.4 $Å^2$/molecule, we estimated the amount of the molecules with the diffraction limited IR beam spot to be ~1.8 attomoles (1.8×10^{-18} mole).

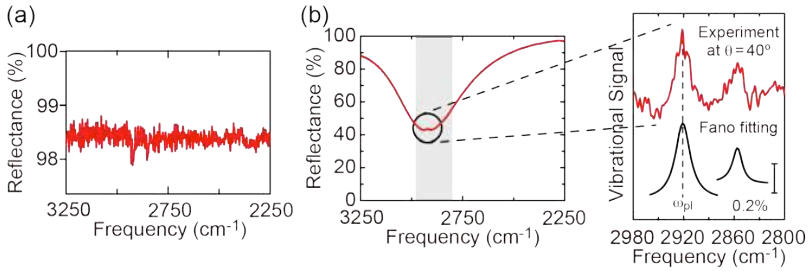

Figure 2 Background suppressed SEIRA for high sensitive molecular detection.

When we make the size of unit cell of metamaterial absorber down to several hundreds nanometers, the absorption bands move to the visible light region. We present a simple yet efficient approach for ink-free color printing employing sub-micrometer scale plasmonic pixels of single constituent metal structure that supports near unity broadband light absorption at two distinct wavelengths, facilitating the creation of saturated colors [2]. The dependence of these resonances on two different parameters of the same pixel enables controllable color attributes such as hue, brightness and saturation across the visible spectrum. Here we present an up scalable color printing scheme using plasmonic pixels of single constituent metal structure, enabling the design of full colors with controllable color attributes. Figure 3 shows the experimental results; Fig. 3(a) is RIKEN's logo observed by optical microscope and (b) is its structure observed by SEM. Fig. 3(c) shows a full color palette made by controlling the size of unit cell of the metamaterial.

Abstract- We will review recent advances in metamaterials research directed towards the development of switchable and tunable functional nanostructures. Metamaterials research has migrated from the study of exclusively metallic plasmonic structures to embraces a large variety of advanced material platforms, including dielectrics, semiconductors, superconductors, topological insulators and complex hybrid systems. We will discuss coherent control of metasurfaces, all-optical and electro-optical switching with reconfigurable nano-opto-mechanical and phase-change metamaterials and ways in which functional metamaterials can be integrated with optical fiber platforms.

A three-dimensional negative index medium and a miniature surface plasmon polariton amplitude modulator

**E-mail: tjyen@mx.nthu.edu.tw*

In this talk, I introduce two metadevices. Firstly, we design and construct a three-dimensional (3D) negative index medium (NIM) composed of gold hemispherical shells to supplant an integration of a split-ring resonator and a discrete plasmonic wire for both negative permeability and permittivity at THz gap. [1] With the proposed highly symmetric gold hemispherical shells, the negative index is preserved at multiple incident angles ranging from 0° to 85° for both TE and TM waves, which is further evidenced by negative phase flows in animated field distributions and outweighs conventional fishnet structures with operating frequency shifts when varying incident angles. Finally, the fabrication of the gold hemispherical shells is facilitated via standard UV lithographic and isotropic wet etching processes and characterized by μ-FTIR. The measurement results agree the simulated ones very well. Next, we present a miniature surface plasmon polariton amplitude modulator (SPPAM) by directing and interfering surface plasmon polaritons on a nanofabricated chip. [2] Our results show that this SPPAM enables two kinds of modulations. The first kind of modulation is controlled by encoding angular-frequency difference from a Zeeman laser, with a beat frequency of 1.66 MHz; the second of modulation is validated by periodically varying the polarization states from a polarization generator, with rotation frequencies of 0.5-10k Hz. In addition, the normalized extinction ratio of our plasmonic structure reaches 100. Such miniaturized beat-frequency and polarization-controlled amplitude modulators open an avenue for the exploration of ultrasensitive nanosensors, nanocircuits, and other integrated nanophotonic devices.

Transformation behind equivalent metamaterial chains for caustic generation

F. Zhong[1], H. Liu[1], S. Zhu[1] and J. Li[2]

Abstract- We establish a metric interpretation to generate plasmonic caustic using one-dimensional chain of metamaterial atoms with variable orientation profile. Such an approach can be straight-forwardly applied to generate caustic with arbitrarily given shape. We also explore the relationship of the metric interpretation of caustic to motion in curved space-time using a Lorentz-like transformation between equivalent trajectories with experimental realizations.

In 2015, Capasso's group used a line of metallic nano-holes to generate surface plasmon wakes with circular polarized light and interpreted it as analogue Cherenkov radiation[1]. The effect is achieved by the variation of the orientation of the nano-holes, the generated surface plasmon polariton (SPP) signal carries an additional geometric phase[2] and provides a way to generate the wave-front. In terms of the analog motion of the charged particle, it corresponds to a constant velocity.

On the other hand, if the orientation profile of metallic nano-holes on the straight trajectory is non-linear or the trajectory of the nano-holes is curved, a caustic, instead of a planar wavefront, forms[3,4]. In the current work, we would like to investigate the analogy of such a scenario to accelerated particle motion, and explore the transformation between equivalent nano-hole trajectories to generate the same caustic.

For a given caustic to generate, we can write it as a parametric function $\big(X(\tau), Y(\tau)\big)$. If we instruct a one-dimensional chain of nano-slots with variable orientation profile $\alpha(l)$ along a curved trajectory l to generate such a caustic, we have established the metric of problem as

$$d\tau^2 = |\nabla\tau|^2(dl^2 - (4/k_{SPP}^2)d\alpha^2) \tag{1}$$

where τ is the caustic parameter connecting to the trajectory, l is the length along trajectory and k_{SPP} is the wave-number of the surface plasmon polariton. With such a metric interpretation, the orientation profile $\alpha(l)$ can be straight-forwardly obtained by integrating the metric using

$$\alpha(l) = \frac{k_{SPP}}{2}\int\sqrt{dl^2 - \frac{1}{|\nabla\tau|^2}d\tau^2} \tag{2}$$

Fig.1(a), (b) and (c) shows the simulation, experimentally measured SPP profile and SEM (scanning electron microscopy) picture of the sample for generating a given caustic by shining LCP (left-handed circular polarization) light to the sample, showing the validity of such a metric interpretation.

Such a metric interpretation also allows us to establish a coordinate transformation between equivalent trajectories (along l and along l') to generate the same caustic as

$$|\nabla\tau|\begin{pmatrix}\Delta l\\ 2\frac{\Delta\alpha}{k_{SPP}}\end{pmatrix} = |\nabla\tau|'\begin{pmatrix}\cosh\zeta & \sinh\zeta\\ \sinh\zeta & \cosh\zeta\end{pmatrix}\begin{pmatrix}\Delta l'\\ 2\frac{\Delta\alpha'}{k_{SPP}}\end{pmatrix} \tag{3}$$

The coordinate transformation is in analogy to a Lorentz transformation where ζ plays the role of rapidity in conserving the metric in Eq. (1). The rapidity between the two frames also satisfy an analog velocity subtraction formula in relativity:

$$\tanh\zeta = 2\left(\frac{d\alpha}{dl} - \frac{d\alpha}{dl'}\right) / \left(k_{SPP}^2 - 4\frac{d\alpha}{dl}\frac{d\alpha'}{dl'}\right) \quad (4)$$

Fig.1(d), (e) and (f) shows such an equivalence using again simulation, experimentally measured SPP profile and SEM picture of the sample for generating the same caustic but along a different trajectory (Fig. 1(f)) by shining LCP (left-handed circular polarization) light to the sample. There is a caustic marked in white dashed line appearing both in simulation and experiment for the two cases (flat and curved trajectories). In some cases, there might be another caustic due to the SPP signal without carrying geometric phase.

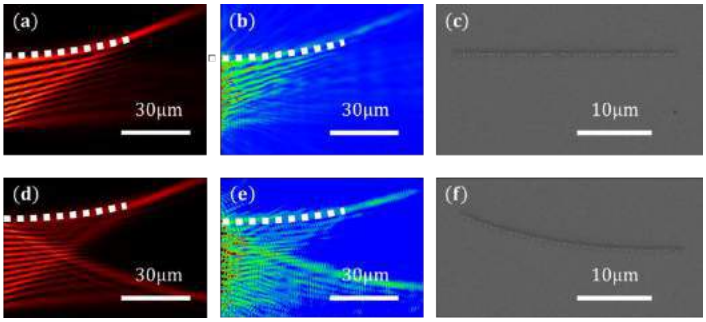

Figure 1 (a) simulation, (b) experimental results of using LCP to excite metallic nano-holes placed in a straight line as in (c) SEM picture. (d) simulation, (e) experimental results of using LCP to excite metallic nano-holes placed in a curved line as in (f) SEM picture.

In summary, we have provided a metric interpretation to generate plasmonic caustic using one-dimensional chain of metamaterial atoms with variable orientation profile. Such an approach can be straight-forwardly applied to generate caustic with arbitrarily given shape. We also explore the relationship of the metric interpretation of caustic to motion in curved space-time.

Reconfigurable beam steering using gate-tunable metagratings

Ragip A. Pala,[1,2] Ghazaleh Kafaie Shirmanesh,[1, 2] Ruzan Sokhoyan,[1] Yao-Wei Huang,[1,2] Ho Wai Howard Lee,[1,2] and Harry A. Atwater[1, 2]

Abstract - *We experimentally demonstrate gate-tunable metasurfaces that enable electrical control of the phase of the plane wave reflected from the metasurface. Our design utilizes field-effect modulation of the complex refractive index of indium tin oxide (ITO) layers incorporated into metasurface antenna elements which are configured in reflectarray geometry[1]. We measured a phase shift of 180^o by analyzing the reflection phase from the metasurface elements at their design wavelength of 1550nm using Michelson Interferometry. We also show possibility of controllable beam steering up to 40^o by applying independent bias on individual antenna elements. This work provides insight towards reconfigurable beam steering devices, dynamic holograms, and tunable ultrathin lenses based on electrically tunable metasurfaces.*

Novel ultrathin optical components based on metasurfaces were recently proposed such as flat lenses, wave plates, holographic surfaces and surfaces with angular momentum manipulation and detection. However, while metasurfaces hold considerable promise for fundamental advances and novel applications, lack of dynamic tunability and low optical efficiency limits their use in a wide range of applications. A successful implementation of tunable metasurfaces requires large phase shifts ($\theta > 270^o$), moderately large amplitude response, and robustness to structural variations and surface roughness. To enable a large phase shift, a substantial change in the permittivity is required to sufficiently shift the resonances, while a small loss parameter is necessary to enable a resonance bandwidth smaller than the spectral bandwidth of the phase shift. On the other hand, in any dispersive material system, these quantities are coupled to each other which imposes a limit on the achievable phase shift. Due to these limitations, it's critical to develop effective resonant metasurface designs to achieve large phase tunability under applied bias.

In this work, I discuss several optical designs that we have critically evaluated for effective beam steering, exploiting tunable electronic properties of conducting oxide materials. For the phase control, a gate-tunable metasurface enables dynamic electrical control of the plane wave reflected from the metasurface (Fig. 1A-B). Tunability arises from field-effect modulation of the complex refractive index of conducting oxide layers incorporated into metasurface antenna elements of fishbone shape (Fig. 1C-D). The fishbone structure provides an additional parameter to independently control the resonance properties through the length of antenna, which is an essential element for realization of 2-dimensional phase control of the metasurface array.

Reflectance spectra of metasurfaces with different antenna lengths (160 nm to 200 nm) are shown in Fig. 1E. By choosing an appropriate antenna length, we can ensure that the magnetic dipole plasmon resonance occurs at a target wavelength in the near-infrared region. We measure a phase shift of 180° and ~30% change in the reflectance by applying 2.5 V gate bias at our operation wavelength of 1550nm with modulation frequencies exceeding 10 MHz (Fig. 1F). Additionally, we demonstrate electrical switching of ±1 order diffracted beams by electrical control over subgroups of metasurface elements and show controllable beam steering up to 40° by applying independent bias on individual antenna elements, a basic requirement for electrically tunable beam-steering phased array metasurfaces (Fig. 1G). This demonstration at NIR frequencies opens the path to applications in ultrathin optical components for imaging and sensing technologies, such as reconfigurable beam steering devices, dynamic holograms, tunable ultrathin lenses, nanoprojectors, and nanoscale spatial light modulators.

Abstract- We present our recent development on the use of tunable transparent conducting oxides to demonstrate an electrically tunable metasurfaces that can tune the optical phase and amplitude for on-chip beam steering devices and perfect absorbers. We find that ultrathin epsilon-near-zero (ENZ) conducting oxide multilayers absorb >95% of light in 1-1.5 μm wavelength range with field-effect tunability.

Light harvesting and high-resolution optical technologies demand optical coatings with strong light absorption. Recent studies suggest that epsilon-near-zero (ENZ) materials can be useful to make perfect ultrathin film absorbers [1-3]. The ultrathin ENZ layers support radiative Berreman and bound ENZ modes [2, 4]. Excitation of these modes in two different incident light configurations leads to resonant absorption. In this work, a broadband perfect absorber has been demonstrated by using a stack of ITO nanolayers with gradually varying electron concentration and hence ENZ frequency. The light absorption dependence on the ENZ layer thickness in the multilayer stack was optimized so that absorption >95% was achieved at deep subwavelength ENZ thicknesses. Electronically tunable absorption via formation of electron accumulation/depletion layer in the field-effect devices was studied.

The ENZ multilayers are composed of 4 ITO nanolayers. The TM-polarized light absorptance as a function of the wavelength is shown in Fig. 1c. The carrier concentrations of the ITO nanolayers are $N_1 = 1\times10^{21}$ cm^{-3}, $N_2 = 8\times10^{20}$ cm^{-3}, $N_3 = 6.1\times10^{20}$ cm^{-3}, and $N_4 = 4.9\times10^{20}$ cm^{-3}. The optical properties of the ITO are modelled using free electron Drude model. We found that the highest absorption can be achieved with the ITO thickness of ~ 10-30 nm in the ENZ multilayers. The absorptance is attributed to the excitation of the radiative Berreman mode. The ENZ multilayer is supported by a thick gold reflector. The electron concentration decreases, and ENZ wavelength increases, from the top to the bottom of the multilayer stack. Broadband maximum absorption >95% and field enhancement are observed at the ENZ wavelengths by exciting Berreman mode. Excitation of the bound ENZ mode in the Kretschmann-Raether configuration) results in resonant light absorption with much borader bandwidth than the Berreman mode. The absorptance of >95% for more than 500 nm wavelength range is observed for the multilayer stack with 8-nm thin ITO layers.

Tunable absorption can be enabled by the field-effect dynamic in metal-oxide-semiconductor (MOS) configuration. The MOS device consists of a metal substrate, single 8-nm thin ITO layer, and 5-nm-thin HfO_2 layer between them. Electron accumulation occurs in ITO at the ITO-HfO_2 interface when bias is applied between metal and ITO, thus modifying the complex dielectric constant of the ITO. Electron accumulation increases plasma and ENZ frequency and therefore leads to a blue shift of the absorption peak in wavelength [5].

The larger absorptance change (> 300%) is observed at shorter wavelengths due to larger field enhancement in the accumulation layer. These results open the path to develop ultrathin tunable ENZ absorbers and thin-film modulators.

Efficient suppression of reflection is a key requirement for perfect absorption of light. Recently, it has been shown that reflection can be effectively suppressed utilizing a single ultra-thin film deposited on metals or polar materials featuring phonon resonances. The wavelength at which reflection can be fully suppressed is primarily determined by the nature of these substrates, and is pinned to particular values near plasma or phonon resonances – the former typically in the ultraviolet or visible, the latter in the infrared. Here, we explicitly identify the required optical properties of films and substrates for the design of absorbing anti-reflection coatings based on ultra-thin films. We find that completely suppressed reflection using films with thicknesses much smaller than the wavelength of light occurs within a spectral region where the real part of the refractive index of the substrate is $n \lesssim 1$, which is characteristic of materials with permittivity close to zero. We experimentally verify this condition by using an ultra-thin vanadium dioxide film with dynamically tunable optical properties on several epsilon-near-zero materials, including aluminum-doped zinc oxide (AZO). By tailoring the plasma frequency of the AZO, we were able to tune the epsilon-near-zero point, thus achieving suppressed reflection and near-perfect absorption at wavelengths that continuously span the near-infrared and long-wave mid-infrared ranges.

Hot Electron Enhanced Thermionic Emission (HEETE) converters for all-metal optical power generation.

N. Hogan[1], S. Wu[1], and M. Sheldon*[1,2]
[1]Departmetn of Chemistry, Texas A&M University, USA
[2]Department of Materials Science & Engineering, Texas A&M University, USA
*corresponding author: sheldonm@tamu.edu

Abstract- We report on our studies of photo-induced charge transport from nanostructured metal metasurface absorbers. In particular, we outline how the remarkable thermal and optical energy concentration provided by plasmonic resonances can enable a new thermodynamic power cycle whereby photo-excited 'hot' electrons and resonant photothermal heating provides a dual excitation mechanism for electron emission. Because this process is closely related to purely thermionic emission, we label an optical power-converting device based on this mechanism a Hot Electron Enhanced Thermionic Emission (HEETE) converter. The strong enhancement of both thermal and optical energy channels, may enable a significantly more efficient strategy for optical power conversion, and one that can theoretically out-perform traditional semiconductor-based solar cells.

Our study emphasizes theoretical and experimental development of refined models for electronic distributions in metals, specifically when characteristic structural features are smaller than the mean free path of excited carriers. In addition, we have developed a mechanistic model of the photo-thermal response of optimized plasmonic absorbers accounting for factors such as spectral width of absorbance and emissivity, as well the role of thermal damping pathways such as conduction and convection. When radiative loss is the dominant cooling mechanism, as can be achieved with thermionic devices in vacuum, we anticipate solar-induced temperature increases over 1500 K without additional optical concentration, and consequent photo-induced current densities with 10^{15} enhancement compared with purely thermionic emission at the equivalent temperature.

The optimal structures to achieve these temperatures have high absorption (> 90%) with spectral bandwidth that spans the visible up to 1100 nm, and emissivity of ~2% throughout the infrared. Importantly, properly designed surfaces also significantly constrain the angular dependence of thermal emission, enabling absorbers that can approach the theoretical maximum temperature achievable under direct sunlight (5800 K). We show a variety of noble metal nanostructures (Au, Ag, Cu), and high melting point metals (W, Ir, Pt), combined with refractory dielectric cladding that can provide these ideal optoelectronic properties due to their thermal tolerance, highly absorbing and tunable plasmon resonances in the visible, and naturally low and tunable emissivity in the infrared. In combination with full-wave optical simulations that guide optimized designs, we have fabricated HEETE device test structures and measured the spectral and temperature performance in vacuum, outlining opportunities for optical power conversion.

Abstract

We experimentally demonstrate an anomalous polarization state emitted by a propagating singular plasmonic field from an adiabatically tapered nano cone. This phenomenon is attributed to the specific 3D geometry of the system allowing the increase and the full transfer of the intrinsic transverse plasmonic spin to the far-field. Our model is numerically tested and experimentally verified in this work..

1. Introduction

Structured light beams have been the subject of an intense work in the last years [1, 2] due to the numerous potential applications they may offer in several disparate technological and research fields, ranging from super-resolution imaging [3] to optical tweezing [4] and nanomanipulation [5] to telecommunications [6].

The possibility to produce and analyze singular optical beams at the micro and the nanoscale led to focus on the interaction of light with metallic nanostructures, resulting in Surface Plasmon Polaritons (SPPs) carrying angular momentum (AM) [7, 8, 9, 10, 11, 12, 13, 14]. We will refer to these waves as Plasmonic Vortices (PVs). Such modes are generally surface confined helical electromagnetic distributions with a field singularity. The strength of the singularity, termed the topological charge of a vortex, is defined by the phase ramp acquired in one round trip about the singularity center. This charge is proportional to the AM carried by the field [15, 2].

Several intriguing phenomena have been already studied in these plasmonic wavefronts, such as particle trapping, plasmonic focusing, optical switching etc [16]. Here, we investigate the interaction of these near-field distributions with the far-field beam. Specifically, we propose a system capable of coupling the PV to the far-field with the given AM and at a given polarization state. Moreover, we study a peculiar phenomenon of the helicity locking due to the transverse plasmonic spin carried by the PV. This angular momentum component is shown to significantly affect the far-field emission in our system. We present a geometric model predicting the resulting far-field helicity and demonstrate its application in an experiment with nanofabricated plasmonic system.

2. Far-field coupling of PV by acelleration on a smoothed taper

As was recently shown, PVs can be generated by using spiral grating couplers, which have been sometimes called plasmonic vortex lenses (PVLs) [9]. We assume an Archimede's spiral whose radius are given by $R_m(\varphi) = R_0 + m \cdot \varphi/k_{SP}$, where R_0 is the smallest radius of the groove, m is the topological order of the spiral and φ is the azimuthal angle. The field distribution of the PV consists of a helical plasmonic wavefront of the form $E_{SP} \propto e^{-il\varphi}$, where l - a quantum azimuthal number is commonly called the topological charge. The AM of the resulting PV is then given by its topological charge, $l = \sigma_i + m$, where σ_i is the circular polarization handedness of the incident light ($\sigma_i = +1, -1$ for right-handed and left-handed state respectively). In contrast with propagating vortices the PV is surface-confined and propagates towards the center of the grating [17, 18, 19] (its z componenmt of the momentum is a purely imaginary number). Accordingly, this near-field distribution is not capable of transmitting AM to the far-field. While propagating optical vortices can play a role of AM transducer for nano-manipulations or an optical communication channel [4, 5, 6] plasmonic structures provide a compact and convenient solution for field manipulation and PV generation. In this context there has been a significant concern as for the far-field coupling of the PVs by means of a nanostructure. Such a component should bring about an important functionality of a PV generation and manipulation in the near-field [13, 20, 12].

In this context we have designed a system comprising of a plasmonic spiral grating with a smoothed conical golden tip placed at its geometrical center [14, 21]. Due to its high guiding and efficiency directionality this plasmonic 3D design have been recently presented as useful tool for nanoscale chemical mapping [22] for enhanced IR plasmonics [23] and intracellular plasmonic sensing [24].

The geometry of the system is presented in Fig. 1 along with the scanning electron micrograph of the fabricated system. We analyze the electromagnetic field distribution by means of the COMSOL ®multiphysics software considering a $\lambda_0 = 780nm$ circularly polarized beam impinging on the grating grooves from the bottom. In Fig. 1 it is clearly seen that by modifying a curvature radius, r_c of the tip base the coupling of the plasmonic vortex to the conical

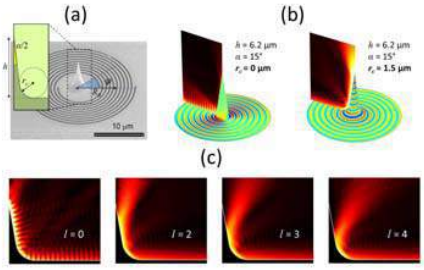

Figure 1: Coupling of PV to the far-field. (a) SEM image of the structure with its geometrical parameters. (b) Comparison of the plasmonic mode coupling to the cone with zero basis curvature versus an optimized one. (c) Plasmonic field distribution on the tip for different PV topological charges.

waveguide can be sufficiently increased. In Fig 1b the two cases are compared - (i) $r_c = 0$ and (ii) the optimized value, $r_c = 1.5\mu m$.

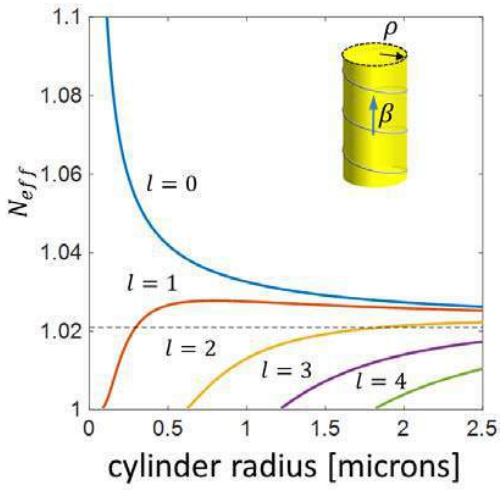

Figure 2: Dispersion of the effective index of the PV mode propagating on a metallic cylinder versus radius.

While in the first case it is evident from the fringes on the surface that most of the PV power is reflected back from the tip, the second case shows a smooth coupling of most of the energy to the guided mode. We also note that this mode is then perfectly coupled to the far-field. The best far-field beaming is obtained for a PV with the topological charge of $l = 1$ (See Fig. 1c) in a form of a point-like source. Higher topological orders produce beams with divergence proportional to their l. We have recently shown that these are Laguerre-Gauss distributions carrying an AM of $l_o \pm \sigma_o$, where σ_o is the emerging light's spin state. The beam was shown to detach from the tip surface at a point where the momentum of the guided mode perfectly matches the one of the corresponding free-space beam.

In Fig. 2 we show a dispersion of the guided mode's effective index, $N_{eff} = \beta/k_0$ (here β is the mode's propagation constant derived from the direct boundary condition solution and $k_0 = 2\pi/\lambda_0$ is the free space momentum) on a metallic cylinder versus the cylinder radius ρ (see the inset). Apparently the mode with $l = 0$ has an increasing index which is manifested by a strong light localization at the apex (Fig. 1). Nevertheless, other modes with $l > 1$ accelerate, and their effective index drops with decreasing radius. At the point where $N_{eff} = 1$ the mode detaches and propagates to the far-field. The mode with $l = 1$ is the only one that survives to the end of the tip, which can be deduced from the asymptotic behavior of the index.

3. Helicity locking

We calculate the transverse field distribution slightly above the detachment points (shown by the yellow dashed line in the insets). The complex field values are used to calculate the local polarization ellipse that is graphically presented on the top of the intensity distribution (Fig. 3). The emerging polarization handedness, $\sigma_o = +1$ is shown in red while $\sigma_o = -1$ is in magenta. Note that the emerging modes are both right-handed and very close to the circular state.

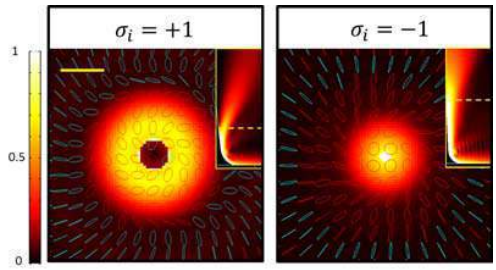

Figure 3: Calculated intensity and polarization distribution at the vortex detachment point for different incident spin states. The insets show the intensity flow along the tip and the yellow dashed line represent the height at which the distribution was taken. The scalebar is 1 μm.

In other words our system emits $\sigma_o = 1$ *independently* on the incident handedness. Apparently, most of the previously discussed axially symmetric scattering architectures, such as circular or coaxial apertures were shown to couple PVs to radially polarized beam, that naturally consisted of almost equal amounts of right and left CP [7, 9, 13]. Here we link the emission of a single-handed polarization to the so-called transverse spin (TS) of the plasmonic mode. The TS of the surface wave propagating in x direction on a metal-air interface is given as

$$\mathbf{s}_\perp \propto \frac{Re\mathbf{k} \times Im\mathbf{k}}{(Re\mathbf{k})^2} \qquad (1)$$

where $\mathbf{k} = k_{SP}\hat{\mathbf{x}} + i\kappa\hat{\mathbf{z}}$ is the the complex valued evanescent wave vector, $\kappa = \sqrt{k_{SP}^2 - k_0^2}$, $k_0 = 2\pi/\lambda_0$ is the vacuum wavenumber and k_{SP} is the in-plane plasmonic wavenumber [25]. This transverse spin results from the

rotation of the resultant of the vectorial plasmonic field, $\mathbf{E}_{SP} = E_p(\hat{\mathbf{z}} - i\chi\hat{\mathbf{x}})$ in a transverse plane with respect to the propagation. Remarkably, the TS is independent of the polarization and solely arises from the amplitude ratio between the longitudinal and the transverse field components χ, that is directly obtained from Maxwell's equations, $s_\perp = \chi = \frac{\kappa}{k_{SP}}$. Accordingly, $s_\perp$ is locked to the SPs propagation direction and can appear with a single handedness. This property has been already utilized for spin-dependent unidirectional plasmonic excitation [26, 27], for nanoparticle tweezing [28, 29, 30, 31] and for study of quantum plasmonic effects [32].

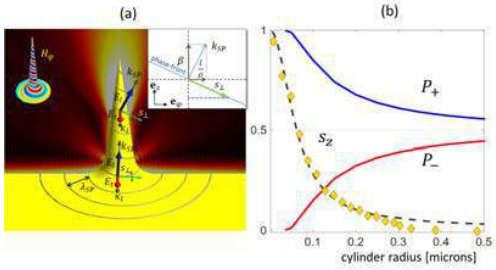

Figure 4: Geometric model of the helicity locking. (a) A conceptual scheme of the TS projection in PV. Details are in the text. (b) Local helicity currents (blue and red lines), TS projection on z axis (dashed) and simulated values of the emerging spin (rhombuses) versus the cylinder radius.

We investigate this phenomenon using the geometry of the system as shown in Fig. 3a. A helical phase-front of the PV (represented as a line spiraling around the cone) propagates on a smoothed cone with a local wave vector k_{SP}. The transverse and the longitudinal components of the local plasmonic field are denoted in the Figure as E_t and E_l, respectively. As can be seen the incidence plane follows the phase-front and gets tilted as the mode propagates upwards. Accordingly, the z projection of the local TS (green arrow) grows.

In a local tangential reference frame $(\mathbf{e}_z, \mathbf{e}_\varphi)$ the complex plasmonic wave vector is represented as $\mathbf{k}_l = \beta\mathbf{e}_z + \frac{l}{\rho}\mathbf{e}_\varphi + i\kappa_l\mathbf{e}_\rho$. By substituting the $\mathbf{k}_l$ in Eq. 1 the TS of the plasmonic wave can be calculated. The z component of the plasmonic TS is then given as,

$$s_z = -\frac{\kappa_l}{k_{SP}^2}\frac{l}{\rho} \tag{2}$$

where $\kappa_l = \sqrt{\beta^2 + \left(\frac{l}{\rho}\right)^2 - (2\pi/\lambda_0)^2}$ and $k_{SP}^2 = \beta^2 + (l/\rho)^2$. The mode detaches from the tip where the effective index becomes unity, i.e. where $\beta = k_0$. The emerging spin at that point is then $s_z = -\left[k_0^2(\rho/l)^2 + 1\right]^{-1}$.

In Fig. 3b we analyze the mode $l = 1$ propagating on a cylinder. We use the calculated fields in the circular basis, $\mathbf{E}_\pm = |\mathbf{E} \pm iZ_0\mathbf{H}|$ (Z_0 is the vacuum impedance) to derive the local field helicity current [33], $\mathbf{P}_\pm = \pm\epsilon_0 k_0 Im\left[\mathbf{E}_\pm^* \times \mathbf{E}_\pm\right] / |\mathbf{E}_\pm|^2$ and depict its integrated value in Fig. 3b. At the same Figure we present the calculated s_z (Eq. 2) as a function of the cylinder radius by using previously derived β values. Finally, we simulate an SP mode propagating on the metallic cone with realistic parameters and directly calculate the TSAM in the vicinity of the cone at different heights. Its integrated values are shown in Fig. 3b as yellow rhombuses. We note that the values of s_z calculated at the real tip fully correspond to the ones extracted from the modal analysis of the cylinder. Moreover, it is clearly visible that for the small radius both, the far-field ellipticity P_+ and the s_z become unity, which indicates the emission of a pure circular polarization with $\sigma_o = sgn(l)$. On the other hand, for large radii the s_z tends to zero. This indicates that if the field was emitted from this point its polarization would contain equal amounts of right handed and left handed CP. The latter behavior is expected from the metal due to its non-duality and was widely discussed elsewhere [34]. Obviously, the described effect of anomalous spin selectivity can be expected from all helical plasmonic modes. This can be understood from Eq. 2 with the real cutoff radius values, where s_z rapidly goes to unity as a function of l.

4. Experiment

The samples were fabricated using a sophisticated multi-step nanofabrication process described elsewhere [35]. The 150 nm gold film was prepared on a Si_3N_4 membrane and a spiral with $m = 0$ and $m = 2$ were milled in it. Then the tip with optimized parameters was formed in the center($r_c = 1.5\mu m$, $h = 6.3\mu m$ and $\alpha = 7.5$ deg). The SEM picture of the sample is shown in Fig. 1. We illuminated this structure from the membrane side with a collimated pigtail CW laser at $\lambda_0 = 780nm$ and by manipulating circular polarizer and analyzer the incident and the emerging polarization state could be controlled. We captured the far-field images by using CMOS camera.

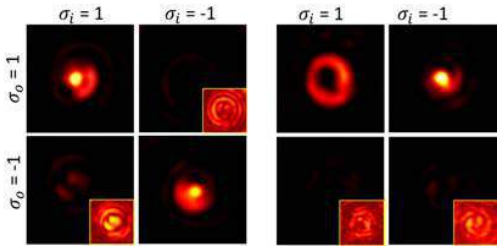

Figure 5: Experimental verification of the helicity locked emission. (a) Cross polarization measurements of the intensities emerging from the tip with $m = 0$ spiral, and (b) with $m = 2$ spiral.

In Fig. 4 the resulting distributions are presented in a table according to the polarization states. We note that for the case of $m = 0$ the system is axially symmetric and as

expected the PV with $l = \pm 1$ is obtained for $\sigma_0 = \pm 1$. In the case of $m = 2$ we obtain a PV with $l = 1, 3$. In this latter case both vortices have positive helicities which results in the only emerging light with $\sigma_o = +1$. In both experiments we measured ratios of at least 1:7 in the intensities of the two emerging polarization components. This high polarization contrast is attributed to the helicity locking of the plasmonic modes due to its intrinsic TS. Note also, that the two presented systems generate the $l = 1$ mode from different incident polarization states. Nevertheless, the emerging polarization state depends *only* on the sign of the topological charge of the PV and not on the incident handedness.

5. Summary

In summary, we have demonstrated a nanoscale plasmonic system capable of producing far-field beaming of a given AM and polarization state. The coupling of light into the system is obtained by a plasmonic spiral grating which generates a PV with a necessary charge. The vortex is then coupled to the far-field by rather a 2D coupling mechanism icorporating MIM waveguiding or a 3D system based on a smooth tip on which the PV propagets untill it detaches to the far-field carrying a desired AM. The helicity locking that stems from the intrinsic transverse spin of the plasmons leads to a purely circularly polarized emission. We beleive that this system can bear an interesting underlying physics as well as technological potential for nanophotonics.

A bottom-up approach towards metamaterials and plasmonics

About Optical Games with Eutectics $ZnO/ZnWO_4$

Abstract - We report an overview of optical properties of eutectics $ZnO/ZnWO_4$. Filtering properties and polarization dependent properties, with together nonlinear optical characterizations in the visible region are presented.

Many different optical interesting and unusual properties of eutectics [1] $ZnO/ZnWO_4$ are presented, ranging from linear up to nonlinear optical properties.

In our experiment, we use a set-up similar to the one used in [2]: a pulsed Ti:Sapphire laser with 130 fs pulse duration, wavelength of 800 nm and repetition rate of 1 kHz is used as a light source. The polarization of the fundamental beam at the laser's output is in p state and it can be tuned by means of rotating a half-wave plate at 800 nm. In order to suppress the SHG signal generated from the half-wave plate, a long pass filter is placed after the plate. The sample is placed on a rotational stage which enables tuning of the angle of incidence α. The light coming out of the sample is then filtered by a shortpass filter and set to p or s state by a polarization analyzer before the detector. With this set-up we measure the intensity of s or p SHG signal at the output as a function of the input polarization or α, and evaluate the corresponding conversion efficiency.

Spectral measurements done with Hamamatsu Spectral Analyzer show that there is a sharp, strong emission peak at λ~400 nm (i.e. SHG), much stronger for the annealed sample as well as a strong supercontinuum generation. For the s output, there is a strong SHG signal at a normal incidence only for the p polarization, while for the p output the α dependence is negligible.

Abstract- We report properties of a self-organized eutectic composite made of ZnO (Transparent conducting oxide - TCO) phase precipitates embedded in $ZnWO_4$ [1] matrix, doped with Al or Ga ions. The ZnO precipitates, with plasmonic properties, are formed as pseudo-periodically dispersed thin (~200 nm in width) layers separated by crystalline matrix. Optical properties, microstructure, chemical analysis, XRD, Raman spectra and photoluminescence will be presented.

In recent years the field of metamaterials and nanoplasmonics developed rapidly. The novel field of metamaterials and nanoplasmonics need new material fabrication techniques, especially bottom-up approaches such as self-organization. Eutectic composites are very promising candidates due to various structural motifs (fibrous/rodlike, globular, lamellar with micron or nanosized precipitates and even split-ring-resonators [2, 3, 4]) and many different component materials. Eutectics can be described as two intersecting crystals in one solid. It means that the eutectic composite in the same time is a monolith and a multiphase material. Eutectic composites can offer many interesting optical properties such as strong second harmonic generation, filtering properties, Faraday effect or nanoplasmonic properties [3], which can be even tunable [4].

Transparent conducting oxides (TCO) such as Al- and Ga- doped zinc oxide (AZO, GZO) are good candidates as plasmonic materials in the near infrared frequency. Dopants (Al^{3+} and Ga^{3+}) substitute Zn^{2+} ions, which enables increase of the free carriers concentration, and results in higher plasma frequency. In such materials carrier concentration is higher than 10^{20} cm^{-3}, so they exhibit metal-like behavior in NIR with low optical losses comparable to the noble metals at this wavelength range. TCOs as alternative plasmonic materials could be used in applications like surface-plasmon-polariton waveguides, metamaterials with hyperbolic dispersion and epsilon-near-zero materials. Plasmonic properties of TCO can be tunable [5, 6].

In this work we present self-organized nanostructure of ZnO-$ZnWO_4$ eutectic doped with different concentrations (1%, 5%, 10% at.) of Al and Ga grown by the micro-pulling down method. The optical properties of the eutectic in visible and IR, as well as polarization studies, and chemical studies will be presented.

Studying the properties of bottom-up meta-atoms based on their T-matrix.

Abstract-The T-matrix of a scatterer expresses how it couples an incident mode to a scattered mode at a given frequency. Here, we outline our recent contributions to develop methods to compute the T-matrix for arbitrary scatterers; possibly composed of many sub-elements. Based on the T-matrix, properties of these scatterers are discussed and applications are explored, e.g. scattering cancelation structures, maximal electromagnetic chiral structures, or bi-anisotropic scatterers. Emphasis is put on meta-atoms amenable for a fabrication with bottom-up approaches.

Meta-atoms that can be realized by self-assembly techniques based on bottom-up approaches are often made from a larger number of small metallic nanoparticles in complicated shapes [1]. They usually exist in solution where they can freely rotate and orient to an external illumination. To study and to quantify their properties, means are required that allow the investigation of these meta-atoms without explicitly considering a specific illumination. This means is provided by the T-matrix. The T-matrix of a scatterer expresses how, at a certain frequency, any incident field expanded in a basis set of orthonormal incident modes is coupled to a basis set of orthonormal scattered modes. In most cases and for scatterers localized in space, vector spherical harmonics are used as a basis set but this is not a strict constraint. The T-matrix can be expressed in any different basis set and, indeed, converting it among different sets can provide complementary insights.

In our contribution, we describe how to compute the T-matrix for an arbitrarily shaped scatterer [2]. This usually requires the solution of multiple full-wave simulations where the scattering response of the object to a specific illumination is solved. Projecting the scattered field on the basis sets allows to deduce the T-matrix by solving a system of linear equations in a least-square sense or exactly, depending on whether a single incident mode has been used for the illumination. In our work, we use finite-element-simulations based on the program JCMsuite and rely on a plane wave basis for the illumination.

Once the T-matrix is known, multiple properties can be deduced thereof immediately. This concerns properties of specific entries such as, e.g. a specific bi-anisotropic response, or properties that can be deduced from the T-matrix as a whole, e.g. the electromagnetic chirality [3]. Moreover, insights into the properties of the meta-atoms can be obtained from analyzing the eigenvalues and eigenvectors of the T-matrix or its singular values [4].

We focus on, but do not wish to restrict our consideration exclusively to, meta-atoms that can be fabricated with self-assembly techniques. These meta-atoms consist of a larger number of metallic nanoparticles that are assembled into complicated geometries. As an example of the analysis, Fig. 1 shows some illustrative results of our approach along with some further explanations.

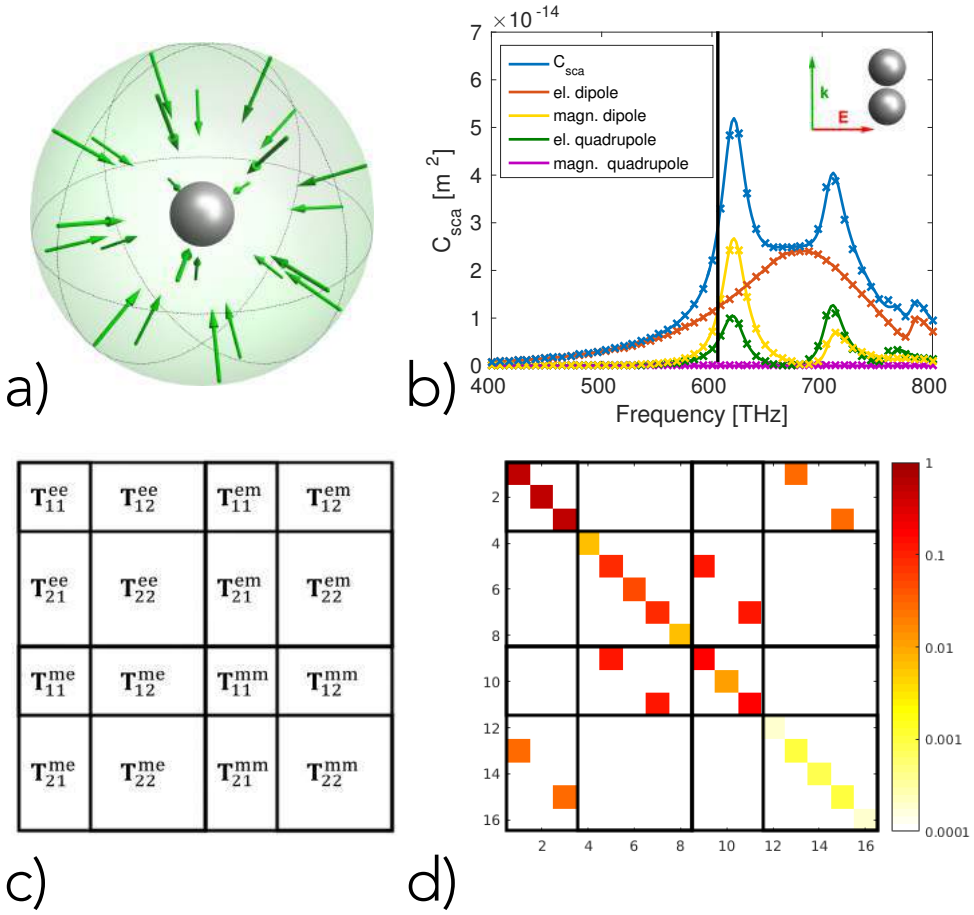

Figure 1: a) General configuration to compute the T-matrix of an arbitrarily shaped object. Many individual plane waves are considered as illumination, the full-wave response is computed and from the scattered field of each plane wave the T-matrix is constructed. b) Basic example of a silver dimer made from spheres with a radius of 30 nm and a center-to-center separation of 63 nm. The scattering cross section for a specific illumination as shown in inset has been solved with Mie theory (solid line) and a finite-element solver (crosses). c) The overall structure how we present the T-matrix, where the different electric, magnetic, and electric-magnetic entries are seen. We consider here up to a quadrupolar order. d) Amplitude of the entries of the T-matrix for the dimer at the frequency indicated by the solid line in b).

Spatial reconfiguration of plasmonic nanostructures has remained challenging using both top-down and bottom-up approaches in the field of active plasmonics. In this talk, I will introduce our work on DNA origami[1] based reconfigurable plasmonic metamolecules. The spatial configuration, and hence, the optical response of such metamolecules can be regulated by external stimuli, such as, excess of fuel DNA strands[1], light[2], change in pH[3]. The spatial reconfiguration is transduced into plasmonic circular dichroism change in the visible wavelength range.

We anticipate that such reconfigurable plasmonic nanostructures with engineered stimuli responses will advance the development of smart nanomaterials with tailored optical functionalities.

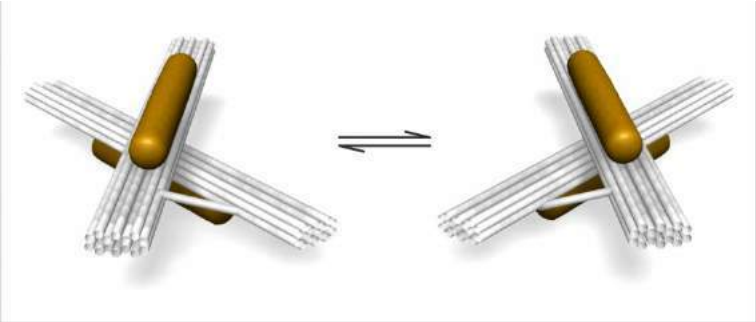

Figure 1. Schematics of reconfigurable plasmonic metamolecules. The metamolecules consist of gold nanorods hosted on switchable DNA origami templates. The precise spatial arrangement of nanorods can be control with external stimulus, e.g. excess of fuel DNA strands, light, change in pH.

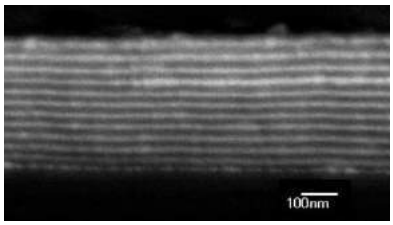
Abstract- Lamellar block copolymer nanostructures were self-assembled on a substrate, with one of the constituent phases including variable amounts of plasmonic nanoparticles. The assembly's uniaxial optical properties were measured using spectroscopic ellipsometry. The presence of an extinction of the TM wave due to a generalised Brewster effet ("topological darkness") is demonstrated, opening interesting perspectives for sensing applications. More importantly, due to high loadings in nanoparticles, we demonstrate that, within a frequency range, the parallel component of the dielectric permittivity tensor becomes negative, of opposite sign to the perpendicular component, revealing a regime of so-called hyperbolic dispersion. This is to our knowledge the first demonstration of hyperbolic behaviour in a bulk, bottom-up, self-assembled structure.

Diblock copolymer thin film engineering [1] offers a genuine technological platform for the generation of nanostructured thin films with different morphologies. The lamellar phase presents a high degree of order and uniaxial symmetry, with layers parallel to the substrate. Here, we use spun-cast lamellar poly(styrene)-b-poly(2-vinyl pyridine) (PS-P2VP) copolymer films. We spin-cast flat and homogeneous films, of controlled thickness between 200 and 700 nm and of large lateral dimensions, which spontaneously develop a multilayered structurally uniaxial thin film of alternate poly(styrene) and poly(2-vinyl pyridine) layers, each of size $d_o/2$=16 nm. We then grow in-situ gold (Au) nanoparticles selectively within the P2VP layers, thus producing a structure of alternating pure polymer (P) and Au nanoparticles: P2VP nanocomposite (NC) layers. This is achieved by dipping successively the film-bearing wafer into an Au salt solution and then into a reducing agent solution. This infiltration procedure is repeated N times, and N controls the final volume fraction of nanoparticles in the (NC) layers. An example of such a film is shown in Figure 1.



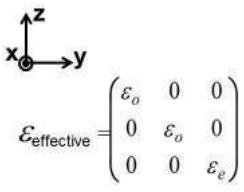


Figure 1. (left) Scanning electron microscopy side-view image (SEM) of a 370 nm-thick film of alternating pure polymer (appearing black) and Au nanoparticles - P2VP nano-composite (appearing white) layers. **(right)** Tensorial form of the anisotropic dielectric permittivity with ordinary ε_o and extraordinary ε_e components.

Variable angle spectroscopic ellipsometry (VASE) was performed in reflection. Figure 2-a shows, on one example of a sample, that for specific angles of incidence and photon energies, the ellipsometric angle Ψ cancels while Δ undergoes a near 180° jump [2]. The sensitivity of this phase jump to modifications of the optical index in the close vicinity of film provides a scheme for high-precision sensing applications.

Next, to evidence hyperbolic dispersion properties of the sample (taken as a whole, effective medium), each multilayer film was measured as a function of the number (N) of gold loading cycles. The VASE data were carefully analyzed [3] using several steps and extracted results were cross-checked with two different methods, so as to finally obtain the uniaxial effective permittivities of the multilayer film. Results (Figure 2-b) show that the components ε_o and ε_e both present a resonance close to 550 nm, with a significantly stronger amplitude for ε_o. For high gold loadings (N=25), the values of the real part of ε_o become negative close to the resonance, and opposite in sign to ε_e, thereby demonstrating the hyperbolic nature of the material.

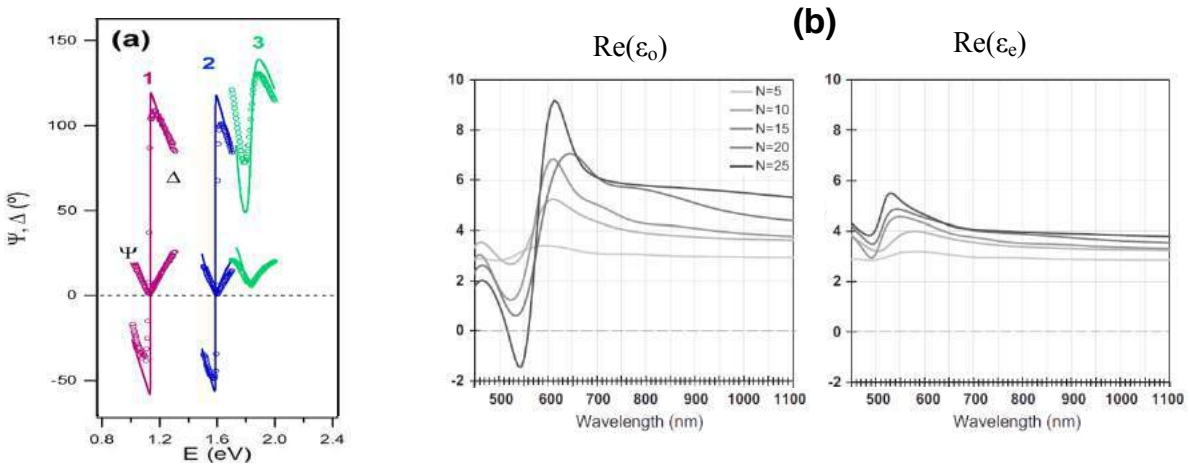

Figure 2. (a) Extinction of Ψ and jump of Δ for two different angles of incidence (trace 1 : 70.35° and trace 2 : 65.71°), while a third angle is shown to be out of extinction (trace 3 : 56.40°). Lines are simulated data for a perfect (defect-free) sample, circles are experimental values. **(b)** Real part of the ordinary and extraordinary components of the dielectric permittivity, showing the strong optical anisotropy of the film, and demonstrating the hyperbolic nature for N=25.

Interband Plasmonic Materials: A promising Platform for Nanophotonics

Abstract-We describe the optical properties of "interband plasmonic" materials and their potential for the design of active optical metamaterials for switching and sensing applications.

Research in plasmonics and metamaterials has shown ways to manipulate light down to the nanoscale by creating artificial media with properties not available in nature. These fields were first developed using noble metal nanostructures as building blocks, and in the latest years they have been enriched by employing alternative plasmonic materials, such as transparent conducting oxides or metal nitrides.[1] The plasmonic response of most of these materials is based on the optical excitation of volume free carriers.

However recently plasmonic effects at visible frequencies have been observed in nanostructures made of semi-metals (bismuth[2]) and chalcogenides (bismuth telluride[3], BSTS[4]). These materials present no optical absorption due to volume free carriers in this spectral region. Nevertheless, they share a common feature with the earlier plasmonic materials: they show a negative bulk dielectric permittivity. In this case, this feature is due to the excitation of strong interband transitions rather than volume free carriers.[4,5,6] Therefore, interband polaritons and surface conducting states have been proposed to drive the plasmonic effects observed in the nanostructures. In this presentation, we will describe the optical properties of this new type of so-called "interband plasmonic" materials in relation with their electronic structure. Their performance will be compared with that of the earlier plasmonic materials, and their potential for the design of active optical metamaterials for switching and sensing applications will be presented.

Nanoparticle trapping, sorting, and ratcheting using light forces near photonic crystal slabs

Abstract-We use the near field of a photonic crystal slab for nanoparticle manipulation. The holes of the photonic crystals form an array of optical traps. In addition to assembling regular arrays of dielectric and metallic particles, we have used this system to demonstrate nanoparticle size selection and optical ratchet motion.

In earlier work, we introduced a technique for creating an array of optical traps in the near field of a photonic crystal [1]. The photonic crystal is designed to support a guided resonance mode for normally-incident light. The mode has high field intensity in the holes of the photonic crystal, making the holes act like optical traps. Previously, we have trapped 2D periodic arrays of dielectric [2] and metallic nanoparticles [3], which can be assembled and released on demand by turning the laser on and off. This capability suggests the ability to dynamically and reconfigurably assemble photonic, plasmonic, and/or metamaterial structures "from the bottom up." Here we demonstrate two new applications of our optical trapping method: *nanoparticle size selection* [4] and *on-chip ratcheting motion* [5].

We demonstrated nanoparticle size selection using a slot-graphite photonic crystal [4]. This structure consists of a silicon slab etched with holes and slots in a pattern based on the graphite lattice [6]. The slots strongly confine light, acting as optical trapping sites. We were able to select one size of particles out of a binary mixture, creating an "optical sieve." In this case, the mixture contained equal concentrations of polystyrene particles with larger (520nm) and smaller (380nm) diameters. 94% of the particles trapped on the photonic crystal were those of the smaller size. This result provides a new method for sorting nanoparticles by size. It also suggests that uniform photonic structures and/or metamaterials can be assembled, even from a nanoparticle solution that is not monodisperse.

Brownian ratchets provide a fundamental mechanism for rectifying random motion, via breaking of spatiotemporal symmetry. We have implemented the first on-chip, near field optical Brownian ratchet [5]. We used a template with nearly triangular holes to break spatial symmetry and modulated the trapping laser. By tracing and analyzing particle trajectories, we conclusively demonstrated ratcheting motion with transport speeds of approximately 1 μm/s.

Abstract
Plasmonic nano-structures have been of great interest in bio-sensing, photonic, optoelectronic, and thermos-plasmonic applications because of their ability to control the light behavior in nanoscale. Aerogels, composed of silica nano-granules with high porosity, have air-like low refractive index and allow us exotic plasmonic phenomena. I introduce our recent results about the plasmonic applications using air-like aerogels such as plasmon resonance, SERS, and so on.

Exploiting structural versatility and fidelity of 3D plasmonic metamolecule, self-assembled on DNA origami pegboard

Abstract-Tailoring optical properties of plasmonic nanoclusters (plasmonic metamolecules) has gained special interest in the field of nanophotonics. However, the difficulties in arranging plasmonic nanoparticle in deterministic way have limited the advancement of the relevant field. To address this challenge, we report a deterministic strategy for assembling 3D cluster using DNA origami as a molecular pegboard.

Self-assembled plasmonic metamolecule, a properly tailored metallic nanocluster which exhibits unnatural electromagnetic property (e.g. artificial magnetic resonance and magnetic based Fano scattering resonance), has been extensively studied as the one of the central idea in the field of metamaterials (1-4). Recently, several studies have shown that optical magnetism can be finely tuned by controlling geometry, dimensionality, and number of nanoparticles (NPs) in nanocluster (3-4). However, reliable assembly of the 3D cluster with high structural integrity and versatility is still lacking, owing to i) difficulties in producing highly uniform metallic NPs and ii) limited ability to arbitrary control the 3D cluster geometries (i.e. symmetry and asymmetry).

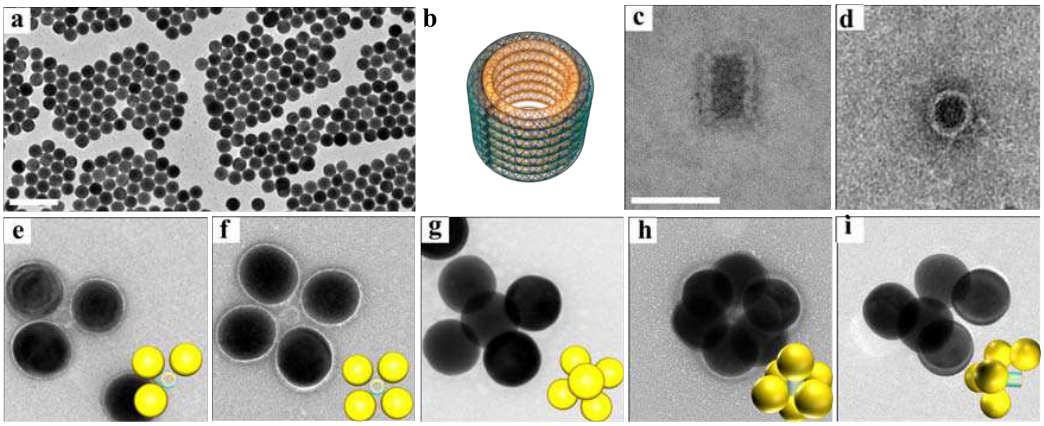

Fig. 1. Extremely uniform AuNPs were arranged into custom geometries by exploiting programmability of

DNA origami. (a) Representative TEM image of synthesized AuNPs. (b-d) Schematic image of Barrel-like DNA origami structure (b) and TEM image viewed at side (c) and top (d). (e-i) Self-assembled plasmonic metamolecules: trimer (e), tetramer (f), 3D pentamer (g), 3D hexamer(h), 3D pentamer with broken symmetry(i). Scale bars are 100nm.

In this work, to tackle these challenges, we first synthesized highly uniform and smooth AuNPs by adopting iterative reductive growth and oxidative dissolution as presented Fig. 1(a). Then, we utilized DNA origami method which provide few nanometer precision for 3D positioning NPs, molecules, and quantum dots in programmable way (6-7). To arrange AuNPs into various geometries (e.g., 3D cluster with broken symmetry) which have been challenging for other self-assembly methods, we designed 3D cylindrical DNA origami structure as depicted in Fig. 1(b-d). The surface of DNA cylinder was encoded with single-stranded DNA sticky ends to host AuNPs in programmable way. As presented in transmission electron microscope (TEM) image, the individual structures were well synthesized in high structural intactness.

Finally, we assembled 3D clusters by assigning programmable location of AuNPs on the DNA origami surface. Fig. 1(e-i) illustrates our current progress of this research. As clearly figured out, the structural fidelity and versatility of spherical AuNPs assemblies were elegantly controlled. Especially, the symmetry breaking was successfully achieved in 3D cluster by applying exotic programmability of DNA origami.

Our ultimate goal is to show that we can gain supremacy over controlling self-assembled plasmonic metamolecule by assembling extremely uniform AuNPs into custom geometry. Our results convincingly demonstrate that programmability of DNA nanotechnology provides an ultimate mean for it. Thus, we believe that our work will pave one of the ways toward a limit of engineering optical properties in nanophotonics.

Abstract: The talk will focus on high throughput, large area and low cost fabrication of quasi-3D and 3D optical nanostructures based on various printing techniques. Based on these techniques functional devices like uncooled neural sensors, mid-IR detectors, flexible reflective color displays and others are realized.

Optically active metastable defects in NBP:nAg,Er^{3+} nanoplasmonic material

B. Surma[1], M. Gajc[1], D. A. Pawlak[1,2]
[1]Institute of Electronic Materials Technology, Warsaw, Poland
[2]Centre of New Technologies, University of Warsaw, Warsaw, Poland
[*]corresponding author: Barbara.Surma@itme.edu.pl

Abstract- We report on the optical properties of the NBP glass nanocomposite doped with silver nanoparticles, nAg, and erbium ions, grown by the NanoParticle Direct Doping (NPDD) method. We observe formation of optically active metastable defects that we interpret as a result of the interaction of the glass matrix ions with the dangling bonds at the surface of silver particles and with erbium ions. Optical features of the defects were explained by using coordinational coordinate model, CC. Additionally we show that the presence of the silver particles leads also to the decreasing the free-OH absorption in boron-phosphate glass.

Most of current fabrication processes of plasmonic materials and materials with plasmonic-related functionalities arrange metal nanostructures at the dielectric surfaces but the fabrication of volumetric nanoplasmonic composites still remains a challenge. Recently we have developed new approach to obtain volumetric plasmonic nanocomposites through a non-chemical process called NanoParticle Direct Doping (NPDD) method.[1] The NPDD method is based on the directional solidification of dielectric matrices and allows to carry out the doping process during the pulling of the glass fiber with any chemical agents and, plasmonic , semiconductor or anisotropic nanoparticles.

In this work by using NPDD method we obtained nanocomposite NBP (sodium borophosphate glass 30%mol P2O5 50%mol Na2O 17%mol B2O3) doped with erbium ions and Ag nanoparticles (20nm in diameter), NBP:nAg:Er3+. The absorption and luminescence measurements at temperature range (4K-300K) were used to study the optical properties of these nanocomposites.

Low temperature luminescence revealed that defect related emissions X2(1.185eV) and X1(1.085eV) appear in NBP:nAg and NBP:Er^{3+},nAg, composites, respectively. Both defects responsible for these emissions have metastable states. Optical features of the defects were explained by using coordinational coordinate model, CC.

For low (residual) erbium concentration the twofold increase of the emission at 1532nm was observed when X2 defect was in the metastable state.

Surface atoms of nAg have a very large number of dangling bonds as the coordination is not completed. These features can give rise to the formation of any localized defect states at the interface formed between nAg and surrounding environment. Recent studies [2] made by using high-resolution transmission electron microscopy revealed that Ag nanoparticles even at room temperature can be deformed like liquid droplet remaining crystalline in their volume. It means that the nanoparticle can be sensitive to the forces of the crystalline field in the glass.

We have stated that presence of nAg in NBP glass leads to the decreasing of free-OH group as compared

to the pure NBP glass. The fact suggests decreasing the amount of the so called non-bridging oxygens that instead of forming the hydrogen-like bounding with free-OH groups can form some kind of connections with silver particle surface.

Abstract- Controlling the magnetic permeability m of artificial materials is expected to offer an unprecedented control of the flow of light in optical devices. Unfortunately, the magnetic response of natural materials is negligible at optical frequencies. A rational design of nano-composites $SiO_2@Ag_n$ enables here the operational extension of the concept of magnetic permeability to visible light. Up to now, artificial optical magnetism has been observed in anisotropic structures thinner than the wavelength of light as a non-local effect which is too complex to be described by an effective magnetic permeability tensor, hence precluding the use of the usual laws of reflection and refraction. In contrast, the reflection of light by the novel magnetic metamaterial described in this talk obeys the classical laws of optics at variable incidence. This fundamental approach, based on the precise control of the structural symmetry of the material at all steps of a hierarchical self-assembly process, provides strict guidelines for the design of magnetic materials described by a valid permeability parameter. This strategy can be readily extended to the future generation of low-loss, all-dielectric metamaterials, hence renewing the interest for extraordinary applications of metamaterials based on non natural values of μ.

Self-organized silver-based eutectic metamaterial

B. Surma[1], K. Sadecka[1], D. A. Pawlak[1,2]
[1]Institute of Electronic Materials Technology, Warsaw, Poland

Abstract- We report on the optical properties of the Bi_2O_3-Ag eutectic nanocomposite with plasmonic properties, grown by the Micro pulling down method. We will present the optical response of metamaterials built from silver, bismuth, bismuth oxides and highlight the tunability in their structure and optical response. The introduction of rare-earth ions to this eutectic material should promote the enhancement of important optical properties, like photoluminescence or up-conversion processes.

Bottom-up manufacturing methods, like self-organization and chemical methods are powerful for obtaining metamaterials with controlled optical properties. One particularly promising approach relies on the growth of self-organized nano- and micro-structures by directional solidification of eutectics.

This work reports the development of a bulk nanoplasmonic Bi_2O_3-Ag eutectic-based metamaterial. Annealing at 600 °C further refined the structure and introduced metallic nanoparticles that exhibited plasmonic resonance in the optical region of the spectrum [1]. Different atmospheres can affect on the intensity and position of the plasmonic resonance, so the plasmonic resonance can be tune between orange and green wavelengths [2].

Demonstration of the impact of LSPR exhibited by the Bi_2O_3-Ag eutectic composite doped with rare earth ions on its optical properties, such as luminescence and nonlinear properties like upconversion will be presented.

For the annealed Bi_2O_3-Ag: Er^{3+} material (which has plasmonic resonance) two-fold enhancement of the Er3+ ions photoluminescence in the range of 520 nm to 570 nm (excitation wavelength of 488 nm) is observed with respect to the as-grown material. Also strong 19-fold enhancement of the luminescence up-conversion from 980 nm to visible in the annealed Bi_2O_3-Ag-doped with Er^{3+} material is observed. Bi_2O_3 as high refractive index material is often added to types of glass to improve their nonlinear properties such as upconversion i.e. the conversion of luminescence from longer to shorter wavelengths. That is why it was interesting to investigate the effect of the material's plasmonic properties on this phenomenon. Measurements of luminescence showed that the upconversion is strongly enhanced for the Bi_2O_3-Ag: Er^{3+} eutectic material exhibiting the LSPR in comparison to the as-grown Bi_2O_3-Ag: Er^{3+} composite (without LSPR) and the Bi_2O_3: Er^{3+} crystal. This is thanks to the fact that the position of the localized surface plasmon resonance in Bi_2O_3-Ag: Er^{3+} material (after annealing) overlaps the up-converting luminescence bands obtained for erbium, which preliminarily confirms the plasmonic enhancement of the upconversion. Moreover Bi_2O_3-Ag doped with rare earth ions may be potentially used as an element in solar cells. Upconverters with properties strengthened by plasmonic resonances may, when used in a solar cell, enable enhancement of its efficiency.

Abstract- The banner of strong field confinement using plasmonic material has been waved for quite some time. In many cases, strong field confinement comes with high loss which has hampered many potential applications. In this paper we show two remarkable examples of nonlinear effects of plasmonic material: third harmonic generation and p-polarization reflectance modulation, using high mobility doped semiconductor of CdO where high absorption and strong field confinement can co-exist.

A quintessential property of surface plasmon polariton mode in metal is the ability to produce nanoscale field confinement. This mode is normally not accessible from free-space due to momentum mismatch. However, when the thickness of the material is of the order the Fermi wavelength, surface plasmon polaritons of the two interfaces couple to a hybridized mode called epsilon-near-zero mode which allows free-space coupling and produces a large uniform field enhancement inside the material[1]. When impedance matched to this mode, 100% of the incident field is absorbed (perfect absorption) and large nonlinear polarization field is generated. Efficient third harmonic generation was shown[2] using indium tin oxide. Recently, using defect equilibrium

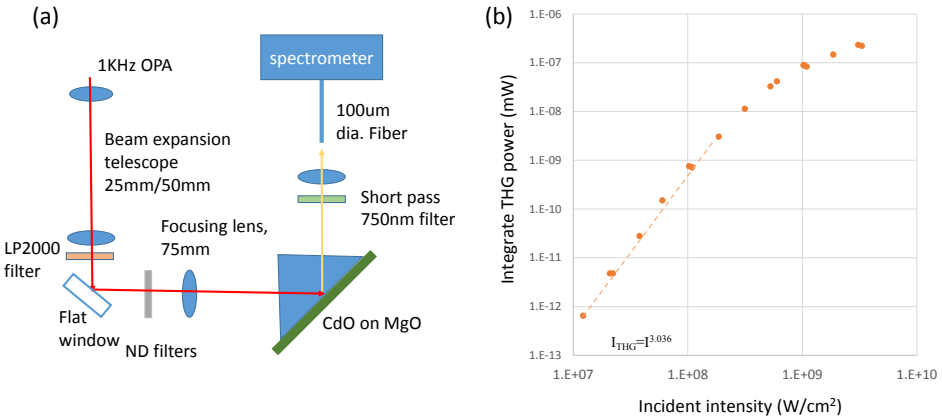

Fig. 1: (a) Schematic representation of the third harmonic generation experiment. (b) Third harmonic power versus incident laser intensity at the fundamental wavelength of 2.1mm. The In:CdO film is 19nm thick and has a carrier density of 2.0×10^{20} cm^{-3} and mobility of 375 cm^2/Vs.

engineering[3], crystalline high mobility conductive oxide can be grown to enable larger field enhancement and

hence higher third harmonic conversion efficiency.

In this paper, we report more than three orders of magnitude enhancement in conversion efficiency $8.3x10^{-22}$ $\%cm^4/W^2$ for In:CdO compared to $5.7x10^{-25}$ $\%cm^4/W^2$ for indium tin oxide[2]. The conversion efficiency metric used here is defined as the ratio of third harmonic to incident power in percent normalized by the square of the incident intensity. Fig. 1 shows the third harmonic generation behavior with pump intensity.

Another nonlinear effect that utilizes strong absorption is reflectance modulator. Low intensity p-polarized probe light at frequency near the epsilon-near-zero value (2.08μm) can be completely absorbed when the impedance matching condition is met as in the case of a 75nm thick In:CdO film with similar properties on an Au[4] substrate. This p-polarized probe beam reflectance can be dramatically increased when a separate high intensity intraband pump pulse is applied to change the carrier temperatures and effective mass. The new epsilon-near-zero frequency is shifted to 2.23μm. Fig. 2 shows that the reflectance at 2.08 μm is switched from 1% to 86% within 200fs. Simultaneously, the reflectance at 2.23μm is dramatically reduced from 73% to 10%.

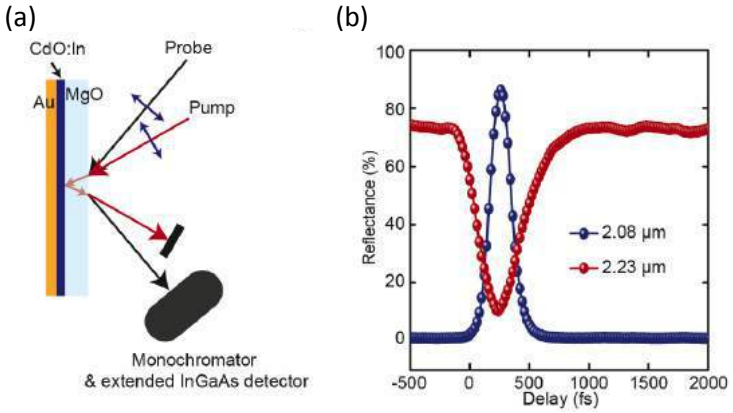

Fig. 2: (a) Schematic representation of the pump-probe reflectance modulation experiment. (b) Shows the temporal p-polarized reflectance response of 2.08 and 2.23 μm at 50 deg angle of incidence after the sample was pumped by another 2.08 μm p-polarized incident angle of 30 deg.

Abstract- Circular Dichroism is the differential absorption of left or right circularly polarized light. In planar artificial structures, like metamaterials, this effect is rather weak. In contrast to that, second harmonic generation circular dichroism (SHG-CD) in artificial materials is more sensitive, than its linear counterpart. Here, we report about a near unity nonlinear circular dichroism for second- (SHG) and third- harmonic generation (THG) from specially designed plasmonic metasurfaces.

Plasmonic metasurfaces are interesting systems to study nonlinear phenomena, due to their strong light-matter interaction. Since, their strong light-matter interaction leads to a strong electric nearfield enhancement, which in turn leads to strong nonlinear response, plasmonic metasurfaces are a perfect tool to investigate nonlinear phenomena. One of these phenomena is SHG-CD, the differential harmonic generation of left or right circularly polarized light, if the material is illuminated with light of different handedness. Strong CD from metamaterials has been demonstrated but the observed CD in most experiments arises from the chirality of 3D nanostructure or from the extrinsic contribution in 2D structures illuminated under an oblique angel. [1-10] In this work, we demonstrate a strong CD for SHG and THG from planar chiral plasmonic metasurfaces.

Experiment

An array of trisceli-type (for SHG) and gammadion-type (for THG) nanostructures were fabricated by electron beam lithography and a lift-off procedure. The Plasmon resonance of the nanostructures was determined to respectively 1165 nm (trisceli-type) and 1230 nm (gammadion-type) by Fourier Transform Infrared Spectroscopy.

The nonlinear experiments were executed by using a femtosecond laser under normal incidence to the metasurface surface. To characterize the nonlinear CD, the nonlinear response of the Metasurface was measured for right and left circularly polarized light. Furthermore, the fundamental wavelength of the laser was tuned between 1100 nm and 1400 nm, to gain information about the wavelength dependents. The results show that for one polarization state the nonlinear responses have local minima at 1275 nm for SHG and 1300 nm for THG, which corresponds to the wavelengths of the strongest nonlinear CD (fig. 1), which was calculated from the nonlinear measurements by using the definition: $CD = (I_{LCP} - I_{RCP})/(I_{LCP}+I_{RCP})$.

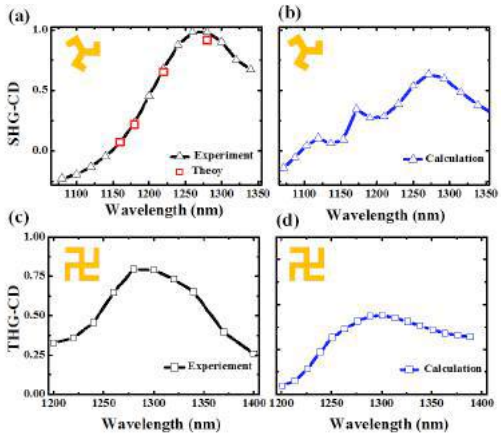

Figure 1. Nonlinear CD for SHG from the trisceli-type structure (a, b) and the nonlinear CD for THG from the gammadion structure (c, d). The values of the squares in (a) are obtained from experimentally determined values of the effective nonlinear susceptibilities of the trisceli-type structure.

Conclusion

In summary, near unity nonlinear circular dichroism for second- and third-harmonic generation with ultrathin trisceli- and gammadion-type plasmonic nanostructures was shown. Moreover, a symmetry controlled generation of left or right handed SHG and THG was demonstrated. Strong SHG-CD and THG-CD are experimentally observed for these planar plasmonic structures with negligible linear optical activity. Especially, the observed SHG-CD is identified to have an achiral origin. In the future, these results, together with simple fabrication methods for plasmonic metasurfaces enable a greater freedom in designing nonlinear optoelectronic devices.

Non-local absorption in quantum hydrodynamictheory: application to plasmonic systems

C. Ciracì[1]

Abstract— The quantum hydrodynamic theory is a promising method for describing microscopic details of macroscopic systems. The hydrodynamic equation is directly obtained from a single particle Kohn-Sham equation. This derivation allows to straightforwardly incorporate in the hydrodynamic equation a viscoelastic term, so that broadening of collective excitation can be taken into account, as well as a correction to the plasmon dispersion. The result is an accurate and computationally efficient hydrodynamic description of the free electron gas.

A reliable description of optical properties of plasmonic nanostructures with different length scalesrequires methods beyond classical electromagnetism. In this context, it becomes very important to develop simulation techniques to take into account quantum microscopic features at the scale of billions of atoms. Density functional theory (DFT) methods are generally unsuitable because their computational cost grows as fast as $O(N_e^3)$ such that their reach is limited to systems with few thousands electrons. Conversely, methods based on effective descriptions have also been proposed [1, 2], although their applicability depends on *a priori* calculations usually relying on a different method and it is limited to the linear response regime.

A promising alternative is given by orbital-free techniques where electron energy functionals are expressed in terms of the electron density n rather than the single electronic orbitals. To this category belongs the *hydrodynamic theory* (HT), in which the quantum dynamics is solved via macroscopic observable quantities, such as, n and the current density $\mathbf{J}$ or the velocity $\mathbf{v}$. The HT has a long history [3, 4] and recently, it has vigorously reemerged in the context of nano-photonics [5, 6], strongly fueled by the proliferation of self-assembling colloidal plasmonic structures [7, 8]. Because of the complexity of the systems involved, however the HT has usually been considered within the limit of the Thomas-Fermi (TF) approximation with the assumption of a constant ground density, neglecting essential effects such as electron spill-out and quantum tunneling. The TF-HT however can be greatly improved by adding a ∇n-dependent contribution to the TF kinetic energy of the free-electron gas. In this way, a space dependent ground density can be easily taken into account. This model usually denominated *quantum hydrodynamic theory* (QHT). A self-consistent approach based on the QHT coupled to Maxwell's equations was recently introduced by Toscano *et al.*, who applied it to show size-dependent blue shift in small noble metal nanowires [9]. Systematic comparisons of QHT with DFT results [10, 11] however pointed out that in order to describe well both near- and far-field features of plasmonic systems, one might need to sacrifice the self-consistency of the method [11]. A precise prediction of the fields near the surface is in fact extremely important for tunneling regimes and nonlinear applications. Moreover, in its present form the QHT does not take into account size-dependent broadening of the plasmonic resonances, although a recent effort in this direction [12] suggested the use of a density-dependent damping rate. As for all orbital-free methods, the challenge is to find an appropriate energy functional that correctly accounts for the electron gas total energy.

In this talk, I first show that the QHT equation can be formally derived form the single particle Kohn-Sham (KS) equation. This non-trivial derivation clearly shows the degree of approximations that are made when using the QHT. This derivation allows to straightforwardly incorporate in the hydrodynamic equation a viscoelastic term, so that broadening of collective excitation can be taken into account, as well as a correction to the plasmon dispersion. Because the QHT intrinsically describes both longitudinal and transverse fields, it is then possible to include in the hamiltonian a current-dependent exchange-correlation (XC) vector potential. Such potential has been developed by Vignale and Kohn [13] in the context current density functional theory (CDFT). The peculiarity of this functional is that it has the form of a divergence of a viscoelastic stress tensor, offering an intuitive and unprecedented way to improve the theory. The results is a theory that can be applied

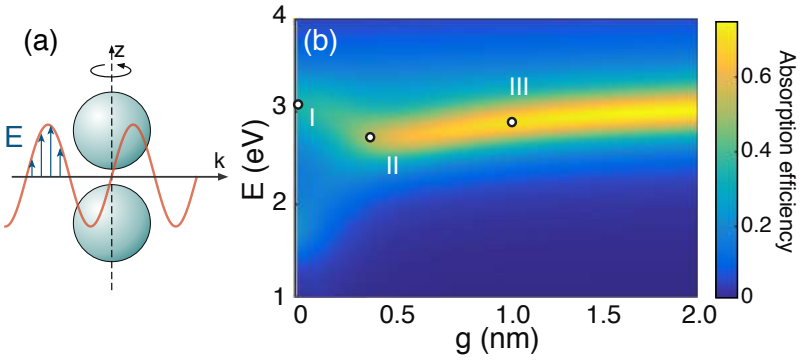

Figure 1: Dimer of Na spheres constituted by $N_e = 398$ electrons each.

to a class of much larger problems compared to DFT techniques, with comparable accuracy. The theory correctly predicts size-dependent plasmon energies and broadening, as well as near-field properties. Application tonanoparticle dimers also show good agreement with DFT calculations previously published, down to the tunneling regime (see Fig. 1).

Abstract— Plasmonic nano-cavities provide the ideal conditions to realize light-matter strong-coupling at room temperature. However, they support multiple types of modes that can be spectrally degenerate, but with different radiative behaviour and field profiles. We demonstrate that quantum emitters simultaneously couple to all modes in plasmonic nano-cavities, a process dominating the spatio-temporal dynamics of the Rabi-oscillations.

Plasmonic nano-cavities provide the ideal conditions to strongly-couple emitters and plasmons, due to the high-field enhancement associated with the plasmon excitation and the radiative nature of higher-order modes that suppresses quenching [1]. This unique combination of properties allows for a single molecule to strongly-couple with a plasmon mode at room temperature [2], which opens the route to bring in ambient conditions quantum information systems.

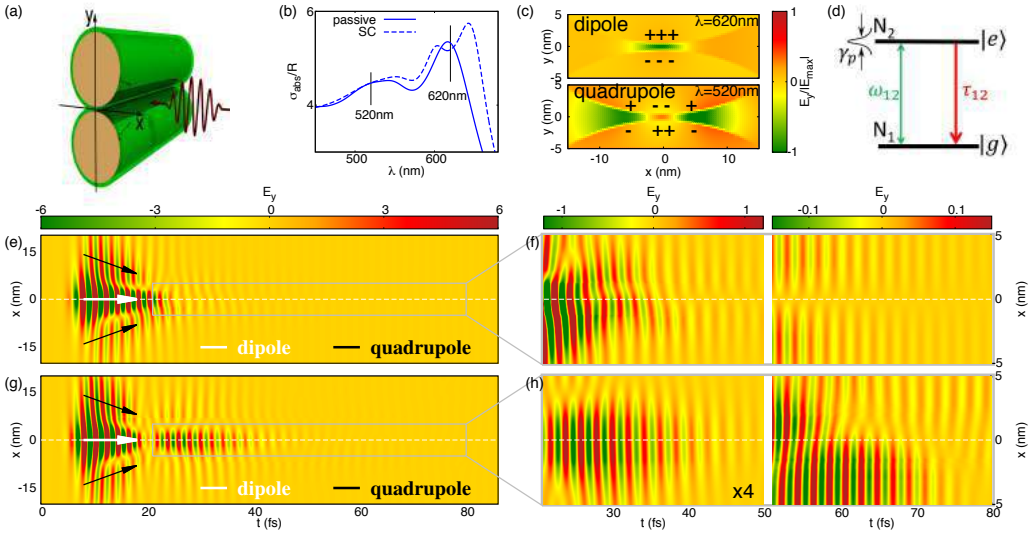

Figure 1: (a) Plasmonic dimer structure, surrounded with a homogeneous layer of QEs (green colour) (b) the absorption cross-section spectra for the plasmonic structure without (passive) and with QEs. (c) The profile of the first two even-bonding modes. (d) QEs are represented by a 2-level system. The spatio-temporal map of (e,f) the passive and (g,h) strongly-coupled system.

In this paper, we explore the coupling of emitters with the multiple type of modes that are present in plasmonic structures. We show that external radiation excites both the even and odd bonding modes of a plasmonic dimer, which are simultaneously exciting and exchanging energy with the QEs. For the plasmonic dimer, these two types of modes occur at the same frequency:

$$\omega_n^{even} = \sqrt{\frac{R_2^n - R_1^n}{2R_2^n}}\omega_p - i\left(\frac{\gamma_m}{2} + \frac{n\pi\gamma_m^4\omega_p^3}{8R_0^2c_0^2}\left(\frac{R_1}{R_2}\right)^2\sqrt{\frac{R_2^n - R_1^n}{2R_2^n}}\right) \quad (1)$$

$$\omega_n^{odd} = \sqrt{\frac{R_2^n - R_1^n}{2R_2^n}}\omega_p - i\frac{\gamma_m}{2} \quad (2)$$

where ω_p and γ_m is the plasma frequency and damping of the metal and R_1, R_2 is the radii of the two cylindrical structures. The two modes have different radiative properties with the even-bonding mode coupling more efficiently to the even continuum (i.e. bright mode), while the odd mode is darker. We model a homogeneous layer of QEs surrounding the dimer structure as a two-level system, whose dynamics are governed by the decay lifetime of the excited state (τ_{12}) and dephasing rate (γ_p). The QEs couple to both modes simultaneously, which leads to spatially asymmetrical Rabi-oscillations and mode beating characteristics (Figure 1).

To excite either type of modes alone, we need to preserve the parity symmetry of the system. We achieve this by exciting the plasmonic dimer structure with two plane-wave sources, incident from opposite directions. The parity symmetry is controlled by the phase difference of the two sources: when in-phase only the even modes are excited, and out-of-phase excitation couples only to odd modes. As expected, odd modes continue to exchange energy with the emitters for much longer times than even modes [3]. Most importantly though, despite their smaller field enhancement, odd modes exhibit identical coupling strength to even mode coupling.

In conclusion, we show that parity symmetry in plasmonic nano-cavities dominates the spatio-temporal dynamics of the plasmon-exciton in the cavity. By tailoring the illumination set-up of the plasmonic structure, we can dynamically control the hybrid states of the strongly-coupled system, and therefore specifically adapt the dressing of molecules with light.

Laser processing of VO_2 for metamaterials applications and THz devices

Alberto Piqué, Nicholas Charipar, Heungsoo Kim, Scott Mathews, Kristin Charipar and Ray Auyeung

[1] Materials Science and Technology Division, Naval Research Laboratory, Washington DC, USA
[*]corresponding author: alberto.pique@nrl.navy.mil

Abstract- Vanadium dioxide (VO_2) undergoes a metal-insulator transition (MIT) whereby its electrical resistivity changes by several orders of magnitude. The combination of fast switching times and response to a broad range of external stimuli make VO_2 an ideal material for a variety of novel devices and sensors. In this talk, we will present details of laser processed VO_2 films and their application for metamaterial devices such as THz emitters and THz modulators.

Vanadium dioxide (VO_2) has been investigated as a tunable functional material because it undergoes a structural phase change between an insulating monoclinic phase and metallic tetragonal phase. This phase change can be induced thermally, mechanically, electrically, or optically and it can occur at ultrafast timescales (~100fs). The combination of fast switching times and response to a broad range of external stimuli make VO_2 an ideal material for a variety of novel devices and sensors. While the MIT in VO_2 has been exploited for a variety of microwave/terahertz applications (i.e. tunable filters and modulators), very few devices exploiting the fast switching time of VO_2 have been reported. The electrical properties of thin film VO_2 (conductivity, carrier concentration, switching speed, etc.) are highly dependent on growth and post-processing conditions. For example, the transition temperature can be tuned via doping or by introducing lattice strain via strain engineering during the growth process [1, 2] (Figure 1).

Metamaterial devices based on the phase changing properties of VO_2 films are very promising as the resonant frequency can be tuned by adjusting the properties of VO_2. For example, hybrid metamaterial devices designed for THz frequency range have been demonstrated by combining split ring resonators (SRRs) with phase changing VO_2 films. In this configuration, changing the conductivity of VO_2 via temperature tunes the behavior of the SRR gap from capacitive to resistive thus modulating the THz beam transmission at the SRR resonance frequencies [3] (Figure 2). Furthermore, VO_2 based devices can also be used for the generation of electromagnetic radiation in the millimeter and terahertz region of the electromagnetic spectrum. We have investigated the use of the ultrafast metal-insulator transition in VO_2 thin films to produce broadband THz radiation [4]. This talk will discuss the effects of various pulsed laser deposition (PLD) growth conditions on the stress/strain state of VO_2 films and the subsequent change in their electrical properties. Finally, results from various VO_2 devices such as THz modulators and THz emitters will be presented.

Frequency conversion in THz metal-insulator-metal disk resonators coupled to semiconductor quantum wells

C. G. Derntl*, M. Wenclawiak, K. Unterrainer, and J. Darmo
Photonics Institute, TU Wien, Gußhausstraße 27-29, 1040 Vienna, Austria
*corresponding author: christian.g.derntl@tuwien.ac.at

Abstract- We present our investigations of asymmetric quantum wells in the THz regime. The combination with 3D full wave simulations and measurements of modified circular patch resonators allows us to study efficient nonlinear frequency conversion when the resonators are coupled to intersubband transitions in asymmetric quantum wells. The flexible tuning of the eigenmodes and the wide range of the cavity modes' quality factors (13-40) allow to optimize the internal nonlinear conversion process as well as the in- and out-coupling of light.

Cavity field enhanced nonlinear frequency conversion processes are already used in many devices, such as lasers, detectors and parametric amplifiers. However, their applications are limited by the need of high input power. To maintain the same field strength for reduced pump power, either the photon lifetime in the cavity has to be increased or the mode volume is reduced. For the latter case plasmonic resonators have the outstanding ability of extraordinary high field confinement, which reaches effective mode volumes smaller than 10^{-3} of λ_0^3 for metal-insulator-metal (MIM) designs [1]. Nonlinear frequency conversion processes can be further improved by using tailored high non-linear susceptibility materials such as semiconductor quantum wells (QW) [2]. Recently, Lee et al. demonstrated experimentally a second harmonic conversion efficiency of 2×10^{-6} W/W^2 in the mid-infrared [3] using a doubly resonant metamaterial (MM) coupled to intersubband transitions (ISBT) in QWs. Furthermore, theoretical investigations predict a conversion efficiency of 1.3×10^{-2} W/W^2 with split ring resonators strongly coupled to ISBTs [4].

Here, we transfer this concept of enhanced nonlinear susceptibility of MM strongly coupled to semiconductor heterostructures to the THz regime and investigate the induced parametric frequency conversion for MIM type resonators. In our study of circular patch resonators, see Figure 1(a), we showed the capability of selective excitation of their eigenmodes, even if they are degenerated [5]. These selection rules for the excitation of the eigenmodes are introduced by breaking the rotational symmetry with slits that additionally offer the control of generating additional eigenmode and eliminating others. Especially the control of the eigenmodes with a wide range of quality factors from 13 to 40 and the high field confinement of circular patch resonators makes this system suitable for doubly and triply resonant frequency conversion in cavity quantum electrodynamic systems, see Figure 2(b). Thus, the generated field mode is out-coupled using a low quality factor, while for the idler mode a high quality factor is chosen to maximize the conversion efficiency. The pumped eigenmode is matched to the spectrum of the pump beam.

On the other hand, for an efficient second order conversion process asymmetric QWs are required (e.g. SHG in [4]) providing a high second order non-linear term of susceptibility $\chi_{zzz}^{(2)}(\omega - \omega_i, \omega, \omega_i) \sim N\, z_{31}\, z_{23}\, z_{12}$, with doping concentration N. The matrix elements z_{ij} are the QW parameters that can be optimized by the well design for improving the conversion process. In Figure 1(c) a step QW and its wavefunctions are shown. The QW is

optimized for the highest product of the matrix elements z_{ij} for the material system GaAs/AlGaAs in the THz regime. We used a Schrödinger-Poisson self-consistent solver to optimize the design of a step quantum well for SHG at terahertz frequencies.

Magnetic-Free Non-Reciprocal Graphene Plasmonics

D. Correas-Serrano and J. S. Gomez-Diaz
University of California, Davis, United States
dcorreas@ucdavis.edu, jsgomez@ucdavis.edu

Abstract – *We discuss recent advances in magnetic-free non-reciprocal plasmonic devices and antennas based on spatiotemporally modulated graphene. We first review the exciting properties and novel functionalities that this technology offers, focusing on achieving large non-reciprocal responses with fully integrated structures. We then address the main challenges that remain to be addressed, including limitations associated to plasmon damping and modulation speed. Finally, we investigate novel routes towards optimal designs. To this purpose, we examine two types of isolators, based on indirect interband photonic transitions and on asymmetric bandgaps for the plasmonic modes. We envision that this technology will open new exciting venues in the field of plasmonics.*

The myriad of graphene plasmonic devices envisioned by researchers in the past decade successfully exploit graphene's field effect to achieve quasi-real-time reconfiguration of devices like waveguides, filters, antennas, and metasurfaces [1] or to realize modulators [2], [3]. Recently, the ultrafast field effect in graphene has been proposed as a mechanism to realize magnet-less non-reciprocal plasmons at THz and infrared [4], achieved by modulating the conductivity of graphene in space and time through multiple gating pads. This imparts linear or angular momentum to the supported plasmons, creating an effective moving medium able to break time-reversal symmetry. Judicious design of the bias voltage signals, namely their phase difference, frequency, and amplitude, allows to create very strong non-reciprocity in compact, fully planar and integrated waveguides [5], antennas [6], or phase shifters [7] without the need of magneto-optic effects. There have been, however, no comprehensive studies on the ultimate capabilities of this technology, or how to realize optimal designs for a given set of constraints. This is particularly important for graphene plasmonics, as loss is arguably the biggest obstacle to practical viability for most graphene devices.

In this talk, we will first review the use of spatiotemporally modulated graphene to realize magnetic-free fully-integrated non-reciprocal devices and leaky-wave antennas, as well as the novel functionalities that this exciting technology enables. Then, will discuss optimal designs in terms of trade-offs between isolation and insertion loss, using an analytical theoretical framework based on coupled-mode theory and finite-element multi-harmonic frequency domain numerical simulations. Fig. 1 illustrates this type of compromise for an isolator based on indirect interband photonic transitions operating at 12 THz. The spatiotemporal modulation imparted to one of the layers ($\sigma_2 = \sigma_0[1 + M\cos(2\pi f_m t - \beta z)]$) creates perfect phase-matching between the odd and even modes in the isolated direction, leading to complete mode and frequency conversion, while full transmission ideally occurs in the opposite one [4]. We note that in this type of isolator maximum isolation requires that both the real and imaginary parts of the modal wavevectors must be matched, and the latter cannot be fully compensated by the simple modulation scheme considered here. Figs. 1b and 1c illustrate this response by plotting the maximum isolation possible and the associated insertion loss for an isolator at 12 THz with M = 0.1, $\tau = 1$ ps and $f_m = 50$ GHz versus layer separation d and chemical potential μ_c. Very large isolation, greater than 30 dBs, can be achieved for those values of d and μ_c for which the damping of odd and even modes is similar, thus defining a clear design

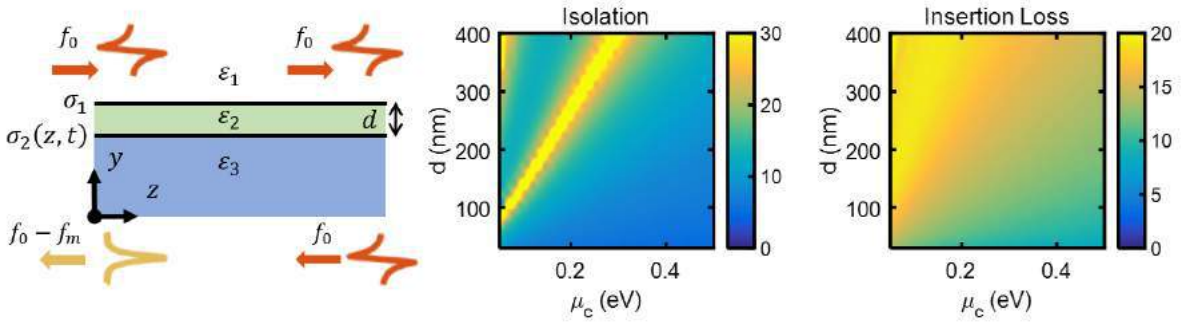

Figure 1. (a) Plasmonic isolator based on indirect transitions between the fundamental modes of a graphene parallel plate waveguide with $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = 1$, operating at 12 THz, for a relaxation time of 1 ps. The conductivity of the bottom layer σ_2 is modulated simultaneously in space and time as $\sigma_2 = \sigma_0(1 + M\cos[\omega_m t - \beta_m z])$, inducing non-reciprocal phase matching between the modes that translates into unidirectional isolation at f_0. (b) Maximum possible isolation versus chemical potential μ_c and sheet separation d (c) Insertion loss in the transmitting direction for the optimal designs of panel b.

rule to realize quasi-optimal designs. Another key factor is related to the undesired partial mode conversion that inevitably occurs in the transmitting direction due to the finite line width of the modes [5]. This effect may be considered a type of loss that depends on the magnitude of the phase mismatch and the modulation amplitude, and its minimization conflicts with that of dissipation loss due to finite carrier mobility in graphene. We will further discuss these trade-offs at the conference, also for isolators based on asymmetric bandgaps.

Recent great strides being made in experimental graphene plasmonics [8] are enabling the emergence of spatiotemporally modulating graphene as novel, multi-functional, and magnetic-free plasmonic platform able to fulfill many of the currently unmet needs for non-reciprocal devices at terahertz and infrared frequencies.

Antenna-coupled Photon Emission from Tunnel Junctions

Abstract- We have studied the ultrafast conversion of electrons localized in vertical Au-hBN-Au tunnel junctions to free-space photons, mediated by resonant slot antennas. We achieve polarized, directional and resonantly enhanced light emission from inelastic electron tunneling and establish a novel platform for studying the interaction of electrons with strong electromagnetic fields.

Optical antennas are elements that couple free space radiation to nanoscale volumes. To date, optical antennas have been driven using light, in contrast to their radio frequency counterparts which are driven by electrical currents. We have realized ultrafast solid-state light-emitting tunnel devices based on arrays of electrically driven optical antennas that significantly alter this paradigm. To achieve this electro-optical transduction, we use vertical Au-hBN-Au tunnel junctions. Electrons tunnel from one electrode to the other

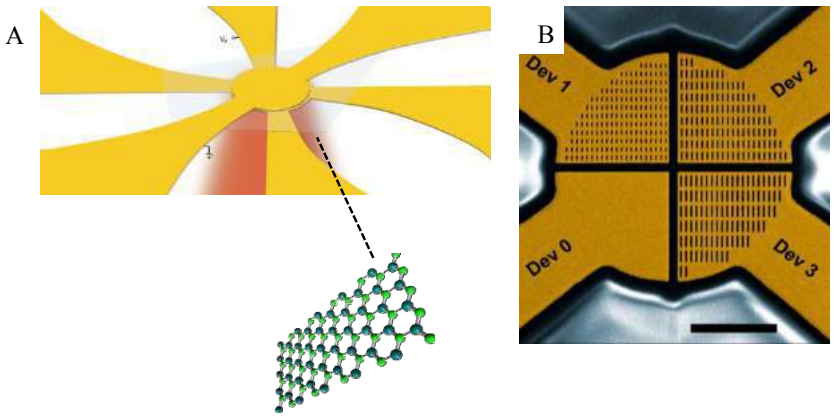

Figure 1. (A) Schematic of the fabricated device comprising two gold electrodes and a thin flake of hBN between them. **(B)** A false color scanning electron micrograph of the bottom electrode before transferring the hBN. The slot antennas in different sectors are different aspect ratios and hence varying spectral resonances. The scale bar is 1 micron.

under an applied bias, and generate highly-confined surface plasmons by inelastic tunneling. Because it does not rely on intermediate excitations such as electron–hole pairs, the response time of such a device is fundamentally only limited by the tunneling time of electrons through the junction, a process that takes place on a femtosecond timescale.

We demonstrate ultrafast temporal modulation of light emission from such h-BN tunnel junctions. The device is driven with an RF signal of frequency f, and a histogram of interphoton arrival times in the resulting photon stream is recorded by employing time-correlated single-photon counting (TCSPC). Figure 2 shows histograms recorded for different modulation frequencies of demonstrating that the photon stream is indeed

time-modulated at the same frequency.

The efficiency of photon emission from our vertical tunnel junction is low, ~1e-5 photons per electron. We show that this can be improved by an order of magnitude by employing Hertzian nanoparticle dimer antennas. Further increase in efficiency can be expected by engineering the tunnel barrier to slow down the electron as they traverse across the gap thus increasing their interaction strength with plasmons (photons). With our tunneling devices we have presented a novel platform to combine electrons and plasmons in nanoscopic volumes. We expect these devices to be useful for ultrafast optoelectronic applications, and also to explore fundamental issues such as plasmon lasing.

Strong couplings of many-body quantum emitters in plasmonic metal nanocavities

Aeshah Muqri[1], **and Jae Yong Suh**[1*]
[1]Michigan Technological University, United States
[*]corresponding author: jsuh@mtu.edu

Abstract We report Rabi splitting in the optical reflection and emission spectra from different types of quantum emitters interacting with metal nanostructures in periodic arrays. Metal-insulator-metal (MIM) nanodiscs show two localized surface plasmon (LSP) flat bands as well as surface lattice resonances (SLRs), which is dipolar particle-particle interactions along the diffraction order. The strong coupling between the SLR and quantum emitters observed in MIM nanocavities exhibits both the narrow line-width and enhanced local fields.

Anti-crossing found in energy-momentum dispersion is a characteristic feature of strong couplings between various quasiparticles excited on semiconductor microcavities or periodic nanostructures. A nanoscale analogy of the macroscopic two-mirror cavity is two metal nanodiscs separated by an insulator of a thickness less than its light wavelength. We fabricated metal-insulator (MI) and metal-insulator-metal (MIM) nanodiscs embedded in various kinds of quantum emitters. We first report strong coupling with MI structure that consists of single metal nanodisc overcoated with J-aggregate cyanine dye molecules in dielectric matrix.

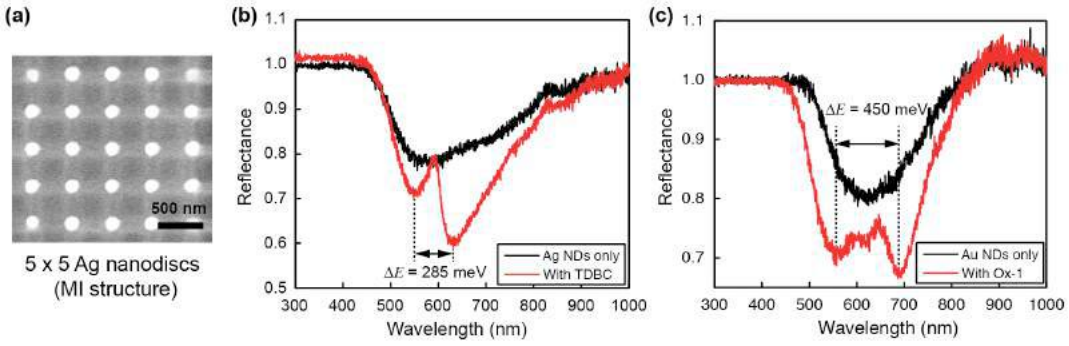

Figure 1. (a) SEM images of Ag nanodiscs in array of 500 nm periodicity. Normalized reflection spectra from (b) TDBC J-aggregates on Ag nanodisc array, and (c) Oxazine-1 dye molecules in PMMA on Au nanodisc array.

The spectral locations of localized plasmon resonances can be engineered by the size and dielectric functions of constituent materials. Figure 1(a) shows silver nanodiscs fabricated by a combination of photolithography and FIB etching. Figure 1(b) shows the experimental reflection spectra from Ag nanodiscs of 140 nm diameter in a square array, overcoated by TDBC molecules in polymer matrix. When there were no TDBC molecules, only the broad LSP resonance of Ag nanodiscs existed centered at 580 nm as shown in black curve. In the presence of the QEs whose absorption band overlapped with the of LSP resonances, the reflectance spectrum clearly showed the

Rabi splitting of frequencies below and above the resonance maximum.

MIM geometry, on the other hand, can support highly localized electromagnetic fields in the gap region due to the near-field interaction between the two metal nanodiscs [1-3]. Specifically, when the coupled LSP resonance at a longer wavelength can interact with SLR mode, an anticrossing can occur at non-zero in-plane *k* vector. This coupling maintains both high local field intensity nearby the MIM structures and relatively narrower line-width, representing a longer lifetime of the plasmon-exciton-polariton quasiparticles in the presence of quantum emitters. Therefore, MIM nanocavities that support extremely small effective mass of the quasiparticle in periodic array can be a good platform to realize exciton-plasmon Bose-Einstein condensates at room temperature [4, 5]

Plasmons in superlattices of graphene on hexagonal boron nitride

Jeil Jung[1*]

[1]ADepartment of Physics, University of Seoul, Seoul 02504, Korea

[*]corresponding author: jeiljung@uos.ac.kr

Abstract- Recent experiments have shown the presence of strong of moire superlattice features in the electronic structure of graphene on hexagonal boron nitride. Our analysis shows that the moire superlattices formed at the graphene-hBN interface offer a rich platform for plasmonics where control of the plasmon modes can be introduced both through carrier doping and twist angle control.

The Recent experiments have shown the presence of strong of moire superlattice features in the electronic structure of graphene on hexagonal boron nitride. The conductivity of graphene on a boron nitride substrate exhibits features in the terahertz (THz) and infrared (IR) frequency regimes that are associated with the periodic moire pattern formed by weakly coupled two-dimensional materials. The THz and IR features are strongest when the two honeycomb lattices are orientationally aligned, and in this case they are Pauli blocked unless the Fermi level is close to ±150 meV relative to the graphene sheet Dirac point. The substrate-induced band splitting is larger at energies below the Dirac point and it can lead to sharp features at THz and IR frequencies in p-doped graphene. We explain how the strongest few THz and IR features arise from critical points in the moire-band joint density of states, which in turn depend sensitively on the way the superlattice Hamiltonian is modeled. Based on the calculations for the plasmon excitation spectrum of massless Dirac fermions in the moire superlattice of graphene on hexagonal boron nitride, our analysis shows that the moire superlattices formed at the graphene-hBN interface offer a rich platform for plasmonics where control of the plasmon modes can be introduced both through carrier doping and twist angle control.

Nonreciprocal Metasurfaces with Temporal Modulation

Xingjie Ni*

Department of Electrical Engineering, Pennsylvania State University, University Park, PA 16802, USA
*corresponding author: *xingjie@psu.edu*

Abstract – We demonstrated a distinct class of active metasurfaces with temporal modulation that truly breaks the Lorentz reciprocity of light propagation. The technique would pave a viable way to realize practical magnetic-free compact nonreciprocal optical components that could enable numerous applications.

Nonreciprocal optical components, which are indispensable building blocks in m any modern optical and communication systems, are almost exclusively based on the magneto-optic effect, making the devices bulky and preventing them from integration. It is in great demand to have a magnetic-free route to achieve on-chip nonreciprocal light propagation in order to isolate and stabilize optical elements. The newly emerging metasurface - an optically thin layer consisting of subwavelength-sized elements that offers tremendous power for manipulating light - is a great platform for building miniaturized optical components. [1, 2] However, the metasurfaces so far all function in static states and there are fundamental limitations. In particular, to violate Lorentz reciprocity in a non-power dependent fashion without resorting to magneto-optic effects, a time-varying response is required. [3] Here, by incorporating an additional temporal modulation, we demonstrate that it is possible to break time-reversal symmetry of the system and thereby achieve nonreciprocal light propagation with an active metasurface.

Efficient broadband Huygens sources made of spherical nanoclusters.

Romain Dezert, **Philippe Richetti**, **Virginie Ponsinet**, **Olivier Mondain-Monval**, **Philippe Barois**, **and Alexandre Baron**

[1]University of Bordeaux, CNRS, CRPP, UPR 8641, 115 avenue Scwheitzer, 33600, Pessac, France
alexandre.baron@u-bordeaux.com

Abstract— We present spherical nanoclusters made of spherical inclusions which act as efficient and broadband Huygens sources. The system is versatile enough that several materials may be used as inclusions and different bands may be targeted by varying some of the parameters. They may serve as the basic building blocks of Huygens metasurfaces and are particularly suited to bottom-up fabrication and self-assembly. We also investigate how these sources interact with ultra-short pulses of light.

1. HUYGENS SOURCES AND THEIR APPLICATIONS

Huygens sources are secondary sources of spherical wavelets which spread in the forward direction with respect to the primary source of light (usually a plane wave). Such sources consist of in-phase superimposed electric and magnetic dipoles of equal amplitudes. Recently, it has been shown that by carefully arranging such sources into a two-dimensionnal periodic array, Huygens metasurfaces could be produced which have the elegant property of imparting a 2π phase shift to an impinging plane wave with a near unity transmittance [1, 2, 3]. Such a coverage enables both spatial and temporal wavefront shaping, making it possible to produce flat optical components such as lenses, polarizers and pulse compressors. However all Huygens metasurfaces that have been proposed up to now have been fabricated by top-down approaches and rely on silicon. This is limiting in many aspects, because it makes it difficult to produce large area metasurfaces and usually imposes the substrate on which the metasurface will be formed.

Here we propose an alternative geometry as Huygens sources, which we believe is very well suited to *bottom-up* approaches. They consist of spherical nanoclusters which can potentially be produced in very large amounts by self-assembly and as a result cover very large areas. They could come in the form of inks consisting of colloidal suspensions making it easy to spray over virtually any substrate. This paper will restrict the discussion to the theoretical description of these nanoclusters, but preliminary experimental results will be presented orally. Not only is it possible to make efficient Huygens dipoles, but the geometry is versatile enough that it can easily be made to satisfy the so-called *generalized Huygens condition*, whereby to higher-order multipolar scattering, which is of particular interest to metasurfaces that require broadband operation and polarization control. We also describe the interaction of theses sources with ultra-short pulses.

2. THEORY : NUMERICAL AND ANALYTICAL APPROACH

We consider spherical clusters made of spherical inclusions. Several inclusions of varying materials are considered: silicon, gold and silver. The clusters are generated by considering the closest packing of equal spheres into a sphere that interact repulsively, which likely describes the formation of pseudo-homogenous colloidal aggragates [4]. The scattering properties of the nanoclusters are computed both by using a T-matrix simulator developped by Mackowski [5] and the commercial finite-element solver COMSOL Multiphysics. The parameter space explored consists in the material of the inclusion, the inclusion size, the numbers of inclusions, the volume fraction of inclusions in the cluster and the refractive index contrast between the inclusions and the host material. Many solutions are found which reveals the extreme versatility of the system. One such solution is shown on Fig. 1. It consists in an icosahedral cluster of 13 closely-packed identical silicon spheres. This shape is the solution to the kissing number problem [6].

Figure 1(a) shows the scattering cross-section efficiency of the electric and magnetic dipoles of the nanocluster as well as the multipolar and total efficiency. We see that both electric and magnetic dipoles scatter with equal amplitudes and phase over a broad band of optical frequencies

of almost 100 nm. The radiation diagram of the cluster is provided in Fig. 1(b) along with the spatial distribution of the near field in Fig. 1(c&d) and shows that virtually the scattered energy is radiated in the forward direction. The operation wavelength can be tuned by varying the volume fraction or else the number of inclusions per cluster.

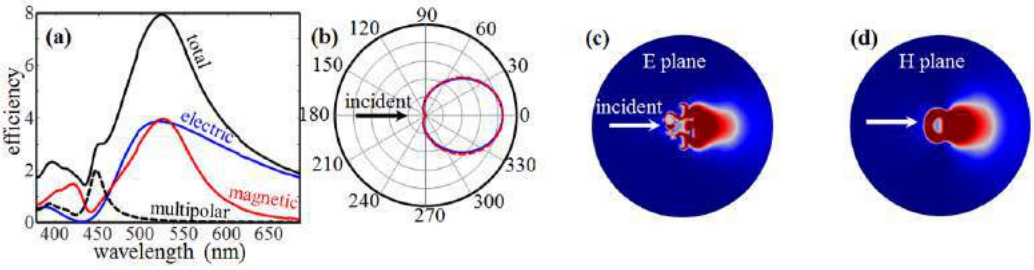

Figure 1: Huygens sources made of spherical clusters

We also adopt an analytical approach which very closely follows the results predicted by our simulations. We consider the nanocluster to be a spherical homogenous nanoparticle made of an effective medium. The effective medium properties (namely the electric permittiy ϵ and magnetic permeability μ) are given by extended Maxwell-Garnett theory which provides

$$\epsilon_{\text{eff}} = \epsilon_{\text{h}} \frac{x^3 + i3fa_1}{x^3 - i\frac{3}{2}fa_1} \tag{1}$$

$$\mu_{\text{eff}} = \frac{x^3 + i3fb_1}{x^3 - i\frac{3}{2}fb_1} \tag{2}$$

where ϵ_{h} is the host dielectric constant, $x = ka$ is the size parameter of the inclusion in which k is the wave vector in the host medium and a is the size of the inclusion. f is the volume fraction and a_1 (b_1) is the first order Mie coefficient describing electric-like (magnetic-like) dipole scattering. Then these effective parameters are used in classical Mie theory to compute the scattering of the nanoclusters and correctly describe the Huygens features exhibited by the system.

3. APPLICATION TO PULSE COMPRESSION

An application will also be described, by considering the interaction of a pulse of light with these sources, which show that femtosecond pulses can be compressed so as to compensate for the strong chromatic dispersion undergone by ultra-short pulses when they propagate through optical components. As noted by Decker *et al.* [1], this is due to the strong group velocity dispersion provided by the Hyugens sources near the simultaneous resonance of the electric and magnetic dipoles.

Abstract— In this talk, I will discuss our current progress toward assembling DNA-mediated plasmonic nanocavities incorporating single quantum emitters. DNA complementarity allows the controllable placement of individual colloidal quantum dots or fluorescence molecules within closely-spaced metallic nanoparticles. Using this pre-programmable approach, we greatly enhance the emission, and the coupling strength of individual emitters with plasmonic modes. The rational engineering of these self-assembled systems are ideally suited to study plasmon-single exciton interactions.

DNA can be used as a pre-programmable tool to rationally engineer metallic nanoparticles (NPs) with nanometer spacing gaps and tunable plasmon resonance. We have recently shown the feasibility of using DNA origami to fabricate plasmonic cavities able to achieve strong coupling between plasmons and molecular aggregates [1]. Here, we use DNA complementary to place individual quantum emitters, such as colloidal quantum dots and fluorescent molecules, within the NPs cavity. As a proof of concept, we show the placement of single QDs between gold nanoparticles (Fig. 1a) displaying several orders of magnitude emission enhancement compared to individual quantum dots. By varying the NP size, the plasmonic nanocavity resonance is off-tuned in respect to the emitter's emission to prevent quenching. On a second example, we demonstrate the assembly capabilities of the DNA-origami technique to fabricate systems with small mode volumes (Fig. 1b). It has recently been shown that one can achieve strong-coupling between plasmons and individual single emitters using plasmonic cavities [2-3]. Since the mode volume of an open cavity depends on the NP radius R and the gap distance d, $V_{eff} \propto R d^2$ [4], it is desired to use small NPs to increase the coupling-strength g which scales as $g \propto 1/\sqrt{V_{eff}}$. Figure 1b shows an array of 15 nm NPs dimers with nanometer-sized gaps assembled with DNA Origami. The DNA template further allows the placement of individual molecules inside the plasmonic cavity. The flexibility of the design of using DNA as an assembly methodology is an ideal approach to study plasmon - single emitters coupling and to integrate nanocompoents for optical applications.

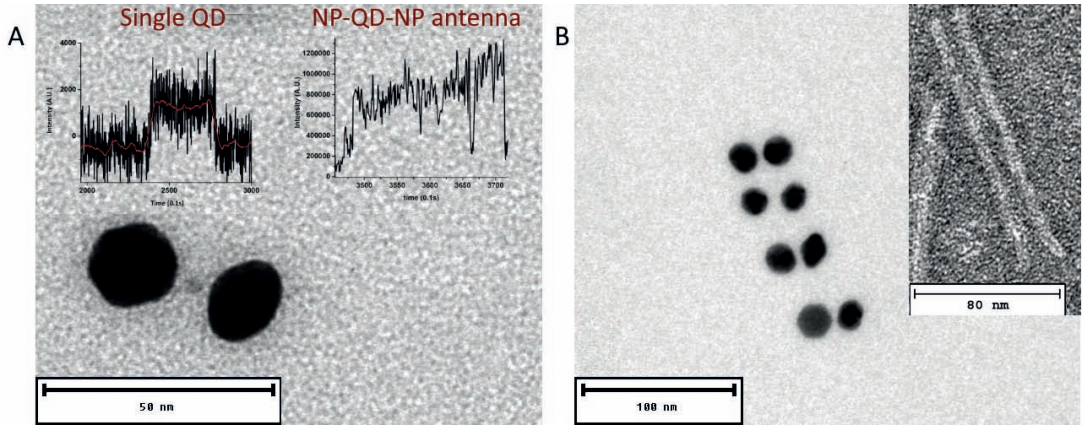

Figure 1: **A)** Individual CdS/ZnS quantum dot placed between 30 nm gold nanoparticles assembled using DNA complementary. The resonance of the cavity is tuned to be blue-shifted in respect to the emitter to avoid quenching. Inset: Fluorescent emission of individual QDs (left) and NP-QD-NP antennas (right). **B)** Array of 15 nm gold nanoparticles assembled using DNA-origami. The DNA template (inset) used for the assembly allows the placement of individual emitters within the plasmonic cavity.

2D materials polaritons

Tony Low
Electrical & Computer Engineering,
University of Minnesota, Minneapolis, USA

Abstract:
In recent years, enhanced light-matter interactions through a plethora of dipole-type polaritonic excitations have been observed in two-dimensional (2D) layered materials. In graphene, electrically tunable and highly confined plasmon-polaritons were predicted and observed, opening up opportunities for optoelectronics, bio-sensing and other mid-infrared applications. In hexagonal boron nitride, low-loss infrared-active phonon-polaritons exhibit hyperbolic behavior for some frequencies, allowing for ray-like propagation exhibiting high quality factors and hyperlensing effects. In transition metal dichalcogenides, reduced screening in the 2D limit leads to optically prominent excitons with large binding energy, with these polaritonic modes having been recently observed with scanning near field optical microscopy. Here, we review recent progress in state-of-the-art experiments, survey the vast library of polaritonic modes in 2D materials, their optical spectral properties, figures-of-merit and application space. Taken together, the emerging field of 2D material polaritonics and their hybrids provide enticing avenues for manipulating light-matter interactions across the visible, infrared to terahertz spectral ranges, with new optical control beyond what can be achieved using traditional bulk materials.

Ultrafast Spontaneous Emission Sources Based on Plasmonic Nanoantennas

Gleb M. Akselrod

For optical interconnects, a need exists for sources of spontaneous emission (LEDs) that rival or exceed the modulation speeds possible with stimulated emission sources (lasers). In particular, LEDs offer the advantages of being more compact and lower energy due to the lack of threshold. The fundamental limitation to the modulation speed of LEDs is the slow spontaneous emission lifetime of typical semiconductors (~1 ns or more). In this talk I will show how plasmonic nanoantennas can be used to dramatically modify the radiative properties of luminescent emitters. Semincoductor quantum dots integrated into the small mode volume, high-field region of the antenna experience ~1,000-fold enhancement in the spontaneous emission rate, resulting in emission lifetimes of ~10 ps. If excited using electrical injection, this emission lifetime points towards LED light sources with modulation rates up to 100 GHz, equaling or surpassing the performance of semiconductor lasers.

New concepts for energy harvesting and photon management

V_2O_5-Sn bilayer thin film mesh electrode for polymer solar cells

Abstract: Electrode modification with suitable metal oxides and or metal buffer layer is an important strategy to improve the light harvesting ability of organic and polymeric solar cells. In this work, square regions of tin (Sn) metal layer over V_2O_5 islands are thermally evaporated onto ITO substrate. The deposited V_2O_5-Sn is expected to act as plasmonic layer improving the carrier collecting ability. Structural, optical and electrical properties of modified electrode are explored and the performance is studied by fabricating polymer solar cells.

Heterojunction polymer solar cells have attracted renowned attention due to advantages like easy fabrication, light weight, potential for low cost solar electricity, portability, compatibility with flexible substrates and scalability [1-5]. However, these devices need improvement in terms of power conversion efficiency, stability and ease of production. Usage of a suitable buffer layer between the active layer and electrode in a polymer or organic solar cell is an important strategy for improving the performance of the cell. Several studies focus mainly on the surface modification of metal oxide by altering their property with self-assembled monolayers by manipulating its morphology, surface energy, etc. Numerous work has been performed in this direction [3, 6-10]. However an exploration by combining metal oxide and a thin layer of metal as a bilayer, especially as a square mesh structure at the active layer-electrode interface is scarce.

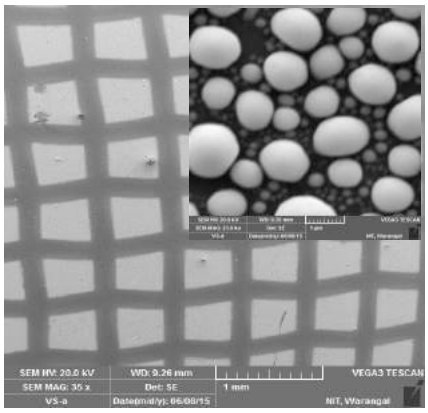

Fig. 1. SEM image of V_2O_5-Sn bilayer mesh on ITO. Inset is the metallic 'Sn' globules.

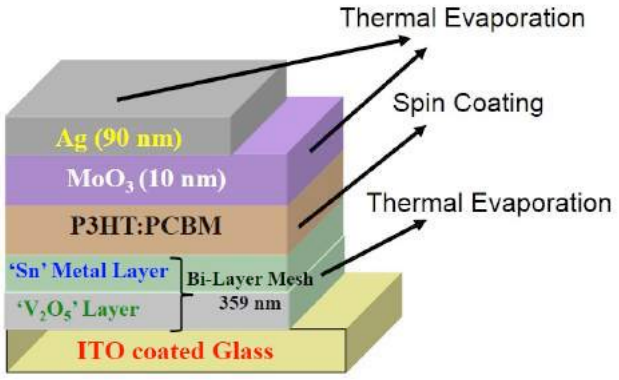

Fig. 2. Device structure of the fabricated polymer solar cell.

Table 1. Electrical transport parameters of the V_2O_5-Sn bilayer mesh film and the measured parameters of the fabricated polymer solar cell device

Carrier concentration (N_b) Cm^3	Mobility (μ) Cm^2/Vs	Resistivity (ρ) Ohm Cm	Conductivity (σ) Ohm Cm^{-1}	V_{OC} (mV)	J_{Sc} (mA/Cm^2)	Fill Factor	Efficiency (%)
1.789×10^{19}	4.251×10^{1}	8.209×10^{-3}	1.218×10^{2}	600	2.24	46.78	0.63

In this work, electrode modification was done by depositing square regions of 'Sn' metal layer over V_2O_5 (Fig. 1) through a shadow mask onto an ITO coated glass substrate by thermal evaporation technique. The deposited metallic tin (Sn) is expected to act as a plasmonic layer to enhance its electron collecting ability. X-ray diffraction showed peaks corresponding to ITO, Sn and V_2O_5. The average thickness of the deposited Sn over V_2O_5 bilayer film was 359 nm as estimated by stylus profiler. The deposited films were having a mesh pattern as seen from the SEM images and the 'Sn' was found to have formed globules. The UV-Vis spectral data showed around 35% transmittance in the visible region. The electrical transport properties of the modified electrode were also obtained by Hall effect measurements (Table 1). We have also fabricated polymer solar cell using the modified electrode showing an efficiency of 0.63% (Fig. 2). These results will be discussed.

Abstract-We have demonstrated experimentally and theoretically that one can use silicon nanoparticles to significantly enhance light absorption in thin perovskite films. We have compared the cases with nanoparticles embedded into the layer and deposited on the perovskite surface. According to our results, absorption in the film with silicon nanoparticles can be increased up to 39% comparing to the film without nanoparticles. Our results are promissing for development and fabrication highly effective perovskite based optoelectronic devices.

In this work, we have investigated the phenomenon of total absorption growth by embedding in volume or deposition on the surface of perovskite film silicon resonant nanoparticles (NPs). For our experiment we have fabricated perovskite films with embedded silicon NPs by the following method: firstly precursor $MAPbI_3$ and solution of toluene with silicon NPs were applied on substrate, which rotated on spinner (1000-5000 t/min), then film was annealing at the temperature of 100 C up to crystallization of the samples and "black phase" formation. To obtain samples with NPs on the surface we have used laser printing method [1]. For measurement of optical transmission (T) and reflection (R) we used normal incidence of linearly polarized light from a halogen lamp and commercial spectrometer with camera. For transmission measurements, the excitation and collection objective with NA=0.95 and NA=0.7 were used, respectively. For reflection measurement, objective with NA=0.42 was used.

We have performed numerical simulations of absorption spectra in Lumerical FDTD Solution as well. We have shown that the absorption coefficient significantly increases in all spectrum from 650 to 950 nm for the case when NPs deposited on the surface. It was demonstrated numerically that the highest absorption increase is equal to around 39% (it's value of integral enhancement of absorption) for the 2% concentration of NPs with radius 130 nm. For the case of the NPs embedded in the perovskite, the maximum of integral absorption is observed for the radius 150 nm and it's around 17%. From our numerical results, one can conclude that the Si NPs deposition on perovskite film surface is more effective than embedded NPs in the volume. We believe that our results will be useful for improve efficiency of perovskite based optoelectronic devices.

Measuring and Exploiting Optical Anisotropies in Nanophotonic Device Architectures

S.J. Brown, R.A. DeCrescent and J. A. Schuller
Electrical and Computer Engineering Department, UC Santa Barbara, CA, USA
*corresponding author: jonschuller@ucsb.edu

Abstract- Nanophotonic architetures provide an attractive approach for enhancing light-matter interactions. A little-discussed aspect of photonic architectures is the presence of strong anisotropies in the electromagnetic field enhancements. These anisotropies are of particular importance in relation to nanostructured materials that possess intrinsic structure-dependent optical anisotropies. In this talk, we describe a novel class of momentum-resolved spectroscopies that provide new insight into structure-dependent optical properties of thin-film material and discuss approaches to exploit these effects in photovoltaic devices that incorporated nanophotonic enhancements.

We use Fourier imaging techniques to measure or control the momentum distribution of in-coming or out-going light rays respectively[1]. These techniques are applied to test-case organic optoelectronic materials that can be deposited with distinct morphologies depending on processing conditions. Using momentum-resolved photoluminescence, we determine the morphology-dependent orientation of transmission and absorption dipoles[2]. We subsequently demonstrate the use of momentum-resolved reflectometry to perform "model-free" measurements of optical constants[3]. The approach provides precise and accurate optical constants with quantified error estimates, obviating the complications associated with highly model-dependent, multi-parameter spectral fitting procedures used in ellipsometry**.** We conclude by describing ongoing efforts to exploit optical anisotropies to enhance light absorption and emission in nanostructured optoelectronics[4].

High Refractive Index dielectric nanoparticles as enhancers of energy harvesting in solar cells: Geometry considerations.

A. I. Barreda[1], F. González[1], and F. Moreno[1*]
[1]Group of Optics, Department of Applied Physics, University of Cantabria, Cantabria 39005, Spain.
[*]corresponding author: morenof@unican.es

Abstract High Refractive Index Dielectric (HRID) nanoparticles have shown to be an alternative to metallic ones. Here, we analyze the possibility of using them for improving the performance of thin film solar cells by studying their Scattering Directionality Conditions (SDCs) as a function of their shape. We demonstrate that cylinders and cubes are the most promising geometries for redirecting the incident radiation into the photosensitive substrate.

At present, solar energy constitute one of the most important renewable energy sources. Its clean and non-polluting energy can be converted into electricity by photovoltaic devices like solar cells, which have become a powerful alternative for solving the problem of climate change. However, the high manufacturing costs, due to great thicknesses of crystalline silicon wafer, which they are made of, make them no competitive with the actual fossil fuel energy resources. For decreasing expenses, thin-film solar cells have been proposed. One of the main drawbacks of these new configurations is the low absorbance of the incident radiation. To increase it, the use of small metallic nanoparticles on top of the photosensitive surface has been suggested[1,2].

Despite the good response of metallic particles in infrared and visible spectral regions, their inherent ohmic losses make them less effective. High Refractive Index Dielectric (HRID) nanoparticles seems to be a promising alternative to address this issue due to their low losses in the infrared spectral region. In addition, HRID nanoparticles can be used for controlling the direction of the scattered radiation. Under some specific conditions, known as Kerker's conditions[3-9], scattered radiation obtained from a single HRID particle can be concentrated either in the backscattering region or in the forward region. In this work, we analyze the scattering directionality conditions of a silicon nanoparticle as a function of its shape. With this contribution, we will show that cylinders and cubes are the most promising geometries for redirecting the incident radiation into the photosensitive substrate.

Abstract- Excitons predominate optical properties of monolayer transition dichalcogenides (1L-TMDs) due to their two-dimensional confined nature. Nanoscale spatial emission profiles of excitons, trions and defect-bound localized excitons in monolayer tungsten disulfide obtained by using near-field imaging, revealing a close correlation between local charge population and the formation of trions.

Monolayer transition metal dichalcogenides (TMDs) have tremendous potential as atomically thin, direct bandgap semiconductors [1]. They are ideal platforms to study two-dimensionally confined exciton systems and can be used as convenient building blocks for quantum photonic devices. They host various exciton complexes of not only neutral excitons also trions and biexcitons consisting of three or four electrons or holes, routinely observable in room temperature. We used near-field photoluminescence (PL) imaging with ~70 nm spatial resolution and identified the nanoscale structural defects of CVD grown monolayer MoS_2, which were not distinguished by conventional confocal PL imaging [2]. we present nanoscale spatial emission profiles of excitons, trions and defect-bound localized excitons in monolayer tungsten disulfide (1L-WS_2) obtained by using near-field scanning optical spectroscopy and imaging techniques with 70 nm spatial resolution [3]. By providing separate profiles of excitons and trions with their spatially varying peak energies, we were able to visualize maps of local trion dissociation energy and the Fermi level, revealing a close correlation between local charge population and the formation of trions.

Efficient Hot-Electron Harvesting by Hyperbolic Metamaterials

Pai-Yen Chen[1] and Mohamed Farhat
[1]Department of Electrical and Computer Engineering, Wayne State University, Detroit, Michigan 48202, USA
[2]Qatar Environment and Energy Research Institute (QEERI), Hamad Bin Khalifa University, Qatar Foundation, Doha, Qatar
[*]corresponding author: pychen@wayne.edu

Abstract- Hot-electron (internal-photoemission) devices have recently emerged as promising candidates for transducing photons into electrical currents, enabling the sub-bandgap photodetection and solar/infrared energy harvesting. However, practical challenges resides in how to improve their poor photoconversion quantum yields and comparatively narrow bandwidth of operation. In this talk, I will present a new hyperbolic metamaterial structure, as a vertically-integrated hot-electron device, for efficiently coupling light into plasmonically-excited hot electrons, which can be efficiently collected with high external quantum efficiency approaching the physical limit. I will theoretically show that this metamaterial-based hot-electron device can exhibit efficient, broadband and omnidirectional photoconversion for infrared and visible light. Finally, I will also discuss how to experimentally realize this metamaterial optoelectronic device with nanofabrication techniques and 2D materials. Results presented here may shed some light on designing energy-efficient photodetectors and energy harvesters beyond the bandgap spectral limit.

Nanophotonics for Light Management in Luminescent Solar Concentrators

Vivian E. Ferry[1*]
[1]Department of Chemical Engineering and Materials Science, University of Minnesota – Twin Cities, Minneapolis, MN 55455 USA
[*]corresponding author: veferry@umn.edu

Abstract-This talk will discuss strategies to improve the performance of luminescent solar concentrators to harvest both direct and diffuse sunlight. We will discuss the combination of nanophotonic light management strategies with different types of luminophores based on their spectral overlap and quantum yield, and show experimental strategies that maintain high quantum yield of nanocrystals in polymer matrices.

Luminescent solar concentrators (LSCs) concentrate both direct and diffuse sunlight onto solar cells, both enabling the use of smaller devices and changing the form factor of the panel for architectural applications. The concentrator consists of a plastic sheet with embedded luminophores and an edge-mounted solar cell; incident sunlight is absorbed by the luminophore, emitted at a longer wavelength, trapped in the concentrator via total internal reflection, and ultimately collected by the photovoltaic device.

Efficient operation requires several highly performing components. First, the luminophore must have a high quantum yield and small overlap between the absorption and emission bands. Second, the luminophore must be soluble and stable in a high-index polymer matrix with desirable mechanical properties, as many luminophores suffer from reduced quantum yields upon integration with polymer matrices. Finally, the emitted light has to reach the edge of the concentrator, avoiding coupling to the escape cone of the waveguide. If the concentrator is intended as a window replacement, then it must be made sufficiently transparent for daytime use, whereas if it is intended as a different type of architectural panel or in non-architectural applications the surrounding mirrors must be low enough loss to promote collection at the edge by the solar cell.

This presentation will discuss several ways where photonic structures are useful to overcome the limitations of luminophores. First we will discuss strategies for core-shell CdSe/CdS luminophores, which have high quantum yields in solution, somewhat reduced quantum yields in the polymer matrix, narrow emission bands, and small overlap between absorption and emission. In this case, integrating a one-dimensional spectral filter on the front surface traps light that would otherwise be lost to the escape cone, but these trapped photons propagate at steep angles and are frequently lost to other processes before reaching the edge. We show that metasurfaces that shift the angle of the propagating photons are one way to overcome this problem. Our calculations indicate that this design achieves equivalent performance from 76% quantum yield nanocrystals as a standard LSC with 99% efficient nanocrystals. We will describe the design of this surface in more detail, including the desired angles of propagation. We will then discuss other ways to integrate photonics into these LSCs, including modifying the angles of emission from the luminophore, and strategies for other luminescent materials with broad emission spectra but negligible reabsorption losses.

Finally, we will discuss our recent experimental work on embedding luminophores into various polymer

matrices while maintaining high quantum yield and radiative efficiency, based on controlling the surface chemistry of the nanocrystals and their subsequent interactions with the polymer matrix.

A New Type of Heat Engine, Using LED's as Refrigerators

Eli Yablonovitch
Electrical Engineering and Computer Sciences Dept., University of California, Berkeley, USA

Abstract- Very efficient light emitting diodes (LED's), surprisingly, do actually become cold as they operate, since LED light carries away entropy. This cooling requires superb LED efficiency. Of course, we now know that the photovoltaic cell and the LED are really the reciprocal of one another. The slogan: "A great solar cell has to be a great LED" has led to all the new solar cell efficiency records.

What if the electrical output of a photovoltaic cell drives an LED, and the LED light in turn drives the photovoltaic cell? You might fear that it would become a perpetual motion machine. Instead it becomes a heat engine in which a small amount electricity can efficiently provide refrigeration, or conversely a small temperature difference can generate electricity. Such an electro-luminescent heat engine, in which photons are the working fluid, can be more efficient than the competing science, thermo-electrics, in which electrons are the working fluid.

A two-resonance tapping cavity for an optimal light trapping

Jordi Martorell[1, 2*] **Quan Liu,**[1] **Pablo Romero-Gomez,**[1] **Paola Mantilla-Perez,**[1] **Silvia Colodrero,**[1] **and Johann Toudert**[1]

[*]corresponding author: jordi.martorell@icfo.es

Abstract- A two-resonance tapping cavity is proposed and implemented to obtain an effective broadband light trapping in the absorber layer of thin-film solar cells. When this new optical cavity is applied to high performance polymer cells, an optimal light harvesting enhancement is achieved. This leads to a ~20% increase in power conversion efficiency, corresponding to a record performing polymer cell.

Light trapping and guiding in thin films is essential to obtain energy-efficient light harvesting devices. Several decades ago following a ray optics approach, Yablonovitch established that the maximum light trapping in a dielectric slab is equal to $2n^2$ times the incident intensity, being n the refractive index of the slab.[1] To achieve this limit requires a random texturing of both film surfaces to produce a random distribution of light regardless of which direction the beam is coming in.[1,2] Over decades of thin film photovoltaic technology development, many different physical phenomena have been considered and partial success has been reached when a certain degree of light trapping has been demonstrated. However, light trapping or confinement has never been shown to be critical to achieve record performing thin film cells.

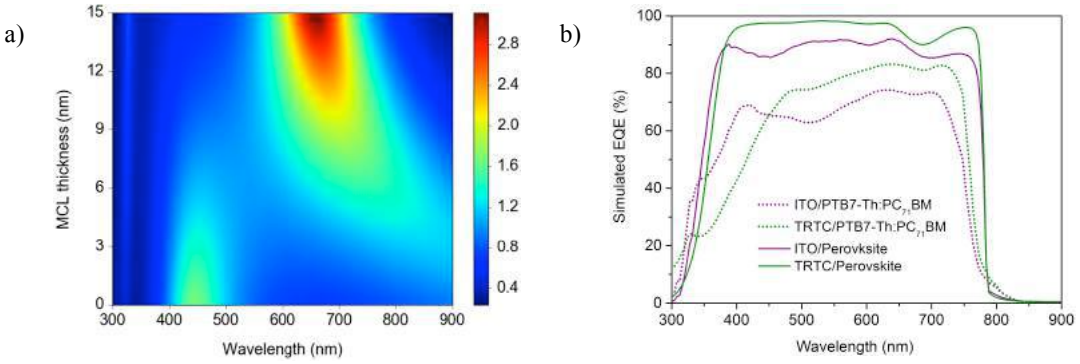

Figure 1 a) Field amplitude inside the cavity. b) External quantum efficiency (EQE).

In this work, we implement a two resonance tapping cavity (TRTC) to reach an optimal broadband confinement for electromagnetic waves.[3] We demonstrate that the combination of an insulator cavity layer with a metal cavity layer (MCL) leads to the formation of an optical cavity that can exhibit a resonant character at two non-harmonic frequencies (See Fig. 1a). The increase in energy storage capacity relies in the inharmonicity of the electromagnetic field propagation within such TRTC. We demonstrate that the energy confinement capacity

seen is to a large extent independent of the material composition or thickness of the active layer, and can be applied to reach efficiency limit performances for any kind of thin film photovoltaic device. We experimentally measured record efficiencies for the PTB7-Th polymer cell and predicted that in the event the TRTC is applied to perovskite cells, as seen in Figure 1b, the EQE would closely match the IQE for a broad frequency range.

We utilize a modeling of non-Markovian open quantum systems, consisting of an excitonic dimer system that displays memory effect due to time delayed interaction with a bath of phonons. We, thus study the effect of delay in the interaction on photosynthetic coherence and excitons dynamics in the time domain investigated experimentally (few hundred femtoseconds). In particular, we show that for high time delays, the coherence is maintained for longer periods. Additionally, if delay is taken into account, coupling to environment can be tuned to lower values, unlike in previous studies.

Hybrid Plasmonics with Quantum Confined Materials and Devices

Superradiance and PT symmetry with plasmonic waveguides

Ying Li and Christos Argyropoulos*

Department of Electrical and Computer Engineering, University of Nebraska-Lincoln, Lincoln, Nebraska, 68588, USA

*corresponding author: christos.argyropoulos@unl.edu

Abstract-Plasmonic waveguides exhibit an effective epsilon-near-zero operation in their cut-off wavelength and Fabry-Perot resonances at lower wavelengths. In this work, we demonstrate a plasmonic route to control coherent collective spontaneous emission effects, such as superradiance and subradiance, from emitters located inside plasmonic waveguides. Our findings will be important to optical computing systems, quantum entanglement of qubits, and efficient sensors. In addition, we will demonstrate a nanoscale parity-time symmetric nanophotonic device, designed based on gain medium embedded inside the plasmonic waveguide nanochannels.

In recent years, realistic metamaterials with effective epsilon-near-zero (ENZ) permittivity response have raised increased interest, especially due to their peculiar transmission properties that provide, in principle, infinite phase velocity combined with anomalous impedance-matching phenomena. This anomalous quasi-static response can be theoretically and experimentally obtained using narrow plasmonic waveguides operating at their cut-off wavelength [1]. Uniform phase distribution and large field enhancement is achieved inside the nanochannels of these narrow waveguides and has been used to enhance fluorescence, squeeze and tunnel light, and boost optical bistability. Moreover, large and uniform local density of states obtained inside the nanochannels are ideal conditions to increase the collective spontaneous emission rate of several emitters [1].

As a collective spontaneous emission response, superradiance has attracted much attention leading to several intriguing applications in laser, sensor, and optical communication technologies [2]. It was proposed that the radiation intensity emitted by N atoms placed in subwavelength distances was proportional to N^2 instead of the usual N. This phenomenon is based on the constructive interference between emitted waves, which can improve the directivity and coherence of the total emitted radiation by an ensemble of quantum emitters. However, this photonic coherent emission effect can be achieved only when the neighboring quantum emitters are placed very closely to each other at highly subwavelength distances, which limits its practical applications.

In this talk, we will present a way to obtain superradiance effects from emitters separated by distances comparable and even larger to the operating wavelength. The superradiance mode is stimulated by a collection of two-level emitters embedded in plasmonic waveguides. The waveguide unit cell is shown in the inset of Fig. 1(a), which is composed of a narrow rectangular glass slit carved in a sliver (Ag) screen. The transmission and reflection spectrum of this waveguide is illustrated in Fig. 1(b) (black lines) and this structure can sustain an ENZ resonance at its cut-off wavelength (λ=1012 nm). At this wavelength point, the electric field enhancement is large and homogeneous along the nanochannel [1]. Below the cut-off wavelength, the first-order Fabry-Perot (FP) resonance (λ=922 nm) is obtained with a typical standing wave field pattern distribution [1]. We use classical electromagnetic calculations to compute the normalized decay factor γ of a pair of emitters embedded inside the channel at ENZ and FP resonances. As it is shown in Fig. 1(a), perfect superradiance (γ=2) is obtained at the ENZ wavelength that is independent of the emitter's separation distance d. Interestingly, the superradiant

mode (γ >1) can be dynamically changed to a subradiant mode (γ <1) at the FP resonance by changing the emitters' separation distance and location. We will also present the collective emission of N emitters uniformly located inside the plasmonic channel at the ENZ wavelength. Our findings can be applied to improve the response of optical computing systems and quantum communications, such as the efficient control of long distance entanglement between qubits [3].

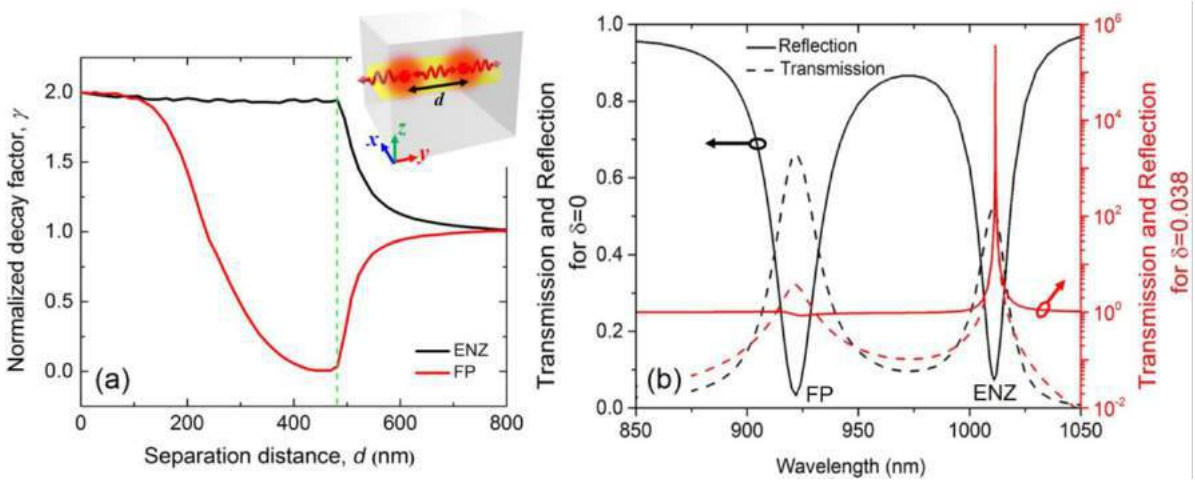

Figure 1 (a) Normalized collective decay factor γ versus separation distance d at ENZ and FP resonances. The green dashed line depicts the end of the waveguide. The inset shows the plasmonic waveguide unit cell loaded with a pair of emitters. (b) Transmission and reflection of the plasmonic waveguide as a function of the incident wavelength with (red) and without (black) gain.

Our plasmonic waveguide can also be used to design a nanoscale parity-time (PT) symmetric system when we introduce an active dielectric material ($\varepsilon = \varepsilon_{glass}+i\delta$) with small gain permittivity coefficient δ inside the nanochannel. The optical loss is introduced by the negative imaginary part of the silver screen permittivity. The effect of introducing gain is more than loss compensation and the strong interplay between loss and gain inside the waveguide will lead to super scattering at exceptional points obtained close to the ENZ resonance. As the red lines demonstrate in Fig. 1(b), giant and narrow transmittance and reflectance can be simultaneously obtained at the exceptional ENZ point (λ=1011.66 nm), when we introduce a small gain coefficient δ=0.038. During our talk, we will also present unidirectional perfect absorption and lasing when the proposed active waveguide is illuminated by two counter-propagating plane waves. Our findings provide a new platform to design nanoscale optical modulators, low threshold nanolasers, and unidirectional coherent perfect absorbers. The addition of optical nonlinearities in this PT-symmetric system will also be studied leading to strong optical bistability and switching around the ENZ exceptional point resonance.

Abstract We discuss a novel quantum description of Surface Enhanced Raman Spectroscopy based on the framework of quantum optomechanics. This theory allows interpreting recent experiment and predicts new effects such as unexpected non-linearities, large correlations of the emitted photons and rich control of the population of molecular vibrational states, which may open new possibilities in the study of molecules coupled with plasmonic systems.

Surface Enhanced Raman Spectroscopy (SERS) exploits the strong plasmonic resonances supported by metallic nanoparticles to enable Raman studies of very small quantities of analyte, up to single molecules. Normally, SERS studies use a simple model based on the classical plasmonic response. However, recent work has established a close connection between SERS and quantum optomechanic systems[1]. This new perspective, combined with recent advances on experimental control of Raman systems[2,3], offer the promise of revealing new phenomena and applications.

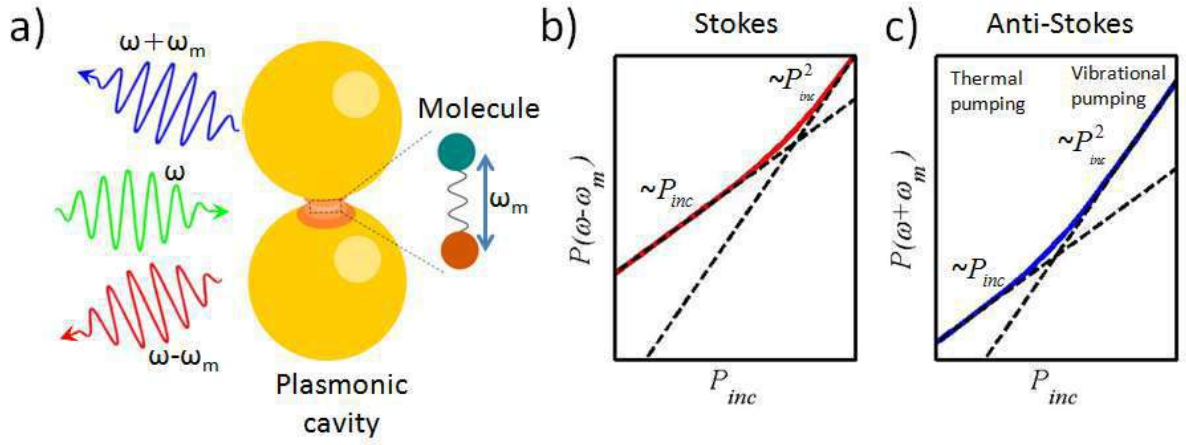
We use a Quantum Electrodynamics (QED) treatment based on this new framework to study both off-resonant and resonant SERS. The system considered is sketched in Fig. 1a, where the interaction between the vibrations of a molecule and a laser is mediated by a plasmonic cavity. For off-resonant SERS, no electronic level is excited resonantly and the Hamiltonian is characterized by a coupling term $\mathbf{H_I=-g a^\dagger a(b^\dagger+b)}$, where **g** is the coupling strength and $\mathbf{a^\dagger}$ ($\mathbf{b^\dagger}$) and **a**(**b**) are the rising and lowering operators, respectively, of the plasmonic mode (molecular vibrations) [1,4]. This description is identical to the one found in standard quantum optomechanical systems, but with very different values of the parameters. Notably, the large plasmonic losses can be compensated by huge coupling strengths, leading to large cooperatives and potentially the exploration of optomechanic regimes not available to other alternatives.

Our quantum model captures the emission at smaller (Stokes) and larger (anti-Stokes) energies of the incoming laser (Fig. 1b-c), and allows studying the relative influence of thermal pumping (vibrations populated due to the temperature) and vibrational pumping (vibrations excited via the Stokes process). We find an unexpected non-linearity of the Stokes signal for very intense lasers, which may be of interest for experiments. In contrast with typical situations in quantum optomechanics, this non-linearity is found also when the laser is tuned to the plasmon frequency. Last, we analyze the correlations between Stokes and anti-Stokes photons and find that, not only very large correlations, but even non-classical states may be reachable. We demonstrate the usefulness of our model by applying it to pico-cavities at cryogenic temperatures, formed due to wandering of gold atoms in nanometer gaps[5]. These picocavities allow to excite single vibrations, and are characterized by

very large optomechanical coupling strengths, in the order of 10s of meV.

Similarly, resonant SERS accepts a description typical of hybrid optomechanics[6]. In this picture, the electronic level of the molecule couples with the plasmon via a Jaynes-Cummings term, and the Franck-Condon approximation is used to model the interaction between molecular vibrational and electronic levels. We find interesting effects, such as avoided crossings in the emitted spectra of, when the sidepeaks of the Mollow triplet associated with the electronic levels cross the Raman lines. The resulting interaction also allows a particularly flexible control of vibrational populations, which may eventually find applications for photochemistry.

We thus show how going beyond standard descriptions to consider the quantum nature of the molecule-plasmon coupling in SERS experiments can open new perspectives in Raman spectroscopy, and may also offer an interesting platform for quantum optomechanical studies



Figures 1: (a) Scheme of the SERS system being studied, where an incoming photon at frequency ω excites a plasmonic cavity coupled with a molecule. The molecular vibrations of ω_m frequency lead to the emission of Raman photons at ω-ω_m (Stokes) and ω+ω_m (anti-Stokes). Sketch of the Evolution of the **(b)** Stokes and **(c)** Anti-Stokes signal with laser power (P_{inc}), for off-resonant Raman. The quadratic dependence of the Stokes signal with P_{inc} at large intensities is not explained by standard SERS models. The change from linear (at low intensity) to quadratic (at large intensity) dependence of the Anti-Stokes signal with P_{inc} is a signature of vibrational pumping. Dashed black lines indicate linear and quadratic dependences for reference.

Quantum Defects of Carbon Nanotubes: Room Temperature, 1.5 μm Single Photon Emitters for Quantum Plasmonic Circuits.

H. Htoon
Center for Integrated Nanotechnologies, Materials Physics and Applications Division,
Los Alamos National Laboratory, USA
*corresponding author: htoon@lanl.gov

Abstract- We demonstrate that exciton localization at covalently-introduced aryl sp3 defect sites in single-wall carbon nanotubes provides a route to room-T single photon emission (SPE) with ultra-high single-photon purity (99%) and the shot-noise limited emission stability. The inherent optical tunability of SWCNTs allows us to generate room-T SPE spanning over 1.3 to 1.55 μm telecom band. We integrate these novel quantum emitters with plasmonic and photonic structures toward achieving control on SPE characteristics and realization of quantum photonic/plasmonic functionality.

Quantum light sources capable of supplying a regular stream of single as well as entangled photon pairs lie at the heart of quantum photonic/plasmonic circuits that are needed for realization of novel quantum information technologies. For practical implementation, these quantum light sources are required to operate at room temperature and telecommunication wavelengths. A compatibility with well-established Si/SiO_2 based microelectronic fabrication technology is also highly desirable. Despite intensive research effort, an ideal quantum material system capable of meeting all of these requirements has not emerged as of today. InGaAs self-assembled quantum dot, one of the materials intensely investigated for this purpose can emit quantum light at 1.3-1.5 micron telecommunication wavelength but operate only at cryogenic temperatures. Another material system, nitrogen vacancy centers in diamond, can operate at room temperature but emit quantum light only in visible spectral range.

Last year, we have demonstrated that room T single photon emission at wavelength approaching 1.3 μm can be achieved via introduction of quantum defect states by covalent oxygen functionalization of (6,5) single wall carbon nanotubes (SWCNTs).[1,2] Because these quantum defect states are created relative to the band edge of the SWCNT, it becomes possible to tune this emission to 1.3 and 1.55 μm via functionalizing larger diameter nanotubes that have smaller ban gap. However, oxygen functionalization becomes difficult to control with the increase of tube diameter. Furthermore, the single photon emission of these oxygen dopant states also becomes unstable at room temperature. As a result, long-desired goal of establishing room-T single photon emission in telecommunication wavelength remain unfulfilled.

Here in this work, we utilize highly controllable aryl diazonium reaction chemistry to create quantum defect states on large diameter, (7,5) and (10,3) SWCNTs and *successfully demonstrate room-T single photon emission*

at wavelengths extending from 1.1 μm to the deep center of the telecom C band, 1.55 μm. We achieved 99% single photon purity, a critical milestone for applications such as quantum key distribution, logic gates, and memory. This figure exceeds the best single photon purity reported in other RT single photon emitters such as NV centers (70%-90%). The single photon emission is also characterized with exceptional, shot-noise limited count rate stability. Under strong CW excitation, we achieve count rates up to 120 kHz despite a low combined photon collection and detection efficiency (0.05%) for the near-IR emission of our dopant states. Direct coupling of emission to waveguides,[3] paired with higher efficiency detectors, can make 10-100 MHz count rates feasible. The defect-state emission rates are thus comparable to the high rates obtained from diamond color centers and InAs quantum dots. Correcting for detection efficiency, we estimate a single photon emission quantum efficiency of ~12%.

These results establish quantum defects states of diazonium functionalized SWCNTs as near perfect single photon sources meeting almost all the key technological requirements. Furthermore, SWCNTs' compatibility with variety of soft nano-lithography and assembly techniques present unique opportunity for integration into nano-optoelectronic devices and incorporation into plasmonic and photonic cavities for further enhancement and manipulation of photoluminescence (PL) behaviors. I will present a few results we have attained in this area.

Abstract-The fast development of top-down fabrication has enabled investigations towards the interaction mechanism between optical fields and metallic/dielectric nanoantennas. In this talk, we will present our recent work on silicon antenna for high-resolution color printing beyond diffraction limit, where we could achieve a color gamut of more than 100% of sRGB. In addition, we will also present our recent work on metallic nanoantenna for the giant enhancement of photoluminescence (PL) and second-harmonic generation (SHG) from monolayer tungsten diselenide (WSe_2).

The plasmonic response of metallic nanostructures has enabled high resolution color prints beyond the optical diffraction limit, with a resolution of ~100,000 dots per inch (d.p.i.).[1] However, plasmonic colors continue to suffer from poor color vibrancy, with a gamut that occupies only a small subset of perceivable colors on the International Commission on Illumination (CIE) 1931 chromaticity diagram.[2] In this presentation, we will present our recent work on using the local magnetic/electric dipole resonances of silicon nanostructures so as to achieve a CMOS compatible, high-resolution, and a color gamut of more than 100% of sRGB. Moreover, tungsten diselenide (WSe_2) is an attractive two-dimensional (2D) transition-metal dichalcogenide (TMDC) with direct bandgap, and it has great potential for various optoelectronic applications.[3] However, the optical interactions with monolayer WSe_2 and optical fields are very weak due to their characteristic of being atomically thin. In this presentation, we will present our recent work on using metallic nanoantennas to enhance the interaction between monolayer WSe2 and the incidence optical fields, so as to achieve a giant enhancement of both photoluminescence and second-harmonic generation emissions.

Abstract Self-assembled plasmonic structures provide enough field-enhancement for single molecule sensitivity in Surface Enhanced Raman Spectroscopy (SERS). We combine this effect with the capability of plasmonic structures to generate high-energy charge carriers to study the oxidation and reduction of single molecules in the plasmonic hot-spot, and demonstrate we can optically control the redox state of these trapped molecules.

Bringing plasmonic nanoparticles close together allows for the coupling of their optical fields. This coupling results in the formation of intense plasmonic hot-spots. Rigid barrel shaped molecular spacers can be utilized to reducibly control the inter-particle spacing between nanoparticles to sub-nm separations.[1] The resulting structure yields field enhancements approaching 3 orders of magnitude.[2] Such high field enhancements allow for sensing guest molecules inside the molecular spacers at the single molecule level by Surface Enhanced Raman Spectroscopy (SERS), and the tracking of their evolution over time.[3]

The non-radiative relaxation pathways of the plasmons provide high energy charge carriers[4] that can be transferred to the molecules captured in the hot-spot. Trapping the charge carriers on molecules sequestered in the spacers results in the oxidation/reduction of these molecules. On account of the high field enhancements in the nanogap, these processes can also be followed in real time via SERS. Here we demonstrate that we can not only follow these processes in real time but also manipulate their redox state.

The redox state of the trapped molecules can be optically controlled by changing the laser intensity, by providing an electron source (see Fig. 1), in this case a molecular reducing agent, for the gold nanostructure to replenish their donated electrons. This reducing agent on itself is not strong enough to reduce the molecules in this configuration. However, switching between a low and high power exposure, after a short delay, switches the molecules' redox state between 2+ and neutral. Demonstrating that optically controlled molecular switches can be made using hot-electron transport between plasmonic structures and molecules.

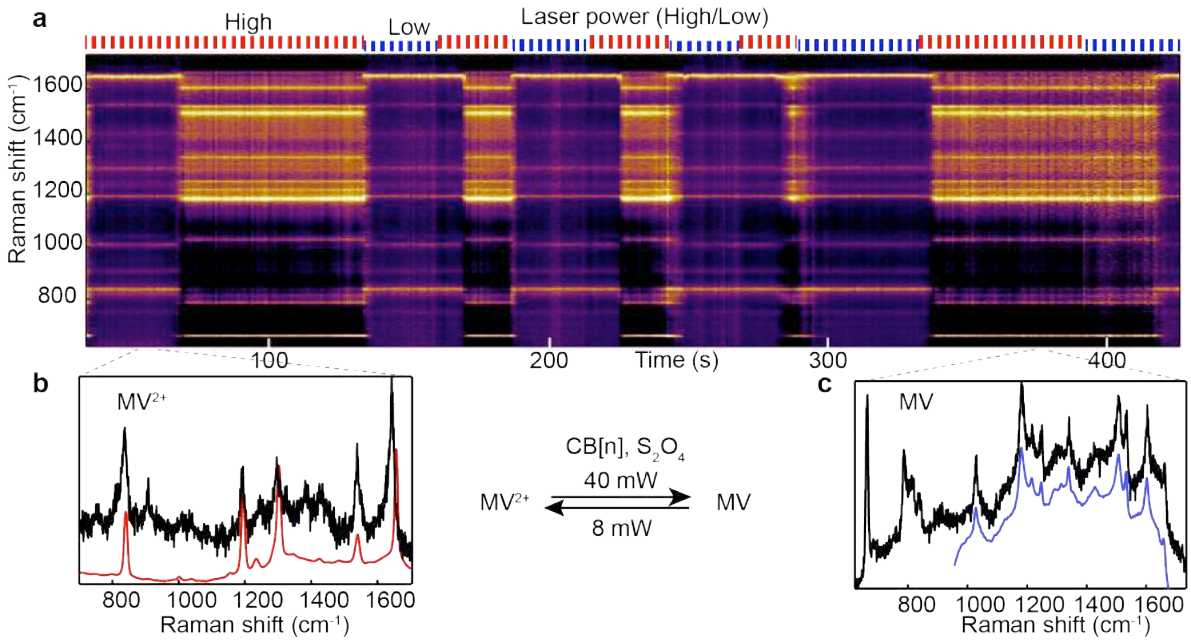

Figure 1: Surface enhanced time scan of self-assembled gold nanoparticles using cucurbit[*n*]uril and a suitable guest (methyl viologen: MV). The redox state of the guest can be switched between MV^{2+} and MV^{0} by switching the laser power. Raman spectra before and after switching match bulk spectra taken of the unreduced and reduced MV respectively.

Quantum and Classical Phenomena in Metal Nanostructures with Hot Spots: Coherent Transfer of Plasmons, Hot Electrons and Heat Generation

Alexander O. Govorov

Department of Physics and Astronomy, Ohio University, Athens, OH, 45701
govorov@ohio.edu

Metal nanocrystals exhibit strong plasmon resonances and have the ability to absorb and scatter light very efficiently. This study concerns special designs of plasmonic nanostructures with electromagnetic hot spots, where the electromagnetic field becomes strongly enhanced. Overall plasmonic nanostructures with hot spots demonstrate strongly amplified optical and energy-related effects.

(1) Using nanoparticle arrays made of different metals, one can transfer plasmonic signals coherently and with small losses [1].
(2) Plasmonic hot spots efficiently generate energetic electrons, which can be used for photochemistry and photodetection [2,3].
(3) Using nanostructures with hot spots, one can strongly enhance optical generation of heat and also confine high photo-temperatures in small volumes [4,5].
(4) Colloidal nanocrystal assemblies with plasmon resonances allow us to strongly enhance chiral optical responses (circular dichroism) of biomolecules and drugs [6,7].

Strong Coupling Between Individual Plasmonic Metal Nanostructures and Quantum Dots

M. Pelton
[1]University of Maryland Baltimore County, Baltimore, MD, U.S.A.
mpelton@umbc.edu

Abstract-Coupling between plasmons in metal nanoparticles and exctions in quantum dots can lead to novel optical properties and phenomena. We predict that a single colloidal quantum dot can induce nearly complete transparency in the much stronger absorption and scattering of a metal nanostructure, and this induced transparency can be switched on and off with control laser pulses. For more than one quantum dot coupled to the same nanostructure, we predict that laser pulses can induce entanglement among the quantum-dot states.

We have developed a model-Hamiltonian formalism to describe plasmonic metal nanostructures coupled to excitons in quantum dots, taking into account the quantum-mechanical nature of both the excitons and the plasmons. Using this model, we have shown that strong plasmon-exciton coupling leads to novel optical properties and phenomena, beyond the enhancement of optical processes that have been widely investigated so far.

For example, we have predicted that a single colloidal quantum dot has the potential to induce nearly complete transparency in the much stronger absorption and scattering spectrum of a metal nanostructure. Short laser pulses can remove or even reverse the induced-transparency dip, changing it into a superscattering pulse (see Figure 1). If more than one quantum dot is coupled to the same metal nanostructure, laser pulses can induce quantum-mechanical entanglement between the occupation states of the quantum dots. Applying our formalism to an idealized model of a dye-sensitized solar cell, we have shown that there is a fundamental limit to the degree to which plasmons can enhance photocurrent.

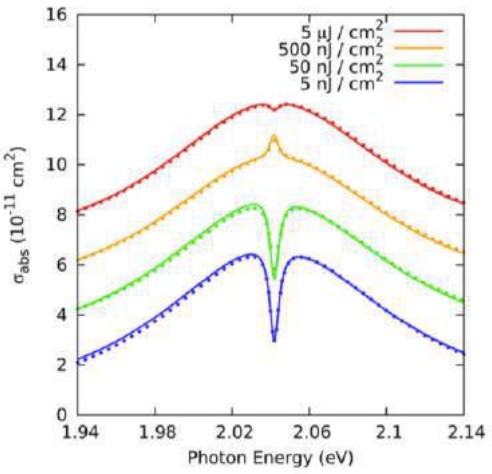

Figure 1. Calculated absorption spectra for a system consisting of a single semiconductor nanocrystal between a pair of gold nanoparticles, for different amounts of energy in an incident laser pulse.

We are currently working on realizing strongly coupled plasmon-exciton systems experimentally. We expect that these systems will enable optoelectronic devices operating at the limit of miniaturization and power consumption, all-optical quantum information processing at the nanoscale, and new paradigms for optical harvesting of solar energy.

Broadband Second-Harmonic Generation based on Active Nonlinear Metasurfaces

J. Yoo and J. Lee*
Ulsan National Institute of Science and Technology, South Korea
*corresponding author: jongwonlee@unist.ac.kr

Abstract-Broadband second-harmonic generation based on Stark-tunable intersubband nonlinearities in multiple-quantum-well structures combined with plasmonic resonators was studied. Theoretically, 5 times broader second-harmonic generation wavelength compared to passive nonlinear metasurfaces and over 0.1% of the maximum conversion efficiency were achieved.

Nonlinear response from optical metasurfaces have opened a new direction in research, with interesting applications such as super-resolution imaging and efficient frequency conversion in subwavelength thin-film with greatly-relaxed phase-matching constraints [1,2]. In a different context, it is well known that intersubband transitions in n-doped multi-quantum-well (MQW) structures may be used to design materials with record second-order nonlinearities up to 4-5 orders of magnitude larger than in traditional bulk nonlinear materials.

Recently, nonlinear metasurfaces with record-high nonlinear optical response up to 1.2×10^6 pm/V for second-harmonic generation (SHG) based on coupling electromagnetic modes in plasmonic nanoresonators with quantum-engineered intersubband nonlinearities in MQW semiconductor heterostructures have been demonstrated [2,3]. However, efficient SHG from the metasurface is only possible near the intersubband resonant frequency due to the resonant characteristics of the intersubband nonlinearities, and thus the operating wavelength for the SHG (SHG bandwidth) is very limited. In this work, we theoretically study active nonlinear metasurfaces for broadband SHG based on Start-tunable intersubband nonlinearities in which the intersubband transition energies in the MQW are modulated from bias voltages applied on the MQW layer. We designed plasmonic resonators to achieve the maximum SHG conversion efficiencies at each bias voltages.

For SHG in the mid-infrared region, we designed a 400nm-thick nonlinear MQW layer that contains 20 repetitions of the $In_{0.53}Ga_{0.47}As/Al_{0.52}In_{0.48}As$ coupled-quantum well structure. One period of the quantum well structure shown in Fig. 1(a) consists of three quantum wells in which the intersubband transition energies between electron subbands for 1 to 2 level (E_{12}) and for 1 to 3 level (E_{13}) can both modulated for bias voltages by quantum confined Stark effect. The modulated intersubband transition energies in the MQW leads to spectral shift of the nonlinear susceptibilities, as shown in Fig. 1(b).

In order to achieve efficient SHG under normal incidence of input pump, the MQW layer is sandwiched between a metal ground plane (bottom contact) and a patterned array of complementary split-ring-resonators (top contact) and the portion of MQW layer without top metal pattern is removed to boost the conversion efficiency (see Fig. 2(a, b))[3]. The nanostructures are designed to induce the enhanced local E_z-field in the MQW layer at both fundamental frequency (FF) ω and SH frequency 2ω for *x*- and *y*-polarized input light, respectively. In this configuration, the highest effective nonlinear susceptibility out of the metasurface is expected for *yxx* polarization combination (the first letter refers to the SH polarization and the last two letters refer to the FF input wave polarization).

For theoretical calculations of SHG conversion efficiencies, we used the input pump intensity of 40 kW/cm^2 for the input pump wavelength range from λ_{FF}=7 to 13μm. The calculated maximum SHG conversion efficiencies and the spectral response of the normalized SH power for the bias voltages from -4V to 4V with 1V step are shown in Fig. 2(c). We obtained a conversion efficiencies over 0.1% for all bias voltages and 5 times broader SHG operation wavelength compared to the passive device (0V). The active nonlinear metasurfaces proposed in this work may have significant practical impact on variety of applications, including broadband frequency up- and down-conversion, spectroscopy and imaging systems requiring broadband operation.

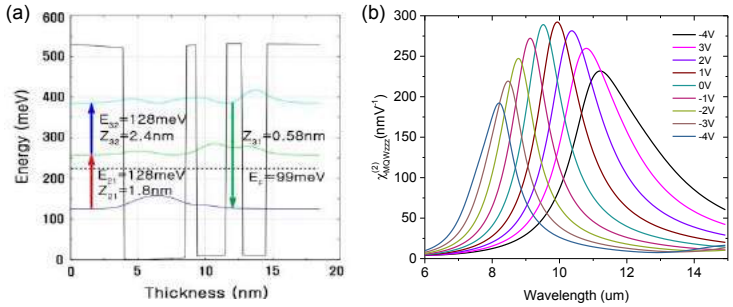

Figure 1. (a) Conduction band diagram of one period of an $In_{0.53}Ga_{0.47}As/Al_{0.48}In_{0.52}As$ MQW structure. The layer sequence (in nm) is **4.0**/4.6/**0.8**/2.2/**1.2**/1.8/**4.0** where barriers are shown in bold, and the first 4.6nm well is n-doped to 3.7×10^{18}cm^{-3}. Abstract - We experimentally demonstrate novel geometries of surface-plasmon-polariton based resonators that exhibit record-high quality factors (>750) in the visible frequency range, and use them to achieve narrow-linewidth lasing.

Coherent optical sources with small device footprints, narrow-linewidth, and room-temperature operation are desirable for potential applications in on-chip optical communications [1]. Surface plasmons, under the form of both stationary localized surface plasmons (LSPs) or propagating surface plasmon polaritons (SPPs), offer an effective route towards achieving lasing at micro- and nano-scale dimensions when integrated with a suitable optical gain media [2]. However, intrinsic absorption and scattering losses have limited the quality factors (Q) associated with plasmonic cavity resonators to <50, thereby limiting the threshold and emission linewidth of plasmonic lasers based on them or requiring low-temperature operation [3, 4]. Recent publications utilizing the template-stripping approach to achieve ultrasmooth metal surfaces have pushed the Q-factors of plasmonic resonators beyond 300, resulting in successful room-temperature lasing operation [5, 6]. In this talk, we will describe recent developments in the field of plasmonic resonators and lasers including our work on experimental realization of plasmon-resonators exhibiting record high Q-factors exceeding 750 in the visible frequency range. The SPP-modes we focus on are bound to the inner metal-dielectric interface of the cylindrical cavity, and exhibit high-Q due to their reflectionless propagation, analogous to the whispering gallery modes in a dielectric resonator. The unique cylindrical open-cavity architecture of the cylindrical plasmonic resonators also makes them suitable for high figure-of-merit optical sensing; for example, the evanescent interaction between analytes and localized electromagnetic fields within a lasing cavity can result in their detection with high sensitivity in a label-free manner [7].

We demonstrate ultralow-power dielectrophoretic trapping of quantum dots, diamond nanoparticles, and gold nanoparticles using sub-10 nm nanogap electrodes. Dielectrophoresis is a scalable electronic method to trap polarizable objects such as molecules or nanoparticles via gradient forces. Using nanometer-scale gaps, we show rapid trapping and positioning of quantum emitters on a chip using sub-1 V AC bias.

These structures were made using atomic layer lithography, which combines standard lithography and atomic layer deposition (ALD) to create ultra-small gaps at the wafer scale. Using an ultra-bright light source, we are able to monitor the trapping process for single nanodiamond particle in real time.

We will discuss applications of this platform for plasmonics and nanophotonics.

Abstract-We investigate dynamics of three classes of plasmonic structures for applications such as ultrafast switching. Through transient extinction and finite difference time domain simulation, we analyze coherence time of mode-specific acoustic phonon distortions for a series of gold bipyramids. We probe the impact of conformally coated phase change material, VO_2, on a doped oxide nanorod array for broadband infrared optical switching. And finally, we examine transient plasmon responses in colloidally prepared doped oxide nanoparticles that exhibit pump-wavelength dependent spectral responses.

We implement static and transient extinction spectroscopy to probe ensembles of plasmonic structures. In particular, we present efforts on gold bipyramids with particularly narrow ensemble size distributions for a wide range of localized surface plasmon resonance (LSPR) energy, nanofabricated doped oxides with an atomic-layer-deposited phase change material that can be optically switched, and colloidally synthesized doped oxides.

LSPRs arising from metallic nanoparticles offer an array of prospective applications that span chemical sensing to biotherapies. Bipyramidal particles exhibit particularly narrow ensemble LSPR resonances that reflect small dispersity of size and shape but until recently were only synthetically accessible over a limited range of sizes with corresponding aspect ratios. Narrow size dispersion offers the opportunity to examine ensemble dynamical phenomena such as coherent phonons that induce periodic oscillations of the LSPR energy. Here, we characterize transient optical behavior of a large range of gold bipyramid sizes, as well as higher aspect ratio nanojavelin ensembles with specific attention to the lowest-order acoustic phonon mode of these nanoparticles. We report coherent phonon-driven oscillations of the LSPR position for particles with resonances spanning 670 to 1330 nm. Nanojavelins were shown to behave similarly to bipyramids but offer the prospect of separate control over LSPR energy and coherent phonon oscillation period. We develop a new methodology for quantitatively measuring mechanical expansion caused by photogenerated coherent phonons. Using this method, we find an elongation of approximately 1% per photon absorbed per unit cell and that particle expansion along the lowest frequency acoustic phonon mode is linearly proportional to excitation fluence for the fluence range studied. These characterizations provide insight regarding means to manipulate phonon period and transient mechanical deformation

Actively tunable optical transmission through artificial metamaterials offers promise for next-generation nanophotonic devices and metasurfaces. Plasmonic nanostructures and phase change materials have been extensively studied to this end due to their respective strong interactions with light and tunable dielectric constants under external stimuli. Integrating plasmonic components with phase change materials, as described, can facilitate phase change by plasmonically enabled light confinement and meanwhile make use of the high sensitivity of plasmon resonances to the variation of dielectric constant associated with the phase change. The platform described is composed of plasmonic indium tin-oxide nanorod arrays (ITO-NRAs) conformally coated with an ultrathin layer of a prototypical phase change material, VO_2, grown via atomic layer deposition, which enables all-optical modulation of the infrared as well as the visible spectral ranges. The interplay between the intrinsic plasmonic nonlinearity of ITO-NRAs and the phase transition-induced permittivity change of VO_2 gives rise to spectral and temporal responses that cannot be achieved with individual material components alone.

Colloidal doped oxide nanocrystals exhibit large magnitude subpicosecond switching of infrared LSPRs. Such nanocrystals offer a solution-processable, scalable source of tunable metamaterials compatible with arbitrary substrates. Under intraband excitation, these nanocrystals display a red-shift of the plasmon feature arising from the low electron heat capacities and conduction band nonparabolicity of the oxide. Under interband pumping, they show an ultrafast blueshift of the plasmon resonance due to transient increases in the carrier density. Combined with their high-quality factor, large changes in relative transmittance (+86%) and index of refraction (+85%) at modest control fluences (<5 mJ/cm^2) suggest that these materials offer use in all-optical switching, wavefront engineering, and beam steering operating at terahertz switching frequencies.

Fano resonances in optics and microwaves: Physics and application

Explicit demonstration of how path interference can enhance plasmonic nonlinearity

Mehmet Emre Tasgin[1]

[1]Institute of Nuclear Sciences, Hacettepe University, 06800 Ankara, Turkey
metasgin@hacettepe.edu.tr

Abstract— We demonstrate why nonlinear frequency generation, e.g. second harmonic generation and four-wave mixing, can be enhanced via interference of conversion paths. We derive a single equation for the amplitude of the generated nonlinear oscillations. On this equation we show that cancellation in the denominator gives rise to conversion enhancement. We utilize this phenomenon to obtain further enhancement using interference of the multiple conversion paths.

Fano resonances on the linear response are shown to enhance the lifetime of plasmon oscillations and can lead to enhanced florescence of the molecules [1, 2]. Enhancement in the plasmon lifetime leads to the observation of spaser [3] —surface plasmon amplification by stimulated emission of radiation. Fano resonances in plasmonic materials are also shown to enhance the degree of the quantum entanglement [4].

Besides the linear response, Fano resonances are shown to enhance and suppress the nonlinear frequency conversion processes [5, 6]. 2 to 3 orders of magnitude enhancement can be achieved on top of the enhancement due to field localization [6, 7]. We explicitly demonstrate —on an expression for the steady-state SHG amplitude— how the presence of a Fano resonance leads to cancellation of nonresonant terms in a SHG process. Cancellation in the denominator gives rise to enhancement in the nonlinearity. The explicit demonstration, we present here, guides one to a method for achieving even larger enhancement factors by introducing additional coupling terms. The method is also applicable to Fano resonances induced by all-plasmonic couplings [8], which are easier to control in experiments.

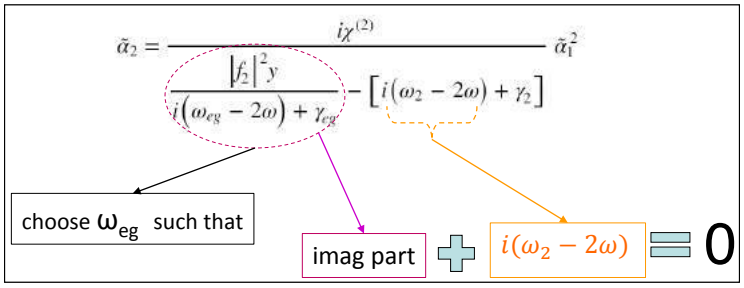

Figure 1: A quick demonstration of how cancellation in the denominator enhances the second harmonic generated plasmons, that is $|\tilde{\alpha}_2|^2$. ω_{eg} (γ_{eg}) is the level spacing (spectral width) of the quantum-emitter (QE), f_2 is the MNP-QE coupling strength, ω_2 (γ_2) is the resonance plasmon frequency (damping rate) of the MNP converter into which SHG take place, y is the population inversion in the QE, $\chi^{(2)}$ is proportional with the nonlinear susceptibility.

Abstract—We study Fano resonances in photonic crystal slabs in conical diffraction mounting. Using two-dimensional coupled-mode theory we obtain simple approximations of the structure's reflection and transmission coefficients. These approximations, which can be interpreted as multivariable generalizations of the Fano line shape, allow to describe a number of important optical effects arising in conical diffraction mounting: cross-polarization excitation of the structure's quasiguided modes, coupling of TE-like and TM-like modes, and emergence of exceptional points.

Photonic crystal slabs (PCS or guided-mode resonant gratings) have found wide use in various optical devices including spectral filters, polarizers, sensors, and pulse shapers. A number of theoretical models were proposed to describe PCS spectra [1, 2, 3, 4]. The simplest models are based on the Fano formula and represent the transmission (reflection) spectrum as a function of incident light frequency ω or in-plane wave vector component k_x [1]. More general approximations consider scattering amplitudes as functions of both ω and k_x [2, 3, 4]. These approximations do not describe a number of important resonant effects arising in conical diffraction mounting when the wave vector of the incident light has two non-zero in-plane components, k_x and k_y.

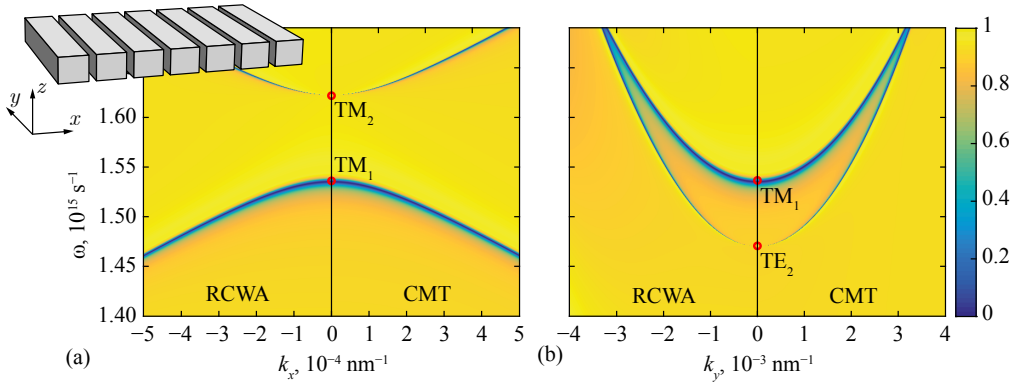

Figure 1: Transmission coefficient $|T(k_x, k_y, \omega)|^2$: calculated using rigorous coupled-wave analysis (at $k_x, k_y < 0$) and approximated using coupled-mode theory (at $k_x, k_y > 0$). Incident wave is TM-polarized. (a) Planar diffraction ($k_y = 0$); (b) conical diffraction at $k_x = 0$. (inset) Photonic crystal slab (period 1000 nm, height 700 nm, fill-factor 4/5; surrounding medium is air, grating permittivity is $\varepsilon = 2$).

Consider 1D PCS shown in the inset of Fig. 1. In this work, we develop 2D spatiotemporal coupled mode theory to describe optical properties of the considered structure. The coupled-mode equations for the PCS in the case of conical mount take the following form [5]:

$$\begin{cases} \dfrac{\partial u}{\partial t} + v_g \dfrac{\partial u}{\partial x} - \dfrac{\mathrm{i}v_g}{2k_1}\dfrac{\partial^2 u}{\partial y^2} + \mathrm{i}\omega_0 u = -\hat{\mathbf{c}}_1 u + \hat{\mathbf{c}}_2 v + \hat{\mathbf{c}}_{e1} f, \\ \dfrac{\partial v}{\partial t} - v_g \dfrac{\partial v}{\partial x} - \dfrac{\mathrm{i}v_g}{2k_1}\dfrac{\partial^2 v}{\partial y^2} + \mathrm{i}\omega_0 v = -\hat{\mathbf{c}}_1 v + \hat{\mathbf{c}}_2 u + \hat{\mathbf{c}}_{e2} f, \\ f_T = t_0 f + \hat{\mathbf{c}}_{t1} u + \hat{\mathbf{c}}_{t2} v. \end{cases} \tag{1}$$

Here ω_0 is light angular frequency; k_1 and v_g are the wave number and group velocity of the mode. To obtain system (1) we considered two paraxial unidirectional wave equations, which describe two counter-propagating modes of the PCS, u and v. These equations are coupled by the terms in the right-hand sides of the equations. The terms contain coupling operators $\hat{\mathbf{c}}$, which are linear differential operators matched with the symmetry of the structure. The third equation of system (1) relates the amplitude of the incident field $f(x, y, z)$ with the amplitude of the transmitted field f_T. A similar equation holds for the reflected field.

We solve system (1) in the Fourier domain to obtain the transmission coefficient of the PCS as a ratio of the transmitted and incident light spectra. The solution has the following form:

$$T = t_0 \frac{v_g^2 k_x^2 - \left(\omega - \omega_{zt} - \eta_{zt} k_y^2\right)\left(\omega - \omega_{p2} - \eta_{p2} k_y^2\right)}{v_g^2 k_x^2 - \left(\omega - \omega_{p1} - \eta_{p1} k_y^2\right)\left(\omega - \omega_{p2} - \eta_{p2} k_y^2\right)}. \quad (2)$$

Here t_0 is non-resonant transmission coefficient, while the other parameters define the ω–k_x–k_y line shape of the resonance. These parameters can be estimated using the rigorous coupled-wave analysis (RCWA) and the scattering matrix approach [4, 5]. Equation (2) provides analytical approximation of the PCS ω–k_x–k_y transmission spectra. This approximation allows to investigate mode excitation conditions and angular tolerances of guided-mode resonant filters.

Figure 1 shows the transmission spectra of the considered PCS. The left part of each subfigure was calculated using the RCWA, while the right part was obtained using approximation (2). It is evident that the obtained formula (2) provides a good approximation of the PCS transmission spectrum. Figure 1(a) shows the transmission spectrum in the case of planar diffraction. In this case no polarization transformation occurs: TM-polarized incident light excites only TM-polarized modes (TM_1 and TM_2). In the case of conical diffraction mounting (Fig. 1(b)) polarization transformation effects result in the excitation of the cross-polarized mode. In this case only one — antisymmetric — cross-polarized mode (TE_2) is exited, due to symmetry considerations.

Another interesting optical effect can be obtained if the frequencies of the TE- and TM-polarized modes are close to each other. In the case of planar diffraction the dispersion curves of these modes are crossing. However, if we introduce non-zero k_y, the cross-polarization light coupling will occur resulting in the coupling of the dispersion curves of the TE and TM modes. To describe this optical effect one can write down the system of coupled-mode equations, similar to Eq. (1). Solution of this system is an analytical approximation of the transmission coefficient as a function of ω, k_x, and k_y. By analyzing this expression one can show that the proper choice of k_x and k_y allows us to obtain an exceptional point. In this case the transmission ω-spectrum will have the pole of the second order: $T(\omega) \approx t + b/(\omega - \omega_p) + c/(\omega - \omega_p)^2$.

In conclusion, we studied optical effects arising in conical diffraction mount in photonic crystal slabs. Let us note, that similar effects can be obtained in the case of planar diffraction of light by *magnetized* PCS. Of particular interest is longitudinal magnetization geometry when magnetization vector is parallel to the y-axis. In this case magnetization of the sample at $k_y = 0$ results in symmetry breaking, analogous to that induced by introducing non-zero k_y for non-magnetized structures. The proposed theory can be used to describe optical and magneto-optical properties of guided-mode resonant gratings. Other applications include spatio-temporal pulse shaping using PCS and guided-mode resonant gratings.

Abstract-Exponentially growing bandwidth requirements of our information society introduce major capacity and energy challenges. We exploit coherent control of light with light on Fano-metamaterials of nanoscale thickness to demonstrate an approach promising massively parallel all-optical information processing at arbitrarily low intensities and with up to 100 THz bandwidth. We experimentally demonstrate parallel all-optical data processing, all-optical pattern recognition and image analysis as well as a fully packaged fiberized metadevice performing several logical operations at GHz bitrates.

Conventional approaches to all-optical information processing rely on nonlinear optical processes to influence one optical signal with another, resulting in tradeoffs between modulation rates and power requirements as fast nonlinearities are weak. However, it is a common misconception that modulation of light with light requires nonlinear optical materials. Consider the interaction between counterpropagating coherent optical signals and a material of substantially sub-wavelength thickness. The thin film can be placed at a node or anti-node of the standing wave formed by the counterpropagating optical signals. At a node, there is no electric field and therefore no light-matter interaction, while constructive interference at the anti-node enhances the light-matter interaction. This linear mechanism allows one optical signal to control absorption of the other almost from 0% to 100%, at arbitrarily low intensities down to the quantum regime and with many THz bandwidth.

We exploit such coherent interaction of light with light on a freestanding gold Fano-metasurface of 60 nm thickness to control intensity of light in spatially distributed optical information channels. Based on optically controlled coherent perfect absorption and coherent transparency of the metasurface (Figure 1), we perform logical operations such as XOR and AND between selected information channels, identify similarities and differences between images, perform pattern recognition by quantifying the similarity between images or data patterns of arbitrary complexity and perform advanced optical image analysis, for example of satellite images to detect the Arctic ice cover, its growth and melting over several decades.

We also demonstrate the first fully integrated data processing metadevice based on coherent interaction of light with light on a gold Fano-metasurface (Figure 2). The fully packaged fibre device is based on a metasurface fabricated on the end face of a polarization maintaining single-mode telecommunications fibre. It can act as an optical logic NOT, XOR and AND gate and has been tested up to GHz frequencies.

In summary, we report a novel, linear approach to all-optical information processing that could deliver orders-of-magnitude improvements in speed and energy efficiency. We illustrate this with a diverse range of experiments ranging from parallel optical processing, recognition and analysis of data and images to

demonstration of a fully integrated fiberized metadevice performing various logical operations at least up to GHz data rates.

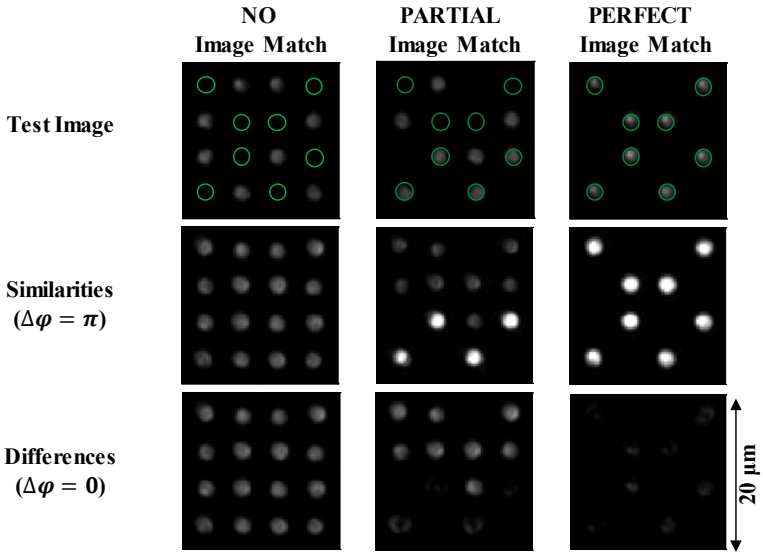

Figure 1. Pattern recognition. Test images (row 1) are compared to a target image (green circles) by projection onto opposite sides of a lossy metasurface using coherent light of 790 nm wavelength. Depending on the optical phase difference Δφ on the metasurface, overlapping image features are perfectly transmitted (row 2) or fully absorbed (row 3), revealing similarities and differences.

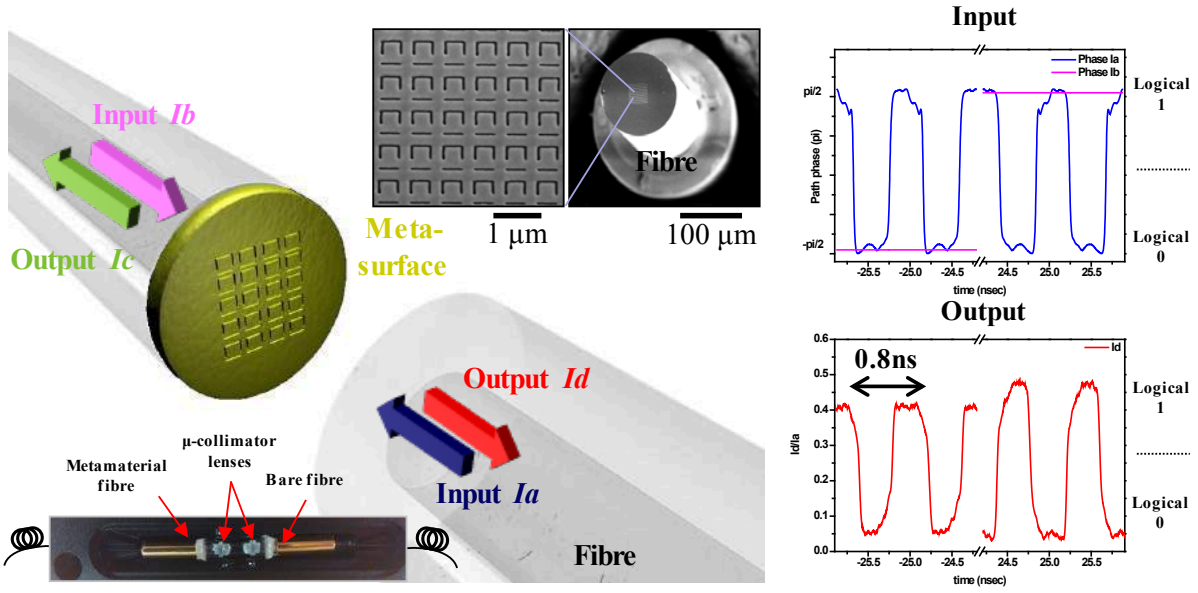

Figure 2. Data processing metadevice based on coherent interaction of input light beams *Ia* and *Ib* on a 70-nm-thick plasmonic metamaterial absorber fabricated on the end face of a single-mode telecoms fibre (1550 nm wavelength). Insets show the nanostructured fibre end and the assembled metadevice. Measurements show an all-optical XOR operation between phase-modulated signals at a data rate of 1.2 GHz: High output (logical 1) results from opposite input bits and low output (logical 0) results from identical input bits.

Mid-Infrared Nonlinear Nanophotonics in Anisotropic Dielectrics Using Surface Phonon Polaritons

Abstract— Surface phonon polaritons provide a unique plattform for mid-infrared nonlinear nanophotonics due to broken inversion symmetry and pronounced crystal anisotropy in many of the host materials. Here we experimentally demonstrate resonant enhancement of second harmonic generation due to excitation of localized and propagating surface phonon polaritons in Silicon Carbide. In particular, we observe drastic additional enhancement of the second harmonic response for resonant interactions of the surface phonon polaritons with anisotropic weak phonon modes in subdiffractional nanostructures.

Surface polaritons are the key building block of nanophotonics, since these excitations provide sub-diffractional light localization accompanied by significant optical field enhancements. Many previous studies have focused on surface plasmon polaritons (SPPs) at the surface of noble metals. Recently, an alternative approach was introduced using surface phonon polaritons[1] (SPhPs) which can be excited in the mid-infrared at the surface of polar dielectrics, where optical phonon resonances lead to the negative dielectric permittivity required for the surface polariton formation.

Here, we undertake a first step towards the largely unexplored domain of mid-infrared nonlinear nanophononics. We study the nonlinear-optical response of (i) localized SPhPs in sub-diffractional nanostructures[2] and (ii) propagating SPhPs using Otto-type prism coupling.[3] Employing an infrared free-electron laser as an intense, narrowband, and tunable excitation source for second harmonic generation (SHG) spectroscopy[4] in both approaches, we observe drastic enhancement of the SHG yield for resonant excitation of SPhPs.

We discuss several unique features of the SPhPs as opposed to SPPs, including the large selection of non-centrosymmetric SPhP materials leading to a wide spectral tunability with large bulk nonlinearity. Additionally, many of the host materials are anisotropic, leading to novel effects of resonant interaction of the surface polaritons with anisotropic material resonances. Specifically for 6H-SiC, a Fano-like interaction between zone-folded weak phonon modes and localized SPhPs has been observed in subdiffractional nanostructures.[5] Here, we observe a drastic enhancement of the SHG yield if localized SPhPs are tuned into resonance with zone-folded weak phonon modes.[2] Surprisingly however, no such enhancement is observed for propagating SPhPs excited in the Otto geometry for the same material system.[3] Our results pave the way for efficient control over the mid-infrared nonlinear-optical properties of nanophotonic systems based on anisotropic dielectrics.

Abstract— This is a theoretical study of the Fano resonance in a hybrid system consisting of spatially separated two-dimensional layers of electrons and excitons interacting by the Coulomb force and exposed to weak magnetic field and light (electromagnetic field). We investigate the conductivity of electrons in this system and show that the electromagnetic power absorption spectrum has a Fano profile. Further we phenomenologically account for the disorder in the system.

1. INTRODUCTION

Bose-Fermi mixtures exist in hybrid complex systems which serve as unique laboratories to study many-body interactions [1]. In the solid-state physics, such systems usually employ exciton gases localized in quantum wells (QWs). They interact with 2D electron gas (2DEG) in neighbouring layers [2].

Motion of particles and their interaction reveals different quantum paths for the system, moreover, these trajectories can interfere among each other. If the interference is destructive, it results in a partial or full suppression of the particle transport. In our paper [3] we investigate the Fano resonance in such a hybrid systems.

2. CYCLOTRON RESONANCE

Let us consider a system which represents two parallel layers of electrons and excitons, see left hand side panel in Fig. 1. The system is exposed to an external electromagnetic (EM) field, $\mathbf{E}(\mathbf{r},t)=(E_0,0,0)e^{i\mathbf{kr}-i\omega t}$. It results in the deviation of the electronic density, $\delta n(\mathbf{r},t)=n(\mathbf{r},t)-n_0$, where $\mathbf{r}$ is a 2D coordinate, and $\mathbf{k}$ is the wave vector. The excitons feel the presence of the EM field indirectly: via the interaction with electrons. A weak uniform magnetic field, $\mathbf{B}$, is applied perpendicular to the layers and we consider zero-temperature case.

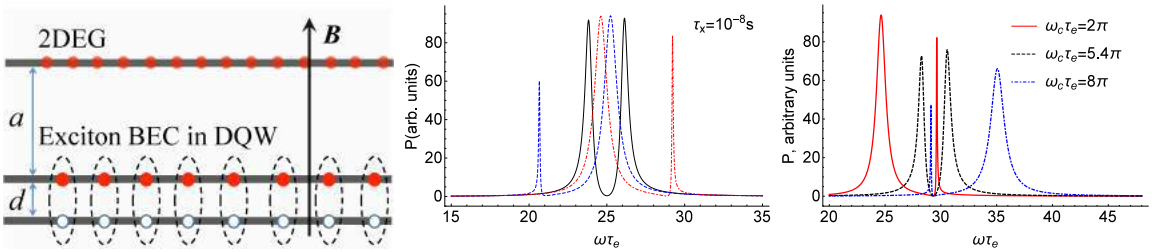

Figure 1: (Left Panel) Structure: excitons are localized in the double quantum well (DQW) structure. The 2DEG lives in other QW at the distance a. (Middle Panel) The power absorption as a function of frequency for the increasing s from (a) to (c) for $\tau_X=10^{-8}$ s (solid curves) and $\tau_X=5\cdot10^{-10}$ s (dashed curves). (Right Panel) Magnetic field effect: power absorption spectrum at $s=7\cdot10^5$ cm/s and different values of magnetic field in units of $\omega_c\tau_e$.

We treat the electrons classically via the continuity equation, $\dot{\rho} + \operatorname{div} \mathbf{j} = 0$: $\delta n_{k\omega} = -\frac{k}{e\omega} j_{k\omega}$. In the Ohm's law,

$$j_{k\omega} = \sigma_B \left(E_0 - \frac{1}{e} F_{k\omega} \right), \tag{1}$$

σ_B is 'xx' component of the conductivity tensor, $F_{k\omega}$ is 'x' component of the applied electromagnetic force, coming from the electron-electron and electron-exciton interaction:

$$F_{k\omega} = -ik(U_k \delta n_{k\omega} + V_k \delta N_{k\omega}), \text{ where } U_k = \frac{2\pi e^2}{\epsilon k}, \; V_k = \frac{2\pi e^2}{\epsilon k} \left(1 - e^{-kd}\right) e^{-ka}, \tag{2}$$

where ϵ is the dielectric function; $\delta N_{k\omega}$ is the fluctuating exciton density in the BEC. The elementary excitations of the BEC are bogolons, we use the model of weakly-interacting Bose gas, and the dispersion then reads: $\varepsilon_k = \sqrt{\frac{k^2}{2M}\left(\frac{k^2}{2M} + 2g_0 n_c\right)}$, where, n_c is exciton density in the condensate, g_0 is exciton-exciton interacting constant,$g_0 \approx 4\pi e^2 d/\epsilon$, and M is the exciton mass. In the long-wavelength limit we come up with the sound quanta, $\varepsilon_k \approx sk$, where $s = \sqrt{g_0 n_c / M}$.

Using the Gross-Pitaevskii equation,

$$i\partial_t \Psi(\mathbf{r}, t) = \left(\frac{(\hbar \hat{\mathbf{k}})^2}{2M} - \mu + g_0 |\Psi(\mathbf{r}, t)|^2 \right) \Psi(\mathbf{r}, t) + \Psi(\mathbf{r}, t) \int d\mathbf{r}' V(\mathbf{r} - \mathbf{r}') \delta n(\mathbf{r}', t), \tag{3}$$

where the last term is treated as a perturbation, we can find the wave function of the condensed particles, $\Psi(\mathbf{r}, t) = \sqrt{n_c} + \psi(\mathbf{r}, t)$.

Finally, the renormalized conductivity, defined as $j_{k\omega} = \tilde{\sigma}_{k\omega} E_0$, reads:

$$\tilde{\sigma}_{k\omega} = \frac{1}{\sigma_B^{-1} + i\frac{k^2}{e^2\omega}\left[U_{k\omega} + V_{k\omega}^2 R_{k\omega}\right]}, \quad \sigma_B = \sigma_0 \frac{i(\omega\tau_e + i)}{(\omega\tau_e + i)^2 - \omega_c^2 \tau_e^2}, \tag{4}$$

where $\omega_c = eB/mc$ is electron cyclotron frequency and $\sigma_0 = e^2 n_0 \tau_e / m$ is the Drude conductivity of 2DEG, $R_{k\omega}$ is the response function. From this main formula, we can calculate the electromagnetic power absorption: $P_{k\omega} = \frac{1}{2} E_0^2 \operatorname{Re} \tilde{\sigma}_{k\omega}$.

3. RESULTS AND DISCUSSION

We calculated the power absorption function using the following parameters: $d = 10^{-6}$ cm, $a = 10^{-5}$ cm, $k = 4.2 \cdot 10^4$ cm^{-1}, and $\sigma_0 = 3.2 \cdot 10^{-5}$ cm/s.

Middle panel in Fig. 1 manifests the Fano resonance in the power absorption spectrum. With the increase of the velocity of the bogolons, s, one can shift the Fano resonance in frequency and even change the disposition of the peaks and the dip of the asymmetric profile.

Right hand side panel in Fig. 1 explains the dependence of the power absorption function on the magnitude of the external applied magnetic field.

Abstract- We propose a coupled photonic crystal cavity-waveguide structure to achieve Fano resonance by placing partially reflecting elements in waveguide, and the Fano resonance can be greatly enhanced by introducing optical gain material into the cavity. Additionally, coupling between photonic molecules and waveguides in photonic crystal slab structures are investigated for ultrafast optical switching with a time scale of a few picoseconds by optimizing the radii of air holes between two cavities of photonic molecule.

To improve the optical device performance, Fano resonance with asymmetric and steep spectral line shape has been intensively used, which arises from the interference between discrete resonance states and continuum states. By modulating the coupling between photonic crystal (PhC) cavity and waveguide, Fano resonance can be achieved due to the constructive and destructive interference of discrete cavity resonance states with broadband continuum waveguide states. In this work, we design a PhC cavity and waveguide structure using Finite-difference time-domain (FDTD) simulation. By placing partially reflecting elements in the PhC waveguide, Fano type transmission line shape is achieved. In addition, gain materials are introduced into PhC cavities to enhance Fano resonance. With introducing the gain materials into cavity, the transmission line shape of the Fano resonance is greatly steepened and a large contrast is achieved by a small frequency shift. In our structure, the transmissivity in the waveguide is increased by a factor of six, which is potentially applicable for optical switches and optical sensors.

In addition, the coupling between photonic molecules and waveguides in PhC slab structures are studied using FDTD method and coupled mode theory. In a photonic molecule with two cavities, the coupling of cavity modes results in two super-modes with symmetric and anti-symmetric field distributions. When two super-modes are excited simultaneously, the energy of electric field oscillates between the two cavities. To excite and probe the energy oscillation, we integrate photonic molecule with two PhC waveguides. In coupled structure, we find that the quality factors of two super-modes might be different because of different field distributions of super-modes. After optimizing the radii of air holes between two cavities of photonic molecule, nearly equal quality factors of two super-modes are achieved, and coupling strengths between the waveguide modes and two super-modes are almost the same. In this case, complete energy oscillations between two cavities can be obtained with a pumping source in one waveguide, which can be read out by another waveguide. Finally, we demonstrate that the designed structure can be used for ultrafast optical switching with a time scale of a few picoseconds.

Control of electromagnetically-induced-transparency-like effect in metamaterials for coherent storage of electromagnetic waves

T. Nakanishi, S. Tohi, and M. Kitano

Department of Electronic Science and Engineering, Kyoto University, Japan
t-naka@kuee.kyoto-u.ac.jp

Abstract— We propose tunable metamaterials, which realize the storage and retrieval of electromagnetic waves, in analogy with electromagnetically induced transparency (EIT) effect in atomic systems. The basic concepts are introduced with coupled resonator models, and we experimentally demonstrate the storage and retrieval of electromagnetic waves in microwave regions. Owing to coherent process, the phase information is also recovered in the retrieved signal.

Electromagnetically induced transparency, or EIT, is a nonlinear optical phenomenon, where an opaque medium becomes transparent in an extremely narrow spectral region by the incidence of auxiliary light called control light, and the EIT effect has been intensively investigated in atomic systems. In the transparency region, the dispersive properties are dramatically modified and the group velocity of the light is significantly reduced. In addition, it is possible even to stop the propagating light in the medium by gradually turning the control light off. In this process, the light is coherently captured in the medium, and the stored light can be released by the reverse process without losing the phase information.

The EIT effect can be emulated by artificial media or metamaterials, and various types of the metamaterials have demonstrated the EIT-like effects, such as sharp transparency and slow propagation, in wide frequency regions from microwave to visible light. The EIT-like metamaterials have two resonant modes, called radiative mode and trapped mode, which are coupled with each other. The radiative mode interacts with propagating waves and the quality factor as a resonator is low owing to the radiation loss. On the other hand, the trapped mode is uncoupled with the propagating waves and the intrinsic quality factor is extremely high. In the presence of the coupling between the two modes, the energy received through the radiative mode is transferred into the trapped mode with low loss, and then is released into free space through the radiative mode. The temporal storage in the trapped mode induces the propagation delay with low loss and contributes to the slow propagation in the metamaterial.

In order to extend the slow-light effect to the storage in the metamaterials, the EIT-like effects in the metamaterial have to be dynamically controlled by external signals in the same manner as the optical storage in atomic EIT medium. In this paper, we propose two types of tunable metamaterials to control the EIT-like effect and demonstrate the storage of electromagnetic waves in microwave regions.

We first introduce an EIT-like metamaterial, which controls coupling between a radiative mode and a trapped mode by external electric signals [1]. The transmission spectra are shown in Fig. 1(a).

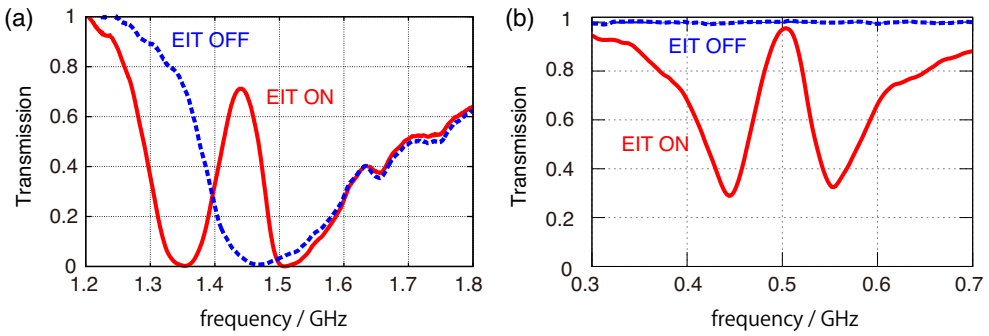

Figure 1: Tunable EIT-like metamaterials. (a) Coupling-controlled metamaterial (b) Radiative-mode-controlled metamaterial.

In the case of "EIT OFF" state denoted by the dotted line, there is no coupling between two modes, and the broad transmission dip attributed to the resonance of the radiative mode is observed. On the other hand, in the "EIT ON" state denoted by the solid line, the coupling is turned on, and a transmission window owing to the EIT-like effect is clearly observed.

As a second example, we introduce another tunable EIT-like metamaterial [2], whose transmission spectra are shown in Fig. 1(b). In this case, the radiative mode and the trapped mode are always coupled with each other. In the metamaterial, a switching element is installed in the radiative mode, in order to control the resonance of the radiative mode. In "EIT OFF" state denoted by the dotted line, the function of the radiative mode as a resonator is deactivated, and the metamaterial shows high transmission in a whole spectrum due to the absence of the resonance mode interacting with external fields. In "EIT ON" state denoted by the solid line, the radiative mode works as the resonator, and the EIT property can be observed.

Both metamaterials realize the storage of electromagnetic waves through the same procedure. First, the EIT state is turned on, and the electromagnetic waves tuned to the transparent region slowly propagate through the metamaterial owing to the EIT effect. In this process, electromagnetic energy is concentrated in the trapped mode. During the propagation, the EIT state is turned off, and the energy is completely captured in the trapped mode. The stored waves can be retrieved by recovering the EIT state.

In this paper, we have proposed two types of EIT-like metamaterials, whose EIT effect can be controlled. The metamaterials have realized the storage of the electromagnetic waves. It is noted that the processes of the storage and retrieval are coherent and the original waves are retrieved without losing the phase information. The experimental demonstration has been conducted in the microwave regions, but the fundamental concept can be applied to higher frequencies.

Abstract-We report a series of studies on 3D folded metamaterial, by which Fano resonances can be excited and the line shape, intensity and Q factor can be modulated. Different combinations of the vertical and planar building blocks of the 3D folded metamaterials result in diverse properties of the Fano resonance, which have practical applications in filter, ultrasensitive biosensor, active SERS substrate, etc.

Fano resonance can be excited in plasmonic metamaterials by destructive interference between a bright continuum mode and a discrete dark mode. 3D folded metamaterial has been used for Fano resonance excitation due to its unique configuration - it is composed of vertical part and planar complementary part[1]. Resonance modes are excited on both parts by evanescent field of surface wave and grating coupling of incident light respectively, and the destructive interference results in Fano resonance with asymmetric line shape[2]. Although the sensing[1] and modulation[3] property of 3D metamaterials have been studied recently, the quality factors of these resonance modes are relatively low. Excitation of high-Q factor resonances are usually accompanied with the generation of extremely strong field at subwavelength scale and low energy losses[4], thus a high-Q 3D metamaterial can be a promising candidate for improving the limitation of detection in SERS analysis.

Recently, we found that through judicious design of the building blocks in shape and size, high-Q resonance can be achieved with extremely large spatial electromagnetic field enhancement. The high-Q Fano resonance can be engineered to the target wavelength by modulating the geometric parameters of the building blocks, and it was used for ultrasensitive SERS detection of bio-molecules.

Light-tunable Fano resonances in metal-dielectric multilayer structures

S. Hayashi[1,2*], D. V. Nesterenko[2], A. Rahmouni[2] and Z. Sekkat[2,3,4]
[1]Kobe University, Japan

Abstract-Extending our previous work on Fano resonances in metal-dielectric multilayer structures we demonstrate here the tuning of Fano resonance by light irradiation. The photo-tuning was made possible by incorporating azo-dye molecules in a dielectric waveguide layer. Due to the photoisomerization of the molecules, the refractive index of the waveguide layer changes upon pump light irradiation, resulting in the shift of the Fano line shape. The change in the refractive index estimated from the experimental data falls in a range less than ~7.0×10^{-4}.

Recently, we have demonstrated both theoretically and experimentally the generation of high-Q Fano resonances in planar metal-dielectric multilayer structures [1-3]. The multilayer structures studied consist of a metal layer and two insulator layers (MII structure), which can be regarded as a combination of a metal-insulator interface that supports a surface plasmon polariton (SPP) mode and a planar waveguide structure that supports a planar waveguide (PWG) mode. The appearance of the Fano line shapes in their attenuated reflection (ATR) spectra is due to the interaction between the broad SPP mode and the sharp PWG mode. The Fano MII structure can be fabricated easily without any nanofabrication technique and is applicable to high resolution optical sensing and enhanced spectroscopies.

In recent years, tuning of the Fano resonances in plasmonic nanostructures by applying mechanical stress and electric field has been demonstrated. However, clear experimental evidence of the tuning by light has not been reported yet. We extended our previous work to realize the photo-tuning of the Fano resonance [4]. Our previous Fano MII structure was prepared by depositing an Ag film onto a substrate and successively depositing a low-index Cytop spacer layer and a high-index PMMA waveguide layer. To achieve the photo-tuning, we used a DR1-doped PMMA waveguide layer instead of a pure PMMA layer as schematically shown in Fig. 1b. The DR-1 molecule is one of the azobenzene derivatives that undergoes the *trans-cis* transformation under blue

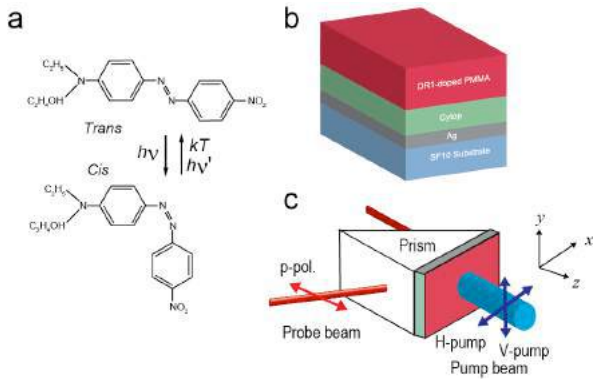

Fig.1 (a) Photoisomerization of DR1 molecule, (b) multilayer sample with a DR1-doped PMMA waveguide layer and (c) Kretschmann configuration of pump-probe ATR measurements.

light irradiation (photoisomerization) (Fig. 1a). Due to the photoisomerization, the refractive index of the DR1-doped waveguide layer decreases upon pump irradiation. We performed pump-probe ATR measurements of the samples attached to a prism in a Kretschmann configuration as schematically shown in Fig. 1c.

Figure 2a shows an angle-scan ATR spectrum under dark probed by a He-Ne laser beam with a wavelength of λ=632.8 nm. We see clearly a Fano line shape around 55° located at the high-angle side of the SPP dip. The Fano resonance is a consequence of the interference between the TM_0 PWG mode and the SPP mode. As can be seen clearly in Fig. 2b, the Fano line shape shifts to a lower angle under the irradiation of blue pump light with a wavelength of λ=488.0 nm. Figure 2c represents the results of systematic measurements performed by varying the power density of pump light for both the vertical and horizontal polarizations of pump light. We see that the Fano resonance shifts more and more as the pump power density increases.

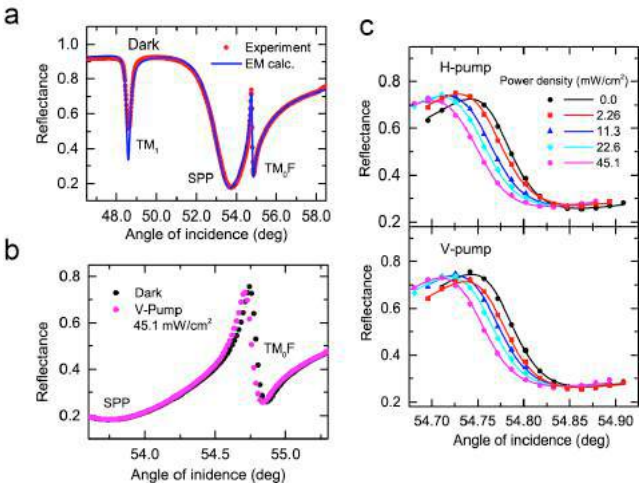

Fig.3 (a) Angle-scan ATR spectrum obtained under dark, (b) shift of Fano line shape caused by optical pumping, and (c) results of systematic observations performed by varying the pump power density for both the horizontal and vertical polarizations.

We analyzed the photo-induced shift of the Fano resonance based on electromagnetic calculations of the ATR spectra and estimated the amount of change in the refractive index of the DR1-doped PMMA waveguide layer. The estimated change in the refractive index falls in a range less than $\sim 7.0 \times 10^{-4}$. This implies that the Fano line shape is very sensitive to the change in the refractive index of the waveguide layer. The photo-tuning of the Fano resonance demonstrated here may open a new avenue for realizing novel optical devices, such as optically tunable sensors and all optical switching elements.−

Interference of plasmonic vortex fields with different angular momenta

Keiji Sasaki*
Research Institute for Electronic Science, Hokkaido University, Japan
*corresponding author: sasaki@es.hokudai.ac.jp

Abstract-We showed that the optical vortex field can be confined into nano-space using plasmonic multimer structures. In this transfer from chiral photons to plasmons, the total angular momentum is conserved, while the orbital and spin angular momenta can be exchanged. Here, we demonstrate that plasmonic nano-vortex field is formed as interference of chiral photons having different angular momenta. We also show that this interference field induces optical torque and central force, which leads to orbital rotation of nanoparticles in nano-space.

Recently, we clarified that multipolar plasmons of metal nano-disks can be selectively excited by circularly-polarized optical vortex beams, i.e., Laguerre-Gaussian (LG) beams [1,2]. The total angular momenta, that is the sum of orbital and spin angular momenta, are transferred from chiral photons to localized surface plasmons. Unfortunately, the mode volume of this plasmonic nanodisk resonator is sub-micrometer dimension that is restricted by the diffraction limit of the surface plasmon wave. In order to realize single-nanometer-sized cavities, we design the tailored plasmonic structure consisting of metal multimer surrounding a nano-gap. We theoretically showed that this metal structure makes it possible to localize the optical vortex field into the gap space with conserving the total angular momenta. However, the orbital and spin angular momenta of the vortex field can be exchanged in accordance with the boundary conditions at the metal surfaces. Therefore, the nano-vortex field is formed as interference of LG-modes having different angular momenta even when the single LG-mode beam is incident on the plasmonic multimer structure.

The transfer of the angular momenta from this interference nano-field to molecules or nanoparticles induces rotational radiation pressure, i.e., optical torque and gradient force directed to the center [3,4], which causes nano-vortex flow of molecules/particles and may lead to chiral structuring of molecule/particle assemblies. We succeeded in rotational manipulation of a 100-nm polymer bead with a gold nano-triangle trimer structure. The plasmonic structure was illuminated with a circularly polarized beam of a near-infrared laser, so that the nano-sized field with the orbital angular momentum as well as the spin is formed within the gap. We will present detailed analyses of the rotational motions and their relations to the chirality of the plasmonic fields.

Tuning of Fano resonances by rotation of continuum: wave faucet.

A.F. Sadreev, A.S. Pilipchuk, and A.A. Lyapina
Kirensky Institute of Physics, Federal Research Center KSC SB RAS, 660036 Krasnoyarsk, Russia

Abstract— We consider wave transmission in a non-axisymmetric waveguide which consists of cylindrical resonator and two semi-infinite cylindrical waveguides whose axes are shifted relative to the resonator. Rotation by the azimuthal angle $\Delta\phi$ of input waveguide does not change the eigenfrequency spectrum of the resonator, it tunes the Fano resonances and respectively gives rise to an analog of a faucet opening and closing wave flux under rotation. Moreover under the rotation of the waveguide numerous events of the Fano resonance collapse occur to evidence for the bound states in the continuum.

Beauty of complex wave fields observed in different areas of physics is related to phase of the field. The first demonstration of the phase effect was done by Thomas Young in 1803 in the historic experiment on double-slit interference [1]. Among numerous phase features we mark bound states in the continuum, Aharonov-Bohm oscillations, asymmetric Fano resonances, and topological singularities which millstone the phase effects in the last century. Typically the Fano resonance asymmetric shape is tuned by reconstruction of eigenvalue spectrum by, for example, application of finger gate potential in quantum dots or magnetic field in rings [2]. But in fact the resonances of open quantum system are given by poles of the S-matrix or the complex eigenvalues of the effective non Hermitian Hamiltonian [3] $\widehat{H}_{eff} = \widehat{H}_R - i\widehat{W}\widehat{W}^\dagger$ where $\widehat{H}_R$ describes the closed system (resonator) with discrete eigenvalue spectrum and $\widehat{W}$ describes the coupling matrix between the closed system and the continua (of attached waveguides). Typically the real parts of complex eigenvalues of the effective Hamiltonian which define the resonance positions follow the eigenvalues of the closed resonator when the coupling is weak. However with growth of the coupling the resonances become to interfere to give rise to tune the Fano resonance profiles. First this way to tune the Fano resonance was demonstrated by Rotter *et al* [4] by implementation of changeable diaphragms at the waveguide junctions. In this letter we consider a system which changes only a

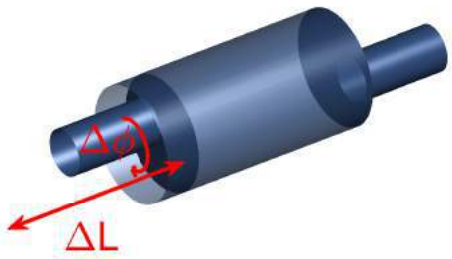

Figure 1: Cylindrical resonator of length L with two non-axially attached cylindrical waveguides. The input waveguide can freely move along the resonator axis and as well as rotate about it.

phase of the coupling matrix by rotation of one of waveguides and show that gives rise to drastic effects beginning with opening and closing the wave transmission (wave faucet) and ending by the bound states in the continuum (BSC). The setup shown in Fig. 1 consists of cylindrical resonator of radius R and length L with two attached semi-infinite cylindrical waveguides with radius $r < R$. If the waveguides were attached coaxially the total system would be invariant relative to azimuthal rotation to split the total Hilbert space of the system into independent subspaces given by the orbital angular momentum (OAM) m (the order of the Bessel functions m also defining the charge of topological singularity). Respectively the wave scattering would not interfere the m sectors with prohibition for OAM conversion. The sound transmission in axisymmetric cylindrical waveguide in the sector $m = 0$ and corresponding BSCs were considered in our first paper [6].

However attachment of the waveguides in a non-coaxial way breaks the azimuthal symmetry giving rise to the OAM conversion. Moreover we assume that one of the waveguides, say the left, can move along the resonator axis to change the resonator length, and rotate by the angle $\Delta\phi$ as shown in Fig. 1. Tuning the shape of the resonator could be performed in a realistic acoustic or electromagnetic experiment by the use of piston-like hollow-stem waveguides tightly fit to the interior boundaries of a cylindric cavity [6] as shown in Fig. 1. This setup unites all above listed phase features. The most striking effect of the rotation is a collapse of the Fano resonances that evidences an occurrence of bound states in the continuum (BSCs) when the resonator traps the propagating mode inside. The last has become one of the actively studied phenomena in different areas of physics [6].

Helical bound states in a microwave-field continuum with an embedded MDM ferrite particle

*Email: kmntsk@bgu.ac.il

Abstract-We consider multiple discrete states of magnetostatic oscillations in a quasi-2D ferrite disk embedded in a common microwave continuum. We examine the microwave transport properties of such a system including the appearance of Fano resonances.

Magnetic-dipolar modes (MDMs) in a quasi-2D ferrite disk are microwave energy eigenstate oscillations with topologically distinct structures of rotating fields and unidirectional power-flow circulations [1, 2]. Quantized vortices in MDM oscillations manifest the long-range phase coherence of magnetic dipole-dipole interaction which are described by a complex-valued order parameter field – the magnetostatic-potential (MS-potential) scalar wave function. Sharp multiresonance oscillations, observed experimentally in microwave structures with an embedded quasi-2D ferrite disk, are related to magnetization dynamics in the sample. For given disk sizes and a given quantity of saturation magnetization of ferrite material M_0, there are two different mechanisms of energy quantization: (*i*) by a bias magnetic field H_0 at a constant signal frequency ω and (*ii*) by a signal frequency ω at a constant bias magnetic field H_0. The fact that there are different mechanisms of quantization allows to conclude that for MDM oscillations in a qusi-2D ferrite disk both discrete energy eigenstate and a continuum of energy can exist. The microwave measurement reflects interaction between a classical device – the microwave structure – and a MDM particle [3].

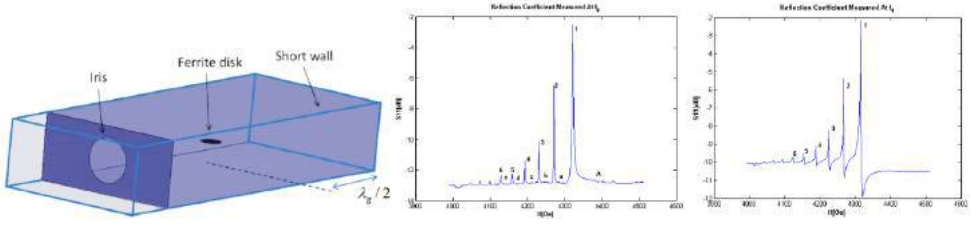

Fig.1. MDM resonances in a microwave cavity in dependence on a bias magnetic field and at different frequencies.

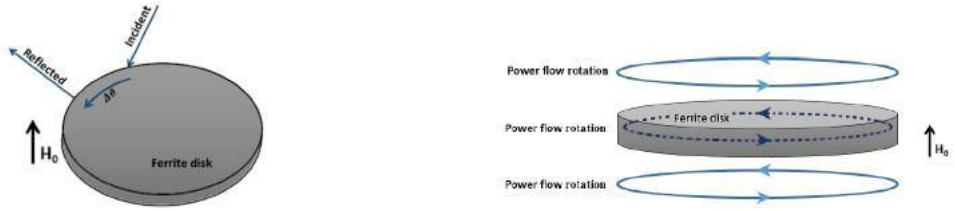
At the cavity resonance frequency f_0 , the bound states are localized in a ferrite disk. The bound states

have a square integrable wave function. When the frequency is shifted from f_0, the edge states flow around the disk. The resonances retain distinctive properties of the bound states. The MDM bound states in a microwave-field continuum have a helical structure with a power-flow current circulating around a quasi-2D ferrite disk [4]. The interference of the resonances results in the formation of a bound state embedded into the continuum of the edge states flowing around the disk [2, 5]. One can say that the MDM disk effectively creates specific boundary conditions for the EM waves in a microwave structure.



(*a*) (*b*)

Fig. 2. (*a*) The topological nature of the rotating fields in a MDM ferrite disk. On a lateral surface of a normally magnetized ferrite disk, one has an azimuthally nonreciprocal phase shift of electromagnetic waves reflected from a ferrite. (*b*) Power- flow circulations at the MDM resonances. For a given direction of a bias magnetic field, the power flow circulations have the same directions inside a ferrite and in the vacuum near-field regions outside the disk.

A MDM ferrite disk is an open *PT*-symmetry system. In the description of such a system, a non-Hermitian effective Hamiltonian can be derived from the Hermitian Hamiltonian including the environment. Because of strong spin–orbit interaction in MDM magnetization dynamics these bound states in the continuum have a helical structure. The MDM bound states are embedded in the microwave continuum but not coupled to it, so it appears unclear how one could actually probe them. We show that the probing becomes possible due to vortex currents induced on metal parts of a microwave structure [5].

Abstract-We present our recent work on photonic-crystal structures based on Fano resonance. We show that the use of Fano interference in combination with optical nonlinearity can enable single-mode operation and self-pulsing in a nanolaser, as well as fast, low-energy all-optical signal processing.

Ultra-compact photonic structures suitable for optical communication at high-speed with low-energy consumption are essential for enabling integrated photonic chips that can meet the growing demand for information capacity [1]. Here we present our recent work on photonic-crystal (PhC) nanocavity structures exploring Fano resonances, and their applications to lasers, switching, nonreciprocity and power limiting, etc.

As for lasers, rather than conventional semiconductor lasers [2]-[5], we demonstrate a new laser concept based on Fano resonance [6], [7]. The structure (Fig. 1(a)) is an InP PhC waveguide sandwiched by a conventional broadband left mirror and a narrowband right mirror, which is realized by the Fano interference between the waveguide continuum and a discrete mode of a side-coupled H0 nanocavity [8]. The laser has 3 layers of InAs quantum dots as active region and is operated at room temperature by exciting with a continuous-wave light source vertically. It was found that the very narrowband feature of the Fano resonance can lead to single mode lasing, with its wavelength almost unaffected by the cavity length. This is in contrast to ordinary PhC line-defect lasers [9]. In addition, when combined with optical nonlinearity, the highly dispersive feature of the Fano resonance can promote self-pulsations at gigahertz frequencies [8] (Fig. 1(b)), which was previously observed only in macroscopic lasers [10].

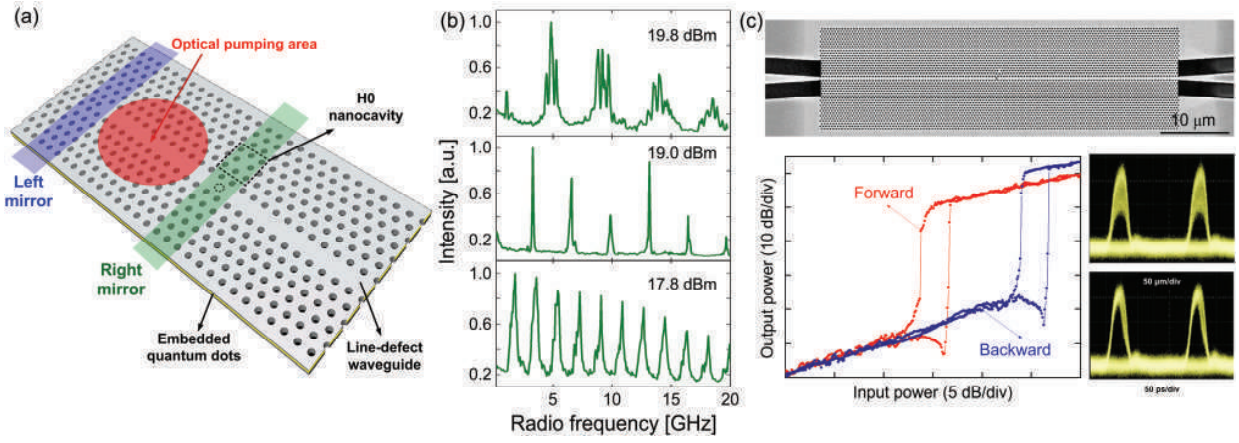

Fig. 1. (a) Schematic of PhC Fano laser. (b) Measured radio frequency spectra of the laser power for different pump powers. (c) SEM image of a fabricated InP PhC Fano switch (top) and its applications for nonreciprocal transmission (bottom left) and power limiting (bottom right).

Compared to traditional Lorentzian structures, Fano resonances can exhibit a sharp spectral shape [11] which enhances the sensitivity of the device to external perturbation, making it especially advantageous for low-energy nonlinear signal processing such as all-optical switching [12]-[13]. Fig. 1(c) shows a fabricated InP PhC 2-port Fano switch, where an H0 nanocavity is side-coupled to a waveguide. A blockade hole is incorporated in the waveguide below the cavity, giving the device's transfer function an asymmetric sharp Fano line shape. By exploiting carrier nonlinearities in the nanocavity, the input signal can be efficiently modulated by itself. This leads to applications such as device nonreciprocity: the forward and backward signal has different transmission coefficients [14] (bottom left panel of Fig. 1(c)); and power limiting: the noise on the injected pulses can be suppressed (bottom right panel of Fig. 1(c)). All the operations are carried out with low energy consumptions on the order of fJ/bit. In the conference, more details about the device fabrication, experimental characterization and the theoretical model will be presented.

Fano-resonant excitations of generalized optical spin waves

Xianji Piao*, Sunkyu Yu, Minpyo Lee, and Namkyoo Park
Photonic Systems Laboratory, Department of ECE, Seoul National University, Seoul 08826, Korea
*corresponding author: xjpiao227@gmail.com

Abstract-Here we show the Fano-resonant excitation of optical spin waves, for longitudinal and transverse axes with respect to the propagation direction. By implementing two linearly-polarized scattering paths to chiral materials, antisymmetric Fano resonances of longitudinal spins are derived with the handedness-dependent asymmetry. We will also introduce the realization of transverse spin guided mode and its Fano-resonant excitations.

The spin angular momentum of light, which corresponds to the handedness of polarization evolutions, is one of the most significant physical quantities of photons. With respect to the propagation direction, three components of electric fields (E_x, E_y, E_z) can derive three pairs of spin components: one for longitudinal spin (Fig. 1a,b) and two for transverse spins [1,2] (Fig. 2a,b). To exploit full degrees of freedom in light-matter interactions [3], topological properties [4], and singularity [5] from these 3-dimensional spins, efficient excitation schemes each for longitudinal and transverse spins should be addressed. In this talk, we introduce the excitation of longitudinal and transverse spins from linearly-polarized incidences, achieving lossless and spectrally-controllable performance features.

First, we will talk about the net achievement of longitudinal spin angular momentum of light, through the mixing of birefringence and chiral resonances (Fig. 1c, [6]). A chiral resonator alone, without the circular dichroism, cannot lead to any net longitudinal spin due to the resonance overlap between two longitudinal spin components. We thus introduce two scattering pathways from birefringent mirrors, which derive antisymmetric Fano resonances (Fig. 1d) from the interaction between each spin mode. The net achievement of the longitudinal spin from the opposite shift of Fano dips, and the realization based on metamaterials are also discussed.

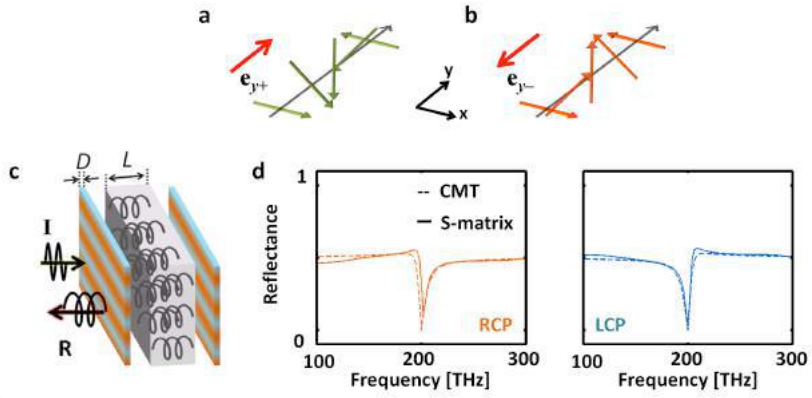

Figure 1. (a,b) Polarization evolutions of longitudinal spins for *y*-propagating wave: (a) positive spin, (b) negative spin. Red arrows denote the spin direction. (c) A schematic of the chiral resonator enclosed within birefringent mirrors for Fano-resonant excitation of longitudinal spins. (d) Reflectance spectra for each longitudinal spin component (RCP and LCP).

In the talk, we will also introduce the realization of guided transverse-spin waves, having a dark-mode feature. The excitation of transverse-spinor dark modes through the grating structure is discussed, revealing the standing wave polarization evolution from opposite transverse spin modes.

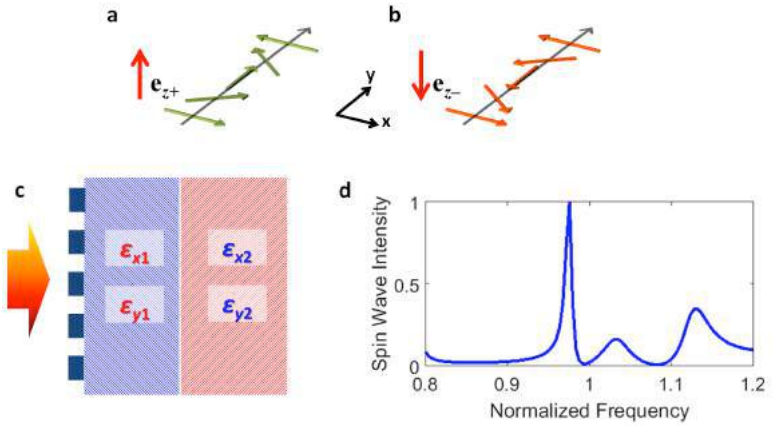

Figure 2. (a,b) Polarization evolutions of transverse spins for *y*-propagating wave: (a) positive spin, (b) negative spin. Red arrows denote the spin direction. (c) A schematic for transverse-spin wave excitations by Fano resonances. (d) Excitation spectra of transverse spin components at the interface.

Perturbation theory for bound states in the continuum on periodic structures

Lijun Yuan[1], **Ya Yan Lu**[2,*]

[1]Chongqing Technology and Business University, China
[2]City University of Hong Kong, Hong Kong
*mayylu@cityu.edu.hk

Abstract— On periodic structures with proper symmetries, guided Bloch modes could exist above the lightline, and they are examples of bound states in the continuum (BICs). Certain BICs on periodic structure are not protected by symmetry in obvious ways. Using a rigorous perturbation theory, we show that these BICs are in fact still closely related to the symmetries.

Periodic structures sandwiched between two homogeneous media are often studied in diffration problems when incident waves are specified, and they can also be regarded as wave-guiding structures on which guided Bloch modes may exist without any incident waves. Typically, the Bloch modes on the periodic structures are found below the lightline, that is, the wavenumber in the homogeneous media is less than the magnitude of the Bloch wavevector, so that there exist no propagationg diffraction channels. The bound states in the continuum (BICs) on periodic structures are special guided Bloch modes existing above the lightline, where one or more diffration channels are still open, but the modes exhibit no radiation. The existence of certain BICs (symmetry-protected BICs) which have incompatible symmetry with the radiating waves are well understood, but there are also BICs that cannot be explained by simple symmetry arguments, and these BICs are often classified as "unprotected by symmetry" [1, 2, 3].

In fact, certain BICs labeled as "unprotected by symmetry" depend strongly on the symmetries. The simplest examples can be found on 2D structures given by a real dielectric function $\epsilon(x, z)$ which is periodic in x, even in x, and even in z (with a properly chosen origin), and bounded by identical homogeneous media (e.g. air) for $z > d/2$ and $z < -d/2$. On such 2D periodic structures, there could be propagating BICs with a nonzero Bloch wavenumber, and they are regarded as "unprotected by symmetry" [2, 3]. However, numerical results indicate that these BICs strongly depend on symmetry. If the structure is perturbed with a perturbation that breaks the reflection symmetry in x or z, the BICs usually disappear and become resonances with finite Q values, and if the perturbation keeps the symmetry, the BIC typically continues to exist with a slightly different frequency and slightly different Bloch wavenumber.

In this paper, we present a perturbation theory that clearly reveals the importance of symmetry. Given a structure described by a real $\epsilon_*(x, z)$, and a BIC with a real frequency ω_* and a real Bloch wavenumber β_*, we consider a perturbed structure given by $\epsilon_*(x, z) + \delta\epsilon_1(x, z)$, and derive a linear system for frequency ω and Bloch wavenumber β for a perturbed Bloch mode near the original BIC. It is shown that if ϵ_1 keeps the reflection symmetries in x and z, then the perturbed frequency and wavenumber are real and can be solved from a real 2×2 linear system, and when ϵ_1 breaks the symmetry, the linear system becomes complex in geneal. Therefore, the perturbation theory reveals the hidden dependence on symmetry for these BICs usually labeled as "unprotected by symmetry". It should be pointed out that our perturbation theory is very different from the standard one which only gives a perturbed frequency for a fixed Bloch wavenumber. Numerical results are provided to validate the perturbation theory.

Fano-Feshbach resonance in metallic nanohole arrays

M. Nishida, and Y. Kadoya

Graduate School of Advanced Science of Matter, Hiroshima University, Higashi-Hiroshima, 739-8530, Japan
mnishida@hiroshima-u.ac.jp

Abstract— Surface bound modes in thin metallic film with an array of nanoholes produce complicated band structure owing to the diffraction caused by the periodicity and the coupling between the surface plasmon polaritons through the holes. If the different branches co-exist adjacently, multiple bound modes contribute to a resonance and cause a Fano-Feshbach resonance, such as electromagnetically induced transparency (EIT) or coupled-resonator induced transparency (CRIT). In this study, we show that appropriate lattice structure of metallic nanohole array yields sharp reflection-transmission spectra. The origin of this resonance is attributed to the CRIT between the two surface bound modes based on the analyses using spatial and temporal coupled mode methods.

In a metallic film perforated by an array of nanoholes, Bloch-wave surface plasmon polaritons (BW-SPPs) on the upper and lower surfaces of the film are coupled by the wave-guide modes of nanoholes and produce variety of surface bound modes [1]. Especially, in a system with mirror symmetry in the direction perpendicular to the film surface, there are two types of surface bound modes, bonding and anti-bonding modes, which have symmetric and anti-symmetric charge distributions, respectively. These modes respond quite differently to incident light.

As an example, Fig. 1 (a) shows the transmission spectrum for the square lattice with period $L_x = L_y = 0.5\mu$m of the holes with the radius of 0.15μm. The dashed (dashed-dotted) lines indicate the dispersion relations of bonding (anti-bonding) modes. Due to the difference of symmetry, the bonding and anti-bonding modes do not have interaction to lead level anti-crossing, and a degenerate point appears in the dispersion relations. At the degenerate point, the interference between the radiations from two bound modes suppress both of reflection and transmission, and nearly perfect absorption is realized [2]. This phenomenon is a kind of Fano-Feshbach resonance which occurs when multiple resonances interfere [3].

On the other hand, another kind of Fano-Feshbach resonance is expected to occur when two modes with same mirror symmetry are located close together in the $\omega - k$ space. These two modes interact with each other via the coupling with radiation fields, and behave as two coupled modes with closer eigenfrequencies. Moreover, one of the widths of resonance becomes narrower and the other becomes broader. These effects yield a sharp dip structure in the resonance spectrum when two bright modes are located close together. This phenomenon is known as coupled-resonator induced transparency (CRIT) [2,3].

In this study, we show that CRIT phenomena can occur in metallic nanohole array systems by using rectangular lattices of nanoholes which are elongated in one direction. Fig. 1 (b) shows the

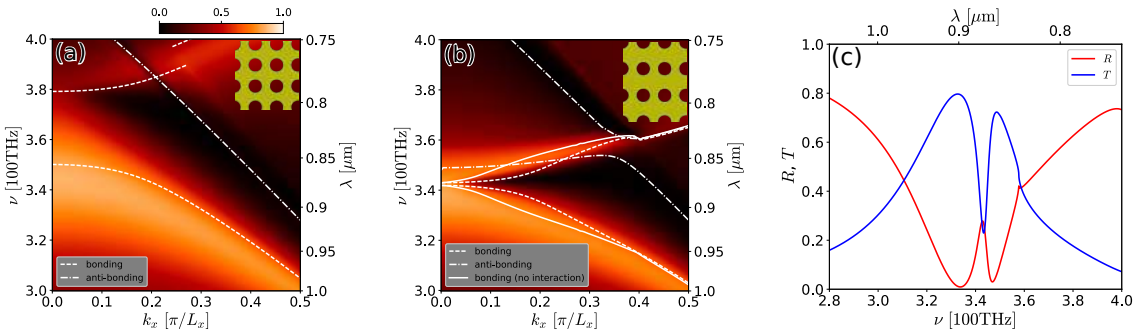

Figure 1: (a) Transmission spectra and dispersion relations of surface bound modes for $L_x = L_y = 0.5\mu$m, and (b) those for for $L_x = 0.5, L_y = 0.63\mu$m. (c) Reflection (R) and transmission (T) spectra at $k_x = 0.1\pi/L_x$.

transmission spectrum and the dispersion relations of bound modes for a rectangle lattice whose period in y direction is elongated to $L_y = 0.63\mu$m from the system used in (a). The solid lines indicate the dispersion relations of bound modes without coupling to radiation field, which are calculated using temporal coupled mode method [4]. We can see that the interaction between these two modes via the coupling with radiation fields put the resonant positions closer and produce quite sharp dip-structure. The panel (c) shows reflection and transmission spectra when the in-plane wave-number is $0.1\pi/L_x$, which have EIT-like profile.

Thus, in metallic nanohole array systems, variety of Fano-Feshbach resonances appear everywhere in the band structure, and yield complicated resonant structures. In the presentation, I will show the general picture of resonant phenomena of this system based on the analyses by the spatial and temporal coupled mode methods.

Fano resonances in light scattering by finite obstacles.

A. E. Miroshnichenko

[1]Nonlinear Physics Centre, The Australian National University, Australia

[*] andrey.miroshnichenko@anu.edu.au

Abstract-Light scattering by finite obstacles, either single particle or a number of particles in arbitrary configuration, exhibits various resonant effects. It turns out that almost any resonant response, either in directional or total scattering light scattering, can be efficiently described in terms of Fano resonance. One of the peculiar feature of the Fano resonance is complete destructive interference, which can be associated with radiationless excitations, such as nontrivial anapole modes.

Fano resonance is a generic phenomenon appearing in various systems where wave interference is permitted. One of the essential features of the Fano resonance is constructive and destructive interferences taking place in a narrow frequency range resulting in asymmetric line shape [1]. Light scattering by a finite obstacle can be unequally described in terms of partial wave scattering coefficients, based on multipolar decomposition. Various multipoles can interfere in a given direction either in phase or out-of-phase producing asymmetric line shape, which can be associated with Fano profile [2]. Such feature was employed to design effective optical nanoantenans.

Alternatively, due to partial waves orthogonality each scattering coefficient can be analyzed independently. It turns out that high index dielectric particles exhibit infinite series of sharp asymmetric Fano resonance in any given partial wave scattering, including complete suppression of scattering [3]. To explain their origin and identify various contributions to destructive interference we analyze the properties of induced field inside dielectric particle by using Cartesian multipoles. In particular, the first zero of the electric dipole partial wave can be described in terms of excitation of anapole mode [4], which is a result of destructive interference electric and toroidal dipole moments [5] in the far-field due to their identical radiation profiles (see Fig.1).

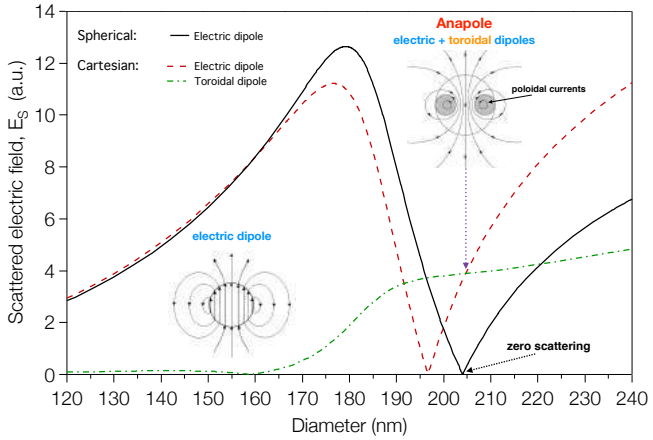

Figure 1. First Fano resonance of electric dipole partial wave scattering (black solid line) and corresponding description of the complete destructive interference in terms of our-of-phase contribution of electric (red dashed line) and toroidal dipole (green dotted line) moments to the far-field.

It can also be considered as an example of localized source excitation, which produces no radiation in the far-field. It now suggests that higher-order zeros of any partial wave scattering can be treated as nontrivial radiationless localized sources. To describe them properly in terms of Fano resonances one needs to introduce higher-order toroidal multipoles.

Abstract— Parity control of Fano resonances in a photonic crystal waveguide coupled to a nanocavity is implemented by controlling the position of a partially transmitting element (PTE) in the waveguide. We experimentally demonstrate regeneration and pulse carving of optical signals by exploiting nonlinearities in the nanocavity in combination with the asymmetrical Fano shape.

Fano resonances can be realized in photonic crystal membrane structures by exploiting the interference between a waveguide continuum and the discrete resonances of a nanocavity [1]. Further, by controlling the details of the coupling between the nanocavity and the waveguide, one can control the sign of the so-called parity of the Fano resonance, i.e., whether the spectral location of the minimum of the transmission is blue (blue-parity) or red (red-parity) shifted with respect to the maximum [2]. In this work, we demonstrate that red-parity can be used for power limiting and pulse carving while blue-parity for signal regeneration applications.

Our device is an InP photonic crystal membrane consisting of a nanocavity side coupled to a line defect waveguide cf. Fig. 1(a). A partially transmitting element (PTE) is placed in the waveguide in two different configurations. In the first case, the PTE is placed in the mirror plane passing through the center of the cavity. This results in red-parity Fano resonance indicated by the red line in Fig. 1(b). In the second configuration, the PTE is placed one lattice constant to the left of the mirror plane leading to blue-parity Fano resonance shown by the blue line in Fig. 1 (b). The structure configurations are shown in the insets of Fig. 1(b).

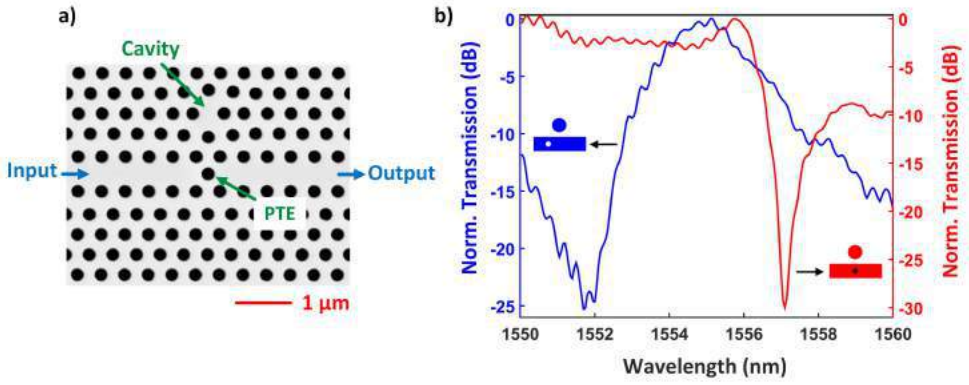

Figure 1: (a) Scanning electron microscope (SEM) image of the fabricated device. It consists of a nanocavity side coupled to a photonic crystal waveguide and a partially transmitting element (PTE) placed in the middle of the waveguide. (b) Measured transmission spectra of two devices with different PTE arrangement giving rise to blue and red-parity Fano resonances.

When an optical signal couples to the nanocavity with Q-factor in the order of 1000, strong intra-cavity field generates free carriers through two-photon absorption leading to free-carrier dispersion and band-filling effects. These nonlinear processes induce changes in refractive index inside the nanocavity resulting in blue shift of the Fano resonance [3]. Depending on the parity of the Fano resonance, very different nonlinear behavior is observed. In the case of blue-parity, the Fano

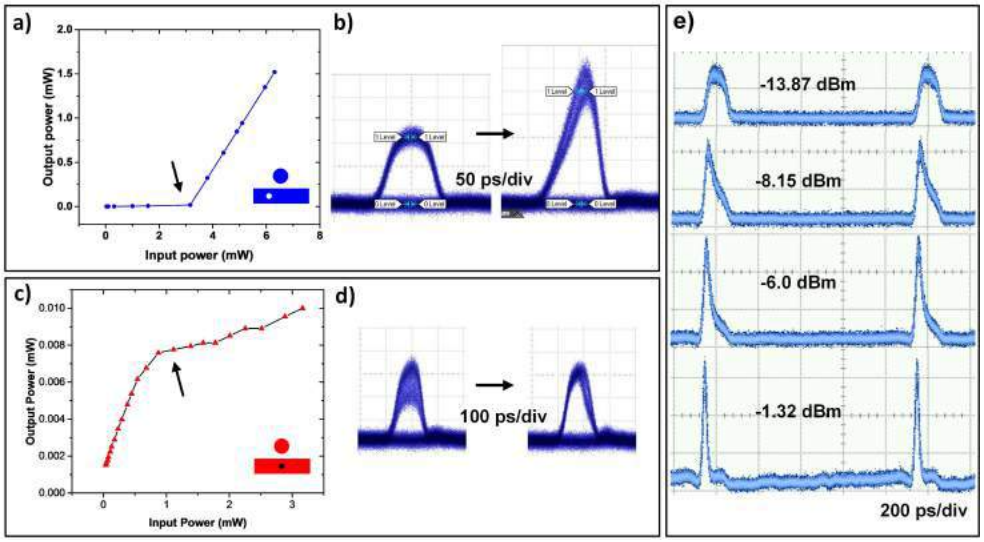

Figure 2: (a) Simulated transfer function of blue-parity Fano resonance. The black arrow indicates the region of operation for extinction ratio improvement. (b) Eye diagram of the input RZ signal (left) and the regenerated signal (right) with approximately 7 dB extinction ratio improvement. (c) Measured transfer function of red-parity Fano resonance used for power limiting experiments. (d) Eye diagram of the degraded input signal (left) and the regenerated signal (right) with reduced intensity noise. (e) Eye diagram for pulse carving of a 93 ps long pulse to a 20 ps pulse. As the input power is increases, the 1 GHz pulse become shorter and shorter.

resonance together with the nonlinear shift possess the transfer function shown in Fig. 2(a) calculated using coupled-mode theory [4]. When the device is operated at the transition point (indicated by the black arrow in Fig. 2(a)), the logical bit 1 experiences a larger transmission than that of the bit 0, which increases the power difference between them, leading to signal regeneration with improved extinction ratio up to 7 dB (Fig. 2(b)).

The red-parity Fano resonance, on the other hand, exhibits a power limiting function Fig. 2(c). Initially, the output power follows the linear increase of the input power, however, as the input power exceeds 1 mW, the output power saturates leading to the power limiting functionality. This can be used to suppress intensity noise in optical signals, hence increasing the signal quality, cf. Fig. 2(d). Compared to the power limiting using Lorentzian resonance [5], the Fano device can show a stronger power saturation as a result of the steeper slope of its spectral shape.

Another interesting application of red-parity Fano resonance is in creating narrow pulses (Fig. 2(e)): when a long pulse spectrally located at the peak of the Fano resonance couples to the cavity, shift in the resonance occurs as a result of nonlinear effects caused by the high peak power of the leading edge of the pulse. This results in reduced transmission for the latter part of the pulse, carving out a short optical pulse from a long one, and at the same time acting as a detector of the long pulse.

Abstract- Superconductor based metamaterial structures pave the way to design switchable metamaterial devices operating at terahertz frequencies. Since, metals possess very high conductivity at terahertz frequencies, the role of superconductors in exciting lossless high Q resonances remains unclear. Here, we used high-Tc superconductor YBCO to design a low asymmetry Fano resonator which supports sharp resonance at extremely low asymmetries but identical metallic meta-atom fails to support any resonance response. We also present the ultrafast switching of sharp Fano resonances in superconductors.

Magnetic interactions and transport properties of parallel coupled magnetic molecules.

S. Alwan, J. D. Vasquez Jaramillo, H. Hammar, and J. Fransson*

Abstract-Parallel coupled quantum dots embedded in a tunnel junction is a typical system that exhibits Fano resonances. Here, we consider magnetic molecules in a similar geometry and consider the electronically mediated magnetic interactions between the localized spins as function of the gate and bias voltages as well as temperature differences between the leads. In addition to regimes of ferromagnetic and anti-ferromagnetic coupling, we show that Fano resonances give rise to vanishing exchange between the localized spins.

Previous predictions of electrical and thermal control of magnetic exchange interactions between localized spin moments in, e.g., magnetic molecules have revealed the ability to fine tune gate and bias voltages in order to deliberately go between regimes of ferromagnetic and anti-ferromagnetic exchange [1,2]. These studies have been focused on serially coupled molecules in which it is well known that interference phenomena such as Fano resonances are normally not occurring. In quantum dots coupled in parallel, however, Fano resonances are known to exist and are well captured within the traditional two-path structure, see e.g., [3], which serve as a prerequisite for the effect. Here, we consider the electronically mediated magnetic interactions between the localizes spin in magnetic molecules, pertaining to e.g, *M*-porhyrins or *M*-phthalocyanines where *M* is a transition metal element (Cu, Fe, Ni, Co, Mn), or analogous compounds. In particular, we address the dependence of the magnetic interactions on the gate and bias voltages as well as on the temperature difference between the leads. In a quite similar fashion as in the serially coupled system, we show that the exchange interaction can be controllably fine tuned between ferromagnetic and anti-ferromagnetic by means of the external control variables. In addition to this control, we also show that sudden absences of the exchange are correlated with Fano resonances and since the transport properties are deeply connected with the magnetic configuration of the spin dimer, this provides a unique way to study the Fano interference phenomena and its influence on magnetic systems.

Abstract— We experimentally and theoretically analyze the role of substrate on the optical bound states in the continuum (BICs). We reveal that a high-index substrate could destroy even in-plane symmetry protected BIC due to leakage into the diffraction channels opening in the substrate. We show how two concurrent loss mechanisms – scattering due to surface roughness and leakage into substrate – contribute to the suppression of the resonance lifetime.

Optical bound states in the continuum (BICs) are localized states with energy lying above the light line and having infinite lifetime [1]. The concept of BIC was firstly proposed by von Neumann and Wigner in 1929 for electron placed in a specific potential [2]. In optics, the term bound state in the continuum first appeared around 2008 [3]. Experimental observation of optical BIC followed only in 2011 [4]. Any losses taking place in real systems result in transformation of the bound states into resonant states with finite lifetime. In this work we theoretically and experimentally analyze transformation of optical BICs into resonant states due to surface roughness and high-index substrate beneath the photonic structure.

The design of the photonic structure under study is shown in Fig. 1(a). It consists of rectangular bars made of crystalline silicon surrounded by fused silica. The parameters of the sample are following: The parameters of the sample (period $a = 1$ μm, bar width $w = 150$ nm, bar height $t = 330$ nm, thickness of SiO_2 spacer $H = 1$ μm) were chosen so that the guided modes are excited in the near-infrared spectral range, where the absorption of silicon is negligible. Wavelength of at-Γ BIC in the considered structure is 1450 nm.

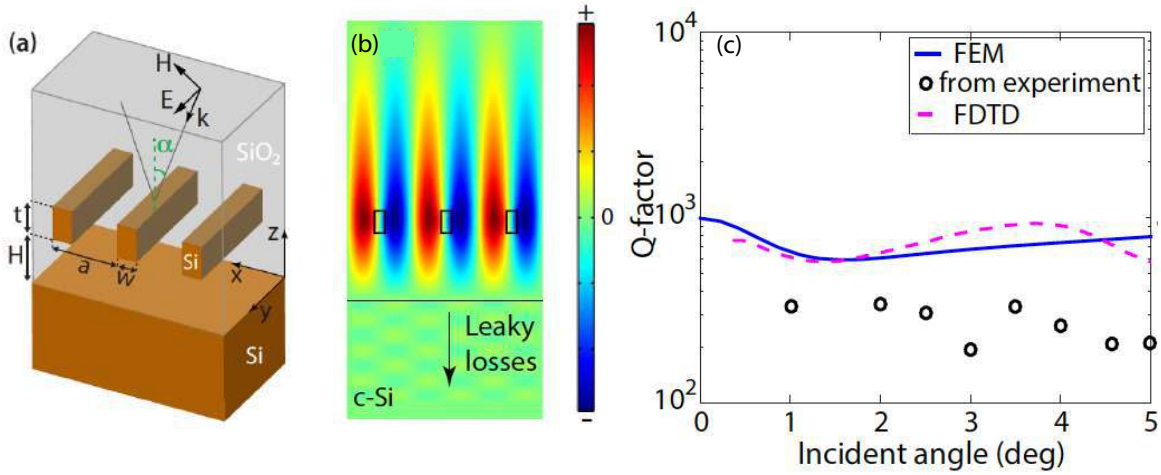

Figure 1: (a) Schematic image of photonic structure under consideration. (b) Calculated distribution of E_y component for TE_1 mode in Γ point. (c) Q-factor versus incident angle extracted from experimental (shown with dots) and FDTD (dashed line) data and calculated with FEM.

To characterize the eigenmode of the system, we carried out the angle-resolved reflectivity measurements. Then we extract the dependence of the Q-factor on the angle of incidence and compare it with results of numerical simulations [see Fig. 1(c)]. One can see that even in the

lossless case the at-Γ BIC transforms into a resonant state in spite of the fact that at-Γ BIC is protected by in-plane symmetry of the structure. Actually, the in-plane symmetry does not protect at-Γ BIC against leakage in diffractions channels opening in the silicon substrate. Figure 1(b) shows how the energy stored in BIC leaks into the silicon substrate via open diffraction channels forming the characteristic interference pattern. Increase of the spacer thickness H results in exponential decay of the leakage. At high H, when the leakage into the substrate is negligible, the scattering due to roughness makes the contribution into the total losses. Therefore, the critical thickness of the spacer, when both loss mechanisms make the same contribution strongly depends on the fabrication quality.

The obtained results provide useful guidelines for practical implementations of structures supporting optical bound states in the continuum and could find a number of applications in optical communications, on-chip photonics, laser physics and sensing.

Harnessing Fano resonances for optomechanics

Simone Zanotto[1]
[1]Istituto Nanoscienze – CNR and NEST Laboratory, Piazza San Silvestro 12, 56127 Pisa, Italy
[*]corresponding author: simone.zanotto@nano.cnr.it

Abstract-Cavity optomechanics relies on the interplay between light and mechanical resonant degrees of freedom in a micro- or nanophotonic environment. In this contribution we will explore the physics of optomechanical devices based on optical Fano resonances, with insights towards self-sustained mechanical oscillations and electro-opto-mechanical interaction in piezoelectric metasurfaces.

The interplay between light science and mechanics dates back to the discovery of radiation pressure force, postulated more than a century ago and subsequently observed in several contexts. Recently the interaction of light with mechanics has experienced a surge of interest, mostly thanks to the potentials of nanophotonics, giving rise to the new field of cavity optomechanics [1]. The interest of mechanical interactions with nanostructured photonic devices is twofold: on one side, the optical forces induce a deformation of the structure, with an increased efficiency due to the optical resonant field enhancement. On the other side, a mechanical perturbation effectively converts into an optical response, with an enhancement which is now governed by the mechanical quality factor. In this contribution I will review some recent results about the mechanical actuation of photonic crystal resonators, i.e., of guided-mode resonant filter metasurfaces. When the geometry is perturbed - for instance, stretched along an axis - the Fano resonances occurring in reflection and in transmission will be tuned by a significant amount. In this sense, the system acts as a tunable optical filter. Moreover, if the resonator is loaded with an absorbing material, also its absorption resonance will be shifted. This effect can be harnessed to synthesize self-oscillating components supplied by a simple steady optical source [2]. To implement these effects two main technological approaches have been explored. First, we employed responsive polymers, which strongly deform through a thermo-optic mechanism. Second, we analyzed piezoelectric semiconductors, where the additional electric degree of freedom could provide further flexibility in view of quantum optomechanics experiments [3].

New type of the Fano resonance in the core-level absorption spectrum of an impurity in one-dimensional superlattice

Abstract—Core absorption spectrum of an impurity embedded in a one-dimensional tight-binding chain is theoretically investigated in terms of complex spectral analysis. The spectrum shows a distinct Fano-profile only with a single intra-atomic transition. The asymmetric Fano absorption profile is attributed to the complex oscillator strength of the transitions to the discrete resonance states belonging to the extended Hilbert space. Nonlinear nature of the effective non-Hermitian Hamiltonian enhances the asymmetric Fano profile of the absorption spectrum.

The Fano effect was first discovered in the photoionization process of an atom, where the two optical transitions are interfered with each other through the autoionization interaction, which brings about the characteristic asymmetric absorption profile known as the *Fano profile* [1]. Since then, the Fano effect has been found to appear ubiquitously in various physical systems, having been interested as a manifestation of a quantum interference in multiple decay processes [3, 4, 5]. According to the progress of nanoscience, the Fano physics is now flourishing as one of the hot topics in modern physics.

It has been considered that, since the Fano effect is the interference of alternative decay processes, multiple decay channels are necessary to cause the Fano effect, for example, the intra-atomic excitation transition followed by the autoionization decay in addition to the direct ionization decay [2]. In this work, we reveal another process of the Fano profile in terms of the complex spectral analysis.

In this work, we study the optical absorption spectrum of a two-level impurity atom embedded in a semi-infinite tight-binding chain as shown in Fig.1, where the two optical transitions from the core level, $\hat{\mu}_d$ and $\hat{\mu}_0$, are taken into account. We describe the electronic system in terms of the single impurity Fano-Anderson model, and have derived the non-Hermitian effective Hamiltonian with the Brillouin-Wigner-Feschbach projection method. The complex eigenvalue problem of the effective Hamiltonian is nonlinear in the sense that the effective Hamiltonian itself depends on its eigenvalue. We have solved the complex eigenvalue problem to obtain the resonance state in the extended Hilbert space by non-perturbative method [6]. Due to the nonlinearity of the eigenvalue problem of the effective Hamiltonian, there appear several discrete resonance states even though the system carries only a single unperturbed state $|d\rangle$ [7].

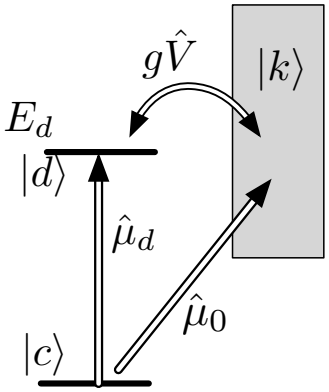

Figure 1: Core-level absorption of the two-level impurity atom in a semi-infinite chain continuum: The ground and excited states are denoted by $|c\rangle$ and $|d\rangle$, respectively, and $|d\rangle$ is coupled with the continuum $|k\rangle$ with $g\hat{V}$. The intra-atomic transition $\hat{\mu}_d$ and the direct transition $\hat{\mu}_0$ to the continuum are taken into account.

In terms of the complex spectral analysis, we found that spectral features are almost exclusively determined by the independent sum of the transitions to the discrete resonance states in the extended Hilbert space. The absorption spectrum due to the transition to a resonance state is then represented by

$$f_j(\omega) = -\frac{1}{\pi}\mathrm{Im}\left[\frac{\mu_d^2}{\omega - z_j}\langle d|\varphi_j\rangle\langle\tilde{\varphi}_j|d\rangle\left\{1 + \frac{\mu_0\, g}{\mu_d\, V}\Sigma^+(z_j)\right\}^2\right], \quad (1)$$

where $|\varphi_j\rangle$ ($\langle\tilde{\varphi}_j|$) is the right(left)-eigenstate of the Hamiltonian with a complex eigenvalue z_j, and $\Sigma^+(z)$ is the self-energy. For $\mu_0 \neq 0$ the second term in the curly bracket causes the ordinary Fano

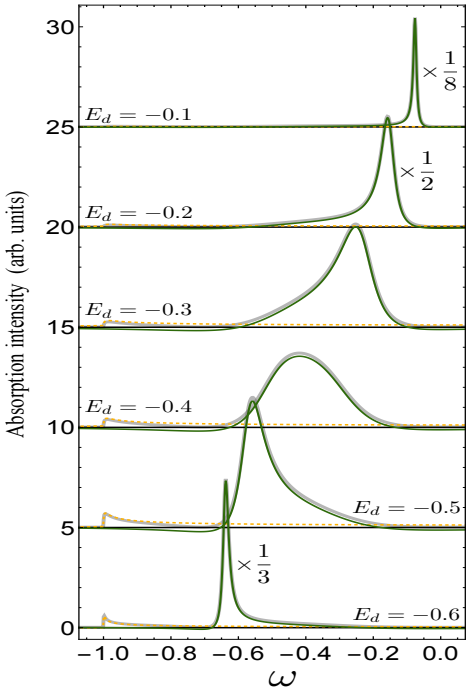

Figure 2: Absorption spectrum of the impurity atom in a semi-infinite chain.

profile, corresponding to the interference between the two optical transition paths of $\hat{\mu}_d$ and $\hat{\mu}_0$. In addition, since the resonance states belong to the extended Hilbert space, $\langle\tilde{\varphi}_j|$ is not a Hermitian conjugate to $|\varphi_j\rangle$, so the factor of $\langle d|\varphi_j\rangle\langle\tilde{\varphi}_j|d\rangle$ becomes complex, which can give rise to the Fano profile. This is very interesting because even with a single optical transition, such as the case with $\mu_d \neq 0$ and $\mu_0 = 0$, we may find the Fano effect in the absorption spectrum, in contrast to the conventional idea that an interference of the alternative transitions is necessary for the Fano effect.

Figure 2 is the result of the absorption spectrum for various values of the impurity state energy E_d for the weak coupling case ($g \ll 1$), where $\mu_d = 1$ while $\mu_0 = 0$. The spectral profile is changed as the bare impurity energy E_d is changed in the continuum. We find that even with the single transition path of μ_d the spectral profile is not at all a simple Lorentzian but a strongly asymmetric Fano type.

This alternative mechanism of the Fano effect is qualitatively different from the ordinary Fano effect, where the several transition channels are interfered with each other. We shall show that the complex spectral analysis is useful to interpret the different types of the Fano effect in the absorption spectrum and applicable to other higher order optical spectroscopies.

Abstract-The engineering of metasurfaces intended to obtain sharp features in their spectral response is studied. We show that in contrast to the conventional hybridization approach exploiting Fano type interference between dark and bright resonant elements, a more flexible and efficient engineering of the spectral response can be achieved by using distinctly different mechanisms for the excitation of dark modes.

The aim of the current contribution is to show that electromagnetically induced transparency [1] and dark mode excitation [2, 3] are not necessary associated. We bring theoretical and experimental evidence in the microwave domain that dark mode excitation can be achieved in an independent manner by using direct excitation mechanisms through symmetry matching of the resonant element and that of the incident electromagnetic field. The presented approach provides higher flexibility for the metasurfaces engineering and results in a great improvement of their spectral performances. Furthermore, by using Babinet's principle to design complementary resonant elements, steep variations in the spectral response can be achieved either in transmission or reflection.

Since the initial seminal paper by Fedotov [4], the concept of trapped or dark mode weakly coupled to free space started to be associated with the phenomenon of EIT transparency. However, recent theoretical advances lead to revisit this commonly shared interpretation. In particular, it was pointed that no dark mode excitation is necessary for EIT resonances. They can be described by the interference of bright modes only [5-7]. In contrast, the Fano interference of two modes with substantially different radiative strength results in a very weak EIT effect. The origin of this apparent contradiction stems from the fact that the eigenmodes of the coupled system can significantly differ from those of the individual elements, and in general they are not orthogonal.

In this study, we show that a metasurface composed of identical Z-shaped resonating elements (Fig. 1a) is able to show dark mode resonance (Fig. 1c and 1e). The dark mode in this case is associated with the first higher order mode of odd symmetry. The excitation of this antisymmetric mode is forbidden under normal incidence but becomes allowed for oblique one when the magnetic component of the incident field intersects the magnetic loops formed by the two V-antennas forming the Z resonant element. By using Babinet's principle we demonstrate in the current contribution direct excitation of the antisymmetric dark mode resulting in a maximum in transmission in a complementary Z resonator (Fig. 1b, 1d and 1f).

Abstract— The interference between electric and magnetic resonance modes in high refractive index dielectric nanostructures can be exploited to control the directionality of the light scattering. Usually, the directional Fano resonances occur either in spherical dielectric nanoparticles or in coupled nanostructures such as silicon sphere dimers. We show both theoretically and experimentally that directionality can be controlled in single silicon cylindrical nanowires, even by exciting either pure electric ou pure magnetic resonances. The directionality can be further tailored using asymmetric nanowires of rectangular cross section.

Recently, high refractive index nanostructures, such as silicon nanoparticles or nanowires, have proven to offer very interesting optical properties thanks to optical Mie resonances. Theses resonances that can be of electric or magnetic nature can be tuned from the near UV to the near IR. Applications are expected in field-enhanced spectroscopies, near field imaging, nonlinear optics or improved photovoltaic devices. [1]
The coupling between electric and magnetic resonances also results in a strong directional scattering of light, which offers new possibilities to design efficient optical nanoantennas. Evidence of pure forward or backward scattering has been shown using semiconductor nanodisk or nanosphere dimers, a phenomenon also associated with Fano resonances. [1, 2]
We show both theoretically and experimentally that directionality can also be controlled in single silicon cylindrical nanowires, in a first step via the nanowire diameter. The polarization of the incident light (TE or TM) with respect to the nanowire axis adds another degree of freedom compared to spheroidal nanostructures as pure TE or TM excitation allows to excite either pure electric or pure magnetic modes, respectively. However, the interference between intense electric fields is still possible in each case and arises from the coupling of either pure electric or pure magnetic modes of different orders. The exception is the smallest nanowires supporting a single nondegenerate TM mode, leading to omnidirectional scattering in that case. [3]
We finally investigate nanowires obtained by electron beam lithography of silicon on quartz substrates. We show that the forward over backward scattering ratio can be engineered as function of the nanowire size and the asymmetry of its cross-section. Fano-like resonances arising for specific wavelengths and geometries can strongly modify the FW/BW scattering ratio compared to nanowires with more symmetric cross sections.
In conclusion, we show that directional scattering of light by high refractive index nanowires can be tuned as function of both shape and dimensions of the nanowire cross-section, and that it can be controlled by the incident light polarization.

A Spectral Method for the Analysis of Fano-like Resonances of Nanoparticles in the Full-Retarded Regime.

C. Forestiere[1], **M. Pascale**[1], **R. Tricarico**[1], **and G. Miano**[1]

[1] Department of Electrical Engineering and Information Technology, Università degli Studi di Napoli Federico II, via Claudio 21, Napoli, 80125, Italy carlo.forestiere@unina.it

Abstract— In this work, we introduce a full-retarded spectral technique to identify the interfering modes responsible for the peaks and the dips of the scattered power spectrum in spherical nanoparticles. Moreover, we show that the interaction of non-orthogonal modes determines the onset of Fano-like resonances. We also investigate the role played by the material properties in enabling or preventing the interference effects behind Fano-like resonances.

The past two decades have witnessed a rapid rise of interest in the resonant electromagnetic scattering from metal and dielectric nanoparticles (NPs). In particular, asymmetric scattering profiles, often referred to as Fano resonances [1], have been observed in metal nanostructures excited by an electromagnetic field at optical frequencies. They generated large interest, particularly in relation to optical sensors which, taking advantage of the sharp resonant lineshape, could potentially offer a significant improvement in sensitivity.

However, despite many advancement in the understanding of NPs electromagnetic scattering, several fundamental questions remain unanswered. First, the resonances in metal or dielectric NPs of size comparable to the wavelength are currently found either experimentally or numerically by exciting the NP with radiation of various frequencies and locating the peaks of the corresponding scattered power spectra. However, this procedure is flawed and can be often misleading. Generally speaking, a peak of the scattered power spectrum cannot be univocally associated to the action of a unique *resonant mode* but may arise from the interplay of several modes. The correct identification of the resonant modes is essential in the description of anomalous scattering behaviours such as the appearance of asymmetric resonant line-shapes where interference phenomena play a key role. Second, why silicon and metal NPs of comparable size exhibit deeply different resonant behaviours in the visible spectral range? In particular, why asymmetric lineshapes in the total scattering spectrum have been observed for Si spheres, but not for metal spheres? In this work, we tackle these issues, introducing a general method to identify the modes responsible for the peaks and the dips of the scattered power spectrum.

We recently introduced a spectral solution for the electric field $\mathbf{E}_S$ scattered from a homogeneous spherical particle of permittivity $\varepsilon_r(\omega)$ [2]:

$$\mathbf{E}_S(\mathbf{r}) = (\varepsilon_r - 1)\sum_{pmnl}\left(\frac{A_{pmnl}}{\alpha_{nl}-\varepsilon_r}\mathbf{C}^{(\alpha)}_{pmnl}(\mathbf{r}) + \frac{B_{pmnl}}{\beta_{nl}-\varepsilon_r}\mathbf{C}^{(\beta)}_{pmnl}(\mathbf{r})\right), \tag{1}$$

where the eigenvalues α_{nl}, β_{nl} and the corresponding eigenfunctions $\mathbf{C}^{(\alpha)}_{pmnl}$, $\mathbf{C}^{(\beta)}_{pmnl}$ are provided in Ref. [2], and

$$A_{pmnl} = \frac{\langle \mathbf{C}^{(\alpha)}_{pmnl}, \mathbf{E}_i\rangle_\Omega}{\langle \mathbf{C}^{(\alpha)}_{pmnl}, \mathbf{C}^{(\alpha)}_{pmnl}\rangle_\Omega}, \qquad B_{pmnl} = \frac{\langle \mathbf{C}^{(\beta)}_{pmnl}, \mathbf{E}_i\rangle_\Omega}{\langle \mathbf{C}^{(\beta)}_{pmnl}, \mathbf{C}^{(\beta)}_{pmnl}\rangle_\Omega}, \tag{2}$$

$$\sum_{pnml} = \sum_{p\in\{e,o\}}\sum_{n=1}^{\infty}\sum_{m=0}^{n}\sum_{l=1}^{\infty}, \qquad \langle \mathbf{A}, \mathbf{B}\rangle_V = \iiint_V \mathbf{A}\cdot\mathbf{B}\,\mathrm{dV}. \tag{3}$$

The modes $\mathbf{C}^{(\alpha)}_{pmnl}$ are of electric type and the modes $\mathbf{C}^{(\beta)}_{pmnl}$ are of magnetic type. We have $p \in \{e, o\}$, $n \in \mathbb{N}$, and $0 \le m \le n$. The number n is associated to the number of lobes of the mode amplitude at any given radial distance. In particular, the modes with $n = 1$ are the dipolar modes, those with $n = 2$ are the quadrupolar modes, and so on. The mode number $l \in \mathbb{N}$ gives the number of maxima of the mode amplitude along the radial direction inside the sphere. We denote the electric and magnetic

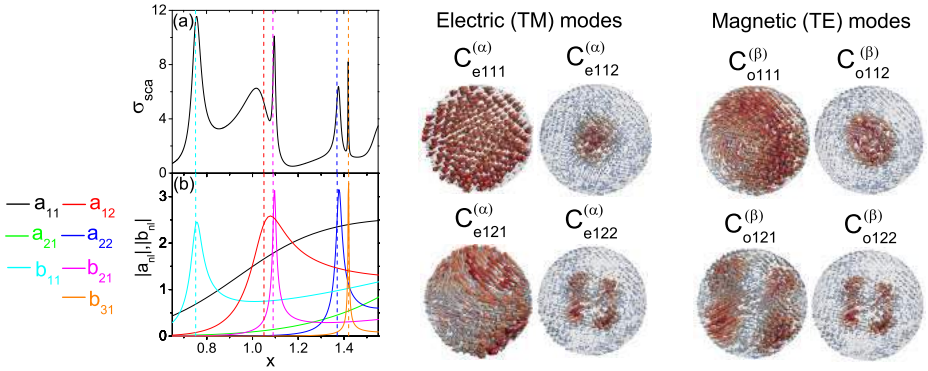

Figure 1: Scattering efficiency σ_{sca} of the Si spheres with $R = 100nm$ as function of $x = 2\pi R/\lambda$. Absolute value of the coefficients a_{nl} and b_{nl} as a function of x. The cone plot of some exemplificative modes is also shown.

modes as *fundamental* when $l = 1$, and as *higher order* modes when $l \geq 2$. In general, we have $\langle \mathbf{C}^{(\delta)}_{pmnl}\, \mathbf{C}^{(\delta')}_{p'm'n'l'} \rangle_\Omega = 0$, $\forall\, (\delta, p, m, n, l) \neq (\delta', p', m', n', l')$, where $\delta, \delta' \in \{\alpha, \beta\}$. Furthermore, due to the spherical symmetry, we also have $\langle \left(\mathbf{C}^{(\delta)}_{pmnl}\right)^*\, , \mathbf{C}^{(\delta')}_{p'm'n'l'} \rangle_\Omega = 0$, $\forall\, (\delta, p, m, n) \neq (\delta', p', m', n')$.

In this work, we show that the only modes that can be resonantly excited in an isolated metal sphere ($\mathrm{Re}\{\varepsilon_r\} < 0$) are the modes with $l = 1$. These modes constitute an orthogonal set, this fact prevents interference phenomena in the total scattered power. Vice versa, the modes that can be resonantly excited in a dielectric sphere with $\mathrm{Re}\{\varepsilon_r\} > 0$ are the magnetic modes and the higher order electric modes ($l \geq 2$). Some of these modes are non-orthogonal, enabling Fano-like resonance phenomena.

Then we apply this approach to investigate the resonances of a silicon (Si) sphere with radius $R = 100$nm and $\varepsilon_{r,Si} = 16$. The scattering efficiency σ_{sca} of the sphere excited by a linearly polarized plane wave is

$$\sigma_{sca} = x^{-2} \sum_n \left(\Big| \sum_l a_{nl} \Big|^2 + \Big| \sum_l b_{nl} \Big|^2 \right), \tag{4}$$

where $x = 2\pi R/\lambda$, λ is the wavelength, $a_{nl} = (\alpha_{nl} - \varepsilon_r)^{-1}\, \tilde{A}_{nl}$ and $b_{nl} = (\beta_{nl} - \varepsilon_r)^{-1}\, \tilde{B}_{nl}$. The coefficients $\tilde{A}_{nl}$, $\tilde{B}_{nl}$ do not depend on ε_r; they vary linearly on $\mathbf{E}_i$, and very slowly on x. Their expression can be found in Ref. [2].

We plot in Fig. 1 (a) σ_{sca}, and in Fig. 1 (b) the magnitude of the coefficients a_{nl} and b_{nl}, corresponding to the contribution of the specific modes. All peaks but one can be attributed to the dominant contribution of a single mode. In particular, the first peak from the left is due to $\mathbf{C}^{(\beta)}_{o111}$, the third one to $\mathbf{C}^{(\beta)}_{o121}$, the fourth one to $\mathbf{C}^{(\alpha)}_{e122}$, and the fifth one to $\mathbf{C}^{(\beta)}_{o131}$. Instead, the second peak arises at $x = 1.02$ from the interplay between $\mathbf{C}^{(\alpha)}_{e111}$ and $\mathbf{C}^{(\alpha)}_{e112}$, as suggested by Fig. 1 (b). In addition, the destructive interference between these two modes, which are not orthogonal, is responsible for the scattering dip enclosed by peaks 2 and 3 at $x = 1.076$, and of the corresponding asymmetry of σ_{sca}. In correspondence of this dip the values of the coefficients are $a_{11} = 0.78 - 0.95i$ and $a_{12} = 0.063 + 1.83i$. It is worth to note that, although the scattering dip is in the close proximity of the third peak, the magnetic dipole $\mathbf{C}^{(\beta)}_{o121}$ cannot be held responsible for it, because it is orthogonal to both $\mathbf{C}^{(\alpha)}_{e111}$ and $\mathbf{C}^{(\alpha)}_{e112}$, and interference cannot take place.

Abstract-Strongly coupled plasmonic nano-architectures are ideal systems for promoting Fano resonance excitation. Here we analyze, both theoretically and experimentally, different trimer configurations supporting, respectively, electric and magnetic Fano modes. In particular, by controlling the dark-mode spectral position and the localized surface plasmon resonance retardation (de-phasing), we were able to clarify the role that these two parameters play in the super- and sub-radiant mode hybridization.

Over the last few years, controlling subwavelength-scale light matter interaction has become an essential focus in nanophotonics. The great field enhancements and highly localized hot-spots associated to plasmonic nanoassemblies have enabled wide applications in the field of near-field microscopy, surface enhanced spectroscopy and biosensing [1]. While electric field manipulation at subwavelength regime constitutes the state-of-the-art in plasmonics [2], handling of the magnetic fields at optical frequencies is still at an embryonic stage. Recently, this study has grown in interest within the context of plasmonic Fano resonances [3], exploiting circulating current configurations in resonance condition [4] via properly tailored plasmonic nano-architectures.

Fano resonances are a general phenomenon occurring, for example, through the coupling between a super-radiant ‘’bright’’ mode and a sub-radiant ‘’dark’’ mode, together with an intrinsic de-phasing among localized surface plasmons (LSPs) [5]. Here, we would like to consider two different trimer architectures in which we could control respectively the dark resonance position and the LSPs retardation, thus clarifying the role that these two parameters play in the super- and sub-radiant mode hybridization. In particular, we will introduce T-shape nanoantennas (see Figure 1a), where the excitation of the horizontal single nanostructure can induce out-of-phase charge oscillation into the vertical dimer and the consequent formation of a dark mode. A direct result of the spectral overlapping between super- and sub-radiant modes consists in the generation of resonant hot-spots inside the inter-particle gap regions. Indeed, if we consider the distribution of the electric field enhancement in correspondence of the Fano condition, we can recognize two identical “electric” hot-spots inside the 10 nm inter-particle separations (see Figure 1a, inset).

The case is totally different if we want to generate intense and localized “magnetic” hot-spots under Fano resonance conditions. Dedicated plasmonic devices able to support close circulating current modes instead of linearly oscillating plasmons are required. A possible strategy consists in replacing the horizontal antenna (Figure 1a, inset) employed in T-shape configuration with a nanodisk structure. The resulting layout is schematically shown in Figure 1b. In Fano resonance condition the plasmonic currents, initially in phase (see Figure 1b,d), undergo a re-arrangement, thus producing a Coil-like plasmonic mode (Figure 1c) and the

consequent formation of a magnetic hot-spot. This transition has been experimentally confirmed by optical characterizing ad-hoc fabricated plasmonic structures. The spectral results are summarized in Figure 1f. The magnetic character of the Fano resonance is clarified by the near-field analysis inside the trimer gap region, as illustrated in Figure 1e where a clear magnetic field enhancement can be recognized. In conclusion, plasmonic Fano resonances represent a key-element in nano-photonics, thanks to their local field enhancement and far-field spectral selectivity (see Figure 1). Furthermore, interesting scenarios can be envisioned in the field of "artificial magnetism" where Fano coil-like resonances could play a prominent role for the local manipulation of the magnetic properties of matter, especially in frequency ranges where the saturation of the magnetic response strongly hinders resonant phenomena [4-5].

Resonant-state expansion in open quantum systems

Naomichi Hatano

Institute of Industrial Science, University of Tokyo, 5-1-5 Kashiwanoha, Kashiwa, Chiba 277-8574, Japan
hatano@iis.u-tokyo.ac.jp

Abstract— A novel complete set of the Hilbert space of open quantum systems is introduced. The complete set contains all possible states with discrete eigenvalues, including the resonant, anti-resonant, bound and anti-bound states. The Fano resonance is microscopically explained in terms of the interference between discrete eigenstates.

We consider here open quantum systems given by the tight-binding model, typically represented by the T-shaped quantum dot. We first introduce a novel complete set of the Hilbert space of open quantum systems [1, 2, 3]. The complete set consists of all possible discrete eigenstates, namely the resonant, anti-resonant, bound and anti-bound states.

We next break down the transmission coefficient into the summation of the discrete eigenstates. It reveals that the asymmetric Fano resonance is caused by interference between two discrete eigenstates. More precisely, we classify the Fano resonance into the following three categories: (i) the interference between a resonant state and an anti-resonant state; (ii) the interference between a resonant-state pair (a resonant state and the corresponding anti-resonant state) and a bound state; (iii) the interference between a resonant-state pair and another resonant-state pair. We thereby give a microscopic description of the Fano asymmetric parameter, which was originally introduced only phenomenologically. One of the expressions indicates that the corresponding Fano parameter becomes complex under an external magnetic field.

In summary, we explain the Fano asymmetry microscopically from the perspective of the resonant state of open quantum systems.

Abstract

We analytically study the spontaneous emission of an optical emitter in the vicinity of a plasmonic nanoshell [1]. Based on classical electrodynamics, we show that the fluorescence enhancement can be tuned by the aspect ratio of the coated nanosphere and the distance between optical emitter and spherical surface. In particular, we show that both the enhancement and quenching of the fluorescence are associated with plasmonic Fano resonances induced by near-field interactions.

1. Introduction

With the advent of nanoplasmonics and metamaterials, the Fano interference has become an essential tool for tailoring and controlling light-matter interaction at the nanoscale [2, 3, 4]. In plasmonic systems, the Fano effect can appear due to the interaction of a localized plasmon resonance with a broad Mie scattering resonance [2].

Here, we study the impact of a Fano resonance of a plasmonic nanoshell on an optical dipole emitter in its vicinity [1]. It is well-known that using the first-order perturbation theory, one can formally calculate from quantum electrodynamics the variation on linewidth and energy level shift of a single atom due to the environment (boundary conditions) [5]. In the weak-coupling regime, the spontaneous emission of an atom follows Fermi's golden rule, in which the atom decays exponentially. A remarkable feature of this approximation is that the emission rate of an atom in the vicinity of a body (normalized by the spontaneous emission rate in vacuum), Γ/Γ_0, can be calculated in the framework of classical electrodynamics [5, 6]. Indeed, by taking the total power emitted by a classical dipole in the vicinity of a body (normalized by the power emitted in vacuum), P/P_0, one can demonstrate that $P/P_0 = \Gamma/\Gamma_0$ [6].

Bearing this equivalence in mind, let us consider a coated nanosphere of inner radius $a = 50$ nm and outer radius $b = 70$ nm embedded in the vacuum. The nanosphere has a lossless dielectric core with refractive index $n_1 = 3.5$ and a dispersive silver shell with a realistic refractive index $n_2 = n_{\rm Ag}(\omega)$ [7]. Now, consider that this sphere interacts with a single optical emitter located at $r_0 = b + \Delta r$ (the spherical coordinate system has its origin at the center of the sphere) with dipole moment $\mathbf{d}_0$ and transition frequency ω_0. The spontaneous decay rate of an electric dipole oscillating orthogonally to the spherical surface reads [1, 5]

$$\frac{\Gamma_\perp}{\Gamma_0} = 1 - \frac{3}{2}\mathrm{Re}\sum_{\ell=1}^{\infty}\frac{\ell(\ell+1)(2\ell+1)}{(k_0 r_0)^4} a_\ell \left[\xi_\ell(k_0 r_0)\right]^2, \quad (1)$$

$$\frac{\Gamma_{||}}{\Gamma_0} = 1 - \frac{3}{4}\mathrm{Re}\sum_{\ell=1}^{\infty}\frac{(2\ell+1)}{(k_0 r_0)^2}\Big\{ a_\ell \left[\xi'_\ell(k_0 r_0)\right]^2 + b_\ell \left[\xi_\ell(k_0 r_0)\right]^2 \Big\}, \quad (2)$$

where ξ_ℓ is the Riccati-Henkel function of first kind, and a_ℓ and b_ℓ are the well-known TE and TM Lorenz-Mie coefficients [8], respectively. The expression for a dipole oscillating tangentially to the spherical surface is analogous [5]. It is worth mentioning that coated spheres can exhibit Fano resonances in the total scattering cross section ($\propto |a_\ell|^2$) and these resonances can be analysed via the Lorenz-Mie coefficient a_ℓ [9, 10, 11, 12, 13].

The fluorescence enhancement factor, $F_{\mathbf{d}_0}$, is defined as the ratio between the observed emission intensities in the presence and in the absence of the sphere in the vicinity of the optical emitter [14]:

$$F^{\omega_0}_{\mathbf{d}_0}(r_0,\omega) = \mathcal{G}_{\mathbf{d}_0}(r_0,\omega) Q^{\omega_0}_{\mathbf{d}_0}(r_0), \quad (3)$$

where the quantities $\mathcal{G}_{\mathbf{d}_0} = |\mathbf{d}_0 \cdot (\mathbf{E}_{\rm in} + \mathbf{E}_{\rm sca})|^2 / |\mathbf{d}_0 \cdot \mathbf{E}_{\rm in}|^2$ and $Q^{\omega_0}_{\mathbf{d}_0} = \Gamma^{\rm rad}_{\mathbf{d}_0}/(\Gamma^{\rm rad}_{\mathbf{d}_0} + \Gamma^{\rm nrad}_{\mathbf{d}_0})$ are the intensity enhancement factor (which depends on ω, the *excitation* frequency) and the quantum efficiency (which depends on ω_0, the *transition* frequency), respectively, with $\mathbf{E}_{\rm in}(\omega)$ and $\mathbf{E}_{\rm sca}(\omega)$ being the incoming and scattered electric fields [1].

2. Results and discussion

In Figs. 1(a) and 1(b), we plot the fluorescence enhancement response as a function of the excitation wavelength. Note that the $F_{||}$ profile changes continuously from a Lorentzian lineshape ($\Delta r = 5$ nm) to a Fano lineshape as we increase Δr, whereas $F_\perp$ remains a Fano lineshape profile from the beginning to the end. This change in $F_{||}$ behavior seems to occur around $\Delta r = 20$ nm and $\Delta r = 30$ nm, which is a local minimum region for the quantum efficiency $Q_{||}$ (see Ref. [1]). Furthermore, being a Fano lineshape described by $f_q(\epsilon) = (q+\epsilon)^2/(1+\epsilon^2)$, where q is the Fano asymmetry parameter, the Fano profiles obtained in the insets of Figs. 1(a) and 1(b) have asymmetry parameters with different sign, namely $q_\perp \approx 2.2$ and $q_{||} \approx -2.9$.

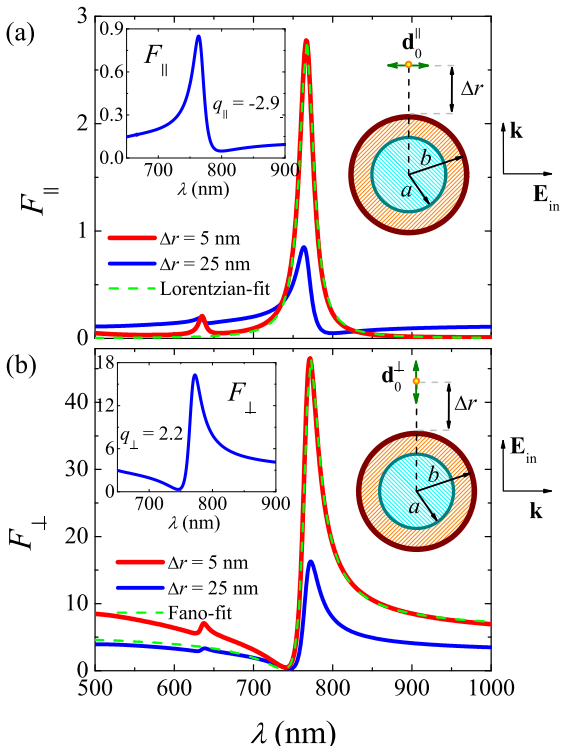

Figure 1: Fluorescence enhancement response associated with an optical emitter (transition wavelength $\lambda_0 = 780$ nm) in the vicinity of a silver nanoshell. The inner sphere has refractive index $n_1 = 3.5$ and radius $a = 50$ nm, whereas the silver nanoshell has radius $b = 70$ nm. (a) The plot shows the Lorentzian lineshape of $F_{||}$ for $\Delta r = 5$ nm (maximum enhancement). The inset shows a Fano lineshape for $\Delta r = 25$ nm with negative asymmetry parameter $q_{||} = -2.9$. (b) The plot shows the Fano lineshape of $F_{\perp}$ for $\Delta r = 5$ nm (maximum enhancement). The inset shows a Fano lineshape for $\Delta r = 25$ nm with positive asymmetry parameter $q_{\perp} = 2.2$.

The sign difference between $q_{\perp}$ and $q_{||}$ and the transition between Lorentzian and Fano lineshapes appear in association with a singular point in the near-field energy flow induced by the Fano effect [3, 15]. For $\ell = 1$, which is the dominant scattering channel for $kb < 1$, we obtain after some algebra [1] the Fano asymmetry parameters of the fluorescence enhancement curves:

$$q_{\perp} = \frac{1}{1+\epsilon''(\omega)}\left[\frac{qy_1(kr_0) - j_1(kr_0)}{qj_1(kr_0) + y_1(kr_0)}\right], \quad (4)$$

$$q_{||} = -\frac{1}{1+\epsilon''(\omega)}\left[\frac{q\chi_1'(kr_0) + \psi_1'(kr_0)}{q\psi_1'(kr_0) - \chi_1'(kr_0)}\right], \quad (5)$$

where $q = \chi_1'(kb)/\psi_1'(kb)$, with j_1, y_1, ψ_1 and χ_1 being the Bessel, Neumann, Riccati-Bessel and Riccati-Neumann functions, respectively. The function $\epsilon''(\omega)$ has a very complicated analytical expression, and it can be estimated from the maximum scattering cross section or the Fano resonance. More details can be found in Ref. [1].

Here, the Lorentzian lineshape in $F_{||}(\lambda)$ in the near-field that changes into a Fano lineshape in the far-field is a consequence of the (dielectric) core-shell (metal) geometry. Physically, the atomic dipole moment $\mathbf{d}_0^{||}$ induces an oppositely directed dipole moment on the plasmonic nanoshell surface, with almost the same amplitude. This interaction cancels out the broad dipole mode at the surrounding medium/plasmonic shell interface, but does not cancel out the narrow dipole mode at the plasmonic shell/dielectric core interface. As the distance between the dipole and the nanoshell becomes greater, the influence of the broad dipole mode in the fluorescence enhancement increases. From the experimental point of view, this result can be applied to control both the enhancement and quenching of the fluorescence response of quantum emitters in the vicinity of plasmonic nanoshells.

3. Conclusion

We have investigated the fluorescence enhancement of an optical emitter in the vicinity of a plasmonic silver nanoshell in the weak-coupling regime. We have demonstrated that a Fano resonance in the total scattering cross section leads to a Fano lineshape response in the fluorescence enhancement as a function of the distance between dipole and sphere. For an optical emitter with dipole moment oriented tangentially to the spherical surface, we have obtained a symmetric Lorentzian lineshape response in the near-field for the fluorescence enhancement. These results may have interesting applications for fluorescence enhancement and/or quenching of optical dipole emitters near plasmonic nanoshells.

Abstract— Generalizing Hermitian topological phases and edge modes to non-Hermitian systems is a pressing open problem. We study edge modes of a non-Hermitian two dimensional Dirac equation, characterizing its three distinct types of edge modes by two topological winding numbers: the Berry phase and a "non-Hermitian charge" carried by non-Hermitian degeneracies of the bulk spectrum. This provides an important step towards a complete topological description of non-Hermitian quantum systems and may be realized in PT-symmetric honeycomb lattices.

The topological properties and classification of Hermitian quantum Hamiltonians has been thoroughly studied in the past decade. Gapped periodic media can be characterized by quantized topological invariants that can only change by tuning the system through a topological phase transition, i.e. a spectral degeneracy. Boundaries between topologically distinct systems host edge modes that cannot be removed without closing the bulk band gap. These "protected" edge modes have potential photonic applications as disorder-robust non-reciprocal waveguides [1].

The generalization of these concepts to non-Hermitian systems is comparatively less well understood, despite the enormous recent interest in non-Hermitian wave effects such as parity-time ($\mathcal{PT}$) symmetry [2], occurring in photonic systems with spatially structured gain and loss. Non-Hermitian wave systems exhibit distinct *exceptional point* (EP) spectral degeneracies which form branch points where the Hamiltonian becomes non-diagonalizable. A natural question is whether these EPs can be associated with non-Hermitian topological invariants and protected edge states, and how they relate to Hermitian topological phases. Under weak gain or loss Hermitian topological edge modes can retain some of their original characteristics [3, 4], but stronger non-Hermiticity combined with a chiral or sublattice symmetry results in EPs and new "anomalous" edge modes qualitatively different from the Hermitian limit, embedded in a gapless spectrum [5, 6].

We study a continuum model of two-dimensional non-Hermitian topological edge modes analogous to the Hermitian Dirac equation [7],

$$\hat{H} = \begin{pmatrix} k_x - isk_y & m \\ m & -k_x + isk_y \end{pmatrix} \equiv (k_x - isk_y)\,\hat{\sigma}_z + m\hat{\sigma}_x \tag{1}$$

parametrized by the momentum (k_x, k_y), the "Dirac mass" m, and the "non-Hermitian charge" s, which determines the sign of the non-Hermitian part of $\hat{H}$. This Hamiltonian has the chiral symmetry $\{\hat{H}, \hat{\sigma}_y\} = 0$ and $\mathcal{PT}$ symmetry ($\mathcal{T}$ is complex conjugation and $\mathcal{P}$ is an x reflection), and can hence have real energy eigenvalues $\hat{H}\psi = \lambda\psi$. The bulk spectrum $\lambda = \pm\sqrt{(k_x - isk_y)^2 + m^2}$ (real part plotted in Fig. 1(a)) hosts EPs when $\lambda = 0$.

Interfaces between domains with different (m, s) host localized zero energy ($\lambda = 0$) edge modes with parametric regions of existence determined by the EPs of the bulk spectrum. We consider in Fig. 1(b,c) an interface in the x direction and find that the edge modes form three classes: "Hermitian-like", "non-Hermitian", and "mixed", distinguished by two topological winding numbers (w_1, w_2) associated with each EP. w_1 is the non-Hermitian generalization of the Berry phase, while w_2 characterizes the chirality of energy eigenvalues in the vicinity of the EP. We find that the difference in these two bulk winding numbers across the interface, $(\Delta w_1, \Delta w_2)$, completely characterizes the edge modes. For example the "mixed" edge modes only occur when $\Delta w_2 = -\frac{1}{2}$ and resemble the "anomalous" edge modes found in Ref. [6].

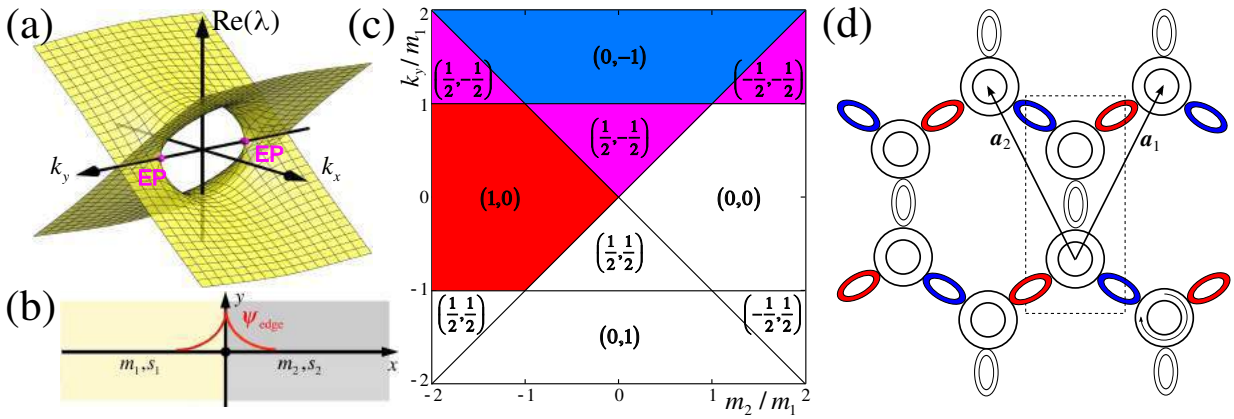

Figure 1: (a) Real part of the bulk spectrum of Eq. (1), hosting two non-Hermitian degeneracies (EPs) separating gapped and gapless regions. (b) Topological edge modes are hosted by interfaces between media with different masses m and non-Hermitian charges s. (c) Phase diagram of edge modes as a function of k_y and relative masses, for media with opposite non-Hermitian charges $s_1 = -s_2 = 1$. Red, purple, and blue regions indicate existence regions of "Hermitian-like", "mixed" and "non-Hermitian" edge modes respectively. Numbers in brackets denote the differences in winding numbers $(\Delta w_1, \Delta w_2)$ across the interface. (d) Possible realization of the model Eq. (1) using a honeycomb lattice of ring resonators with gain (red) and loss (blue) in link rings, with unit cell and lattice vectors indicated by dashed and solid lines respectively.

A possible lattice realization of the effective Hamiltonian Eq. (1) is the 2D photonic ring resonator lattice shown in Fig. 1(d). The required non-Hermitian coupling may be implemented by embedding $\mathcal{PT}$-symmetric gain and loss into the non-resonant link rings. We confirm the existence of zero energy edge modes in this model through diagonalization of the corresponding tight binding Hamiltonian [7]. We therefore anticipate that the zero energy edge modes captured by our continuum model may be observable in a wide variety of non-Hermitian wave systems.

Lorentz-force picture for controlling optical polarizations in non-Hermitian potentials

Sunkyu Yu, Xianji Piao, Choonlae Cho, and Namkyoo Park*
Photonic Systems Laboratory, Department of ECE, Seoul National University, Seoul 08826, Korea

Abstract-We introduce the manipulation of optical polarizations in non-Hermitian potentials, applying the Lorentz-force picture defined by effective material parameters. From the analogy with relativistic E×B drift in electrodynamics, the collective evolution of the states of polarization to the designer pole is demonstrated on the Poincaré sphere. We will also introduce the criteria for the metamaterial realization toward the E×B drift analogy.

Parity-Time (PT) symmetry [1] has opened a pathway toward the unidirectional transition of optical states [2], due to nonorthogonal eigenmodes which also have strong spatiospectral asymmetry. In this talk, we introduce the interpretation of PT symmetry based on the analogy between electrodynamics and classical Maxwell's equations [3], in terms of Lorentz-force picture founded by effective material parameters.

Figure 1a represents the effective Lorentz-force exerted on the state of polarization (SOP) on the Poincaré sphere. The effective electric and magnetic fields are determined by the material parameters of permittivity, permeability, and optical chirality. It is noted that the resulting evolution of the SOP at the exceptional point of PT-symmetric potentials (Fig. 1b) is analogous to the relativistic behavior of the particle (Fig. 1c) driven by electromagnetic fields at $|E| = |B|$ [4].

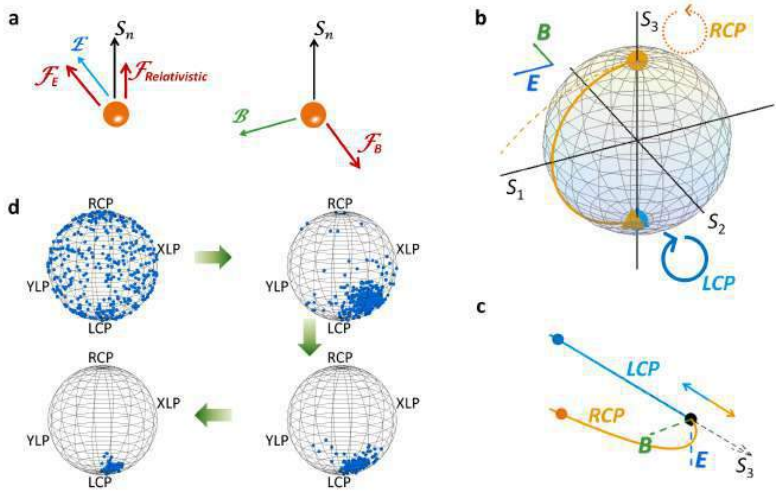

Figure 1. (a) Effective Lorentz force on the SOPs on the Poincaré sphere. (b,c) The analogy between (b) classical polarization evolutions in non-Hermitian optical potentials at the exceptional point, and (c) relativistic particle dynamics driven by E×B drift at $|E| = |B|$. (d) Polarization black hole dynamics to the singularity at the exceptional point in the polarization domain.

To implement the |E| = |B| Lorentz force exerted on the SOP, artificial material realization is necessary to achieve the desired anisotropic complex parameters. Figure 2a,b represents the criteria for the metamaterial design [5], deriving the strong chiral conversion which corresponds to the collective flow of particles by the E×B drift at $|E| = |B|$. In the talk, we will also discuss the singularity at the linear polarization, having the directionality from optical chirality.

Abstract-We predict the self-collimation phenomena (or equivalently, dynamical localization) in 2-dimensional P-symmetric and PT-symmetric complex potentials, with periodic modulations of both gain/loss and refractive index. Non diffractive propagation is analytically predicted and further confirmed by numerical integration of a paraxial model. The parameter space is explored to identify the self-collimation regime in crystals with different complex symmetries.

Artificial structured materials provide the ability to tailor the diffraction of propagating beams leading to the self-collimation phenomena (quantum mechanical analog of the dynamical localization, occurring in modulated lattices); and effect accounted by the appearance of flat segments in the dispersion curves of propagating modes. First predicted in Photonic Crystals (PhCs)1,2,3, the effect was latter shown that also Gain and Loss Materials (GLM) modulated in the wavelength scale 4,5. However, is both cases, either due to the unavoidable presence of losses in PhCs or to the anisotropy of gain in GLM, the absence of diffraction is generally accompanied by diffusive broadening. Yet complex materials allow the independent management of diffraction and diffusion of light beams, by independently modulating refractive index and gain/loss, representing therefore an ideal platform for beam tailoring.

In the present work we demonstrate self-collimation in 2-dimensional (2D) Parity (P) symmetric and Parity Time (PT) symmetric complex crystals (where index and gain/loss modulations are either in phase/counter-phase or de-phased a quarter of the wavelength of the modulation7). In this later case, we consider PT-symmetry eitherthe transverse (or longitudinal) direction and simultaneously in both transverse and longitudinal directions, see Fig.1.

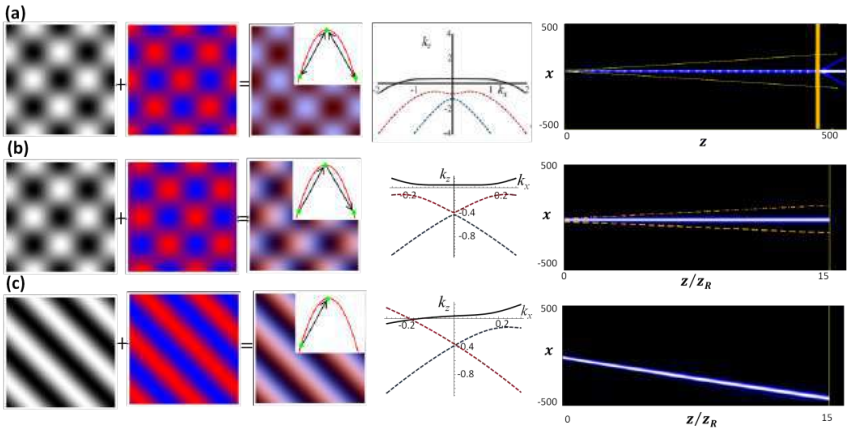

Figure 1. *Self-collimation in 2D complex crystals. The first/second rows display a schematic representation of the real/imaginary modulations of the optical potential, and the third merges both modulations where the inset indicates the coupling provided by the reciprocal lattice vectors — symmetric in (a) and asymmetric in (b) and*

(c)—. The forth row depicts the dispersion for the specific geometries and modulations amplitudes supporting self-collimation and the firth shows the corresponding numerical simulation of non diffractive light beam propagation within the corresponding crystal: (a) P-symmetric 2D lattice; (b) PT-symmetric lattice in the transverse, x, direction, while P-symmetric in z; (c) PT-symmetric lattice both in x and z. The yellow curves in the fifth row of a) and b) denote propagation of the considered beam in an homogeneous medium and are displayed for comparison.

The characteristics required for the suppression of diffraction, specific geometries and relative amplitudes of the gain/loss and index modulations, are analytically explored by a coupled mode analysis (some examples of flat dispersion bands supported for specific complex lattices are displayed in the third column of Fig.1, forth column)

For the case of P-symmetric complex crystals we find regimes of simultaneous suppression of diffusion and diffraction, self-collimated narrow light beams propagate without any distortion while being amplified, see Fig. 1a (since the amplitude of the beam is amplified, is here depicted renormalized at each propagation step). Besides, self-collimation is found either for collinear and non-collinear propagation in such complex crystals.

PT-symmetric lattices also offer the possibility to suppress diffraction. We analytically explore the characteristics of the spatial modulations required for the suppression of diffraction, for situations ranging from the pure PhC limit (system displaying real eigenvalues as for Figs. 1b,1c) to the pure GLM limit, that is to say, at either sides of the PT-transition exceptional point. Non-diffractive beams in GLM-like systems always experience self-broadening due to intrinsic diffusion. We analytically determine the self-collimation regimes for PT-symmetry in the transverse (Fig. 1b), longitudinal (found to be almost equivalent to the transverse one, except for the symmetric /asymmetric energy distribution among modes) and simultaneously in both directions (Fig. 1c). The analytical predictions are further confirmed by numerical simulations performed in paraxial approximation, finding a good agreement (see the last column of Fig. 1).

Finally, we analyze the beam dynamics in such regimes, in particular how the PT-symmetric potentials determine the energy distribution between spatial modes of the self-collimated beams either by the symmetric and or the asymmetric mode coupling. We show how complex lattices open the way to control the energy distribution among spatial modes. The predicted self-collimation effect in complex lattices may be useful to shape the beam profile in integrated optics or optical devices.

Invisibility on Demand

Z.Hayran[1], R.Herrero[2], M. Botey[2], H. Kurt[1], and K.Staliunas[2,3*]

[1] Nanophotonics Research Laboratory, TOBB University of Economics and Technology, Ankara, Turkey

Abstract- We propose a universal integral relation (a generalized Hilbert transform) relating the real and imaginary parts of the complex permittivity function of an object, which can provide invisibility with respect to particular range of directions, and for particular frequency ranges, i.e. on a specific demand. We demonstrate such invisibility by finite-difference-time-domain numerical calculations.

The Kramers-Kronig relation (or more generally the Hilbert transform) in spectrum is related to causality in time. Yet temporal causality implies "invisibility of the future". Analogously, the spatial Kramers-Kronig relation in space [1] can be related with unidirectional invisibility (disappearance of reflections) for waves propagating from a particular direction, either from the left or from the right.

We derive a general procedure to generate the invisibility on demand in two- or three dimensional space, i.e. we propose the modification of the complex permittivity or equivalently the complex refractive index in such a way, that it prevents the scattering of waves (wave reflections) in particular directions ranges and in particular frequency ranges. Such invisibility on demand is respectively less demanding than the conventional Kramers-Kronig relation providing a full unidirectional invisibility.

The procedure, shortly speaking, is the following: starting from the demanded invisibility area in wavenumber domain, and $\theta(\mathbf{k})$ (where $\mathbf{k}$ is a vector in the two-dimensional space $\mathbf{k}=(k_x,k_y)$) one generates its Fourier image $\theta(\mathbf{r})$ which serves as a kernel for a generalized Hilbert transform for complex refraction index: $n_1(\mathbf{r})=n_0(\mathbf{r})-\int n_0(\mathbf{r}_1)\theta(\mathbf{r}-\mathbf{r}_1)d\mathbf{r}_1$. This integral relation (generalized Hilbert transform) allows to modify the refraction index profile of the object from $n_0(\mathbf{r})$ to $n_1(\mathbf{r})$, and the object thus becomes invisible for reflections with respect to the demanded invisibility function $\theta(\mathbf{k})$.

The specific details of the generalized Hilbert transform will be provided [2]. Here we just present finite-difference-time-domain numerical simulations which prove correctness of such transform. Fig.1. shows a complex object (a figure of glass, described by a given real valued refraction index profile), which is visible for reflections, as it scatters incident waves generated at a point source (see Fig.1.a). However when the refraction index is modified according to the above proposed generalized Hilbert transform, the reflections vanish in a particular range of directions (see Fig.2.b), while reflections to other directions remain unaffected (see Fig.1.c).

The proposed transform allows to build the objects with given invisibility geometry from the very beginning, or alternatively to modify the refraction index of the given objects to create the invisibility on demand.

Moreover, it is also possible to follow an iterative procedure based on a chain of generalized Hilbert transforms to provide the invisibility on demand under additional restrictions, for instance restricting allowed

refraction index ranges. In particular it is possible to build the invisible object under the restriction that the refraction index of modified object everywhere remains in a "normal" range $n_{Re}(\mathbf{r})>1$, and that the imaginary parts of the refraction index remains everywhere positive $n_{Im}(\mathbf{r})>0$ (i.e. contains only losses, and no gain).

In the presentation we will provide different cases with invisibility shapes resulting in analytic forms of invisibility kernel; with invisibility shapes ensuring the minimum "expenses" of embedding to achieve invisibility; with invisibility shapes with "smooth" boundaries. We will demonstrate the effect on different complicated objects (the Fig.1. just proves the principles of the idea on a very simple object).

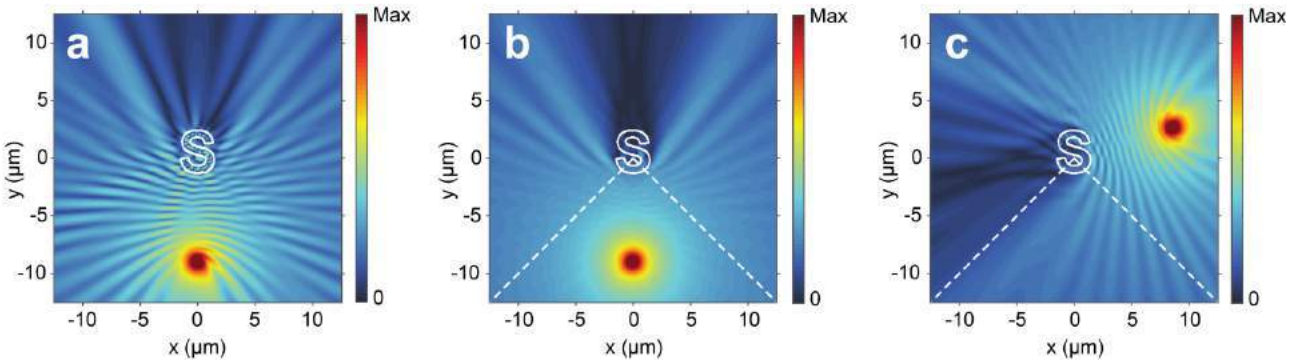

Fig.1 Invisibility on demand: a) the visible object (in this case a pieces of glass), scatters the incoming waves from point source. Back-reflections are evident from the fringed structure between the source and the object. Invisibility is created for particular reflection angles (limited by the dashed lines). b) When the source is within the invisibility area, then back-reflections vanish (since fringes disappear). c) When the source illuminates from some "wrong" angles back-reflections remain unaffected.

PT symmetry and pseudo-unitarity of nonunitrary quantum walks

Ken Mochizuki and Hideaki Obuse
Department of Applied Physics, Hokkaido University, Japan
ken_mochizuki@eng.hokudai.ac.jp, hideaki.obuse@eng.hokudai.ac.jp

Abstract-We study *PT* symmetry of the nonunitary quantum walks whose parameters depend on position and time. At first, we clarify that correlations of parameters in spatial and time directions are necessary to preserve *PT* symmetry. Then, we numerically show that the system can have entirely real spectra even when parameters of coin operators are spatially random and *PT* symmetry is broken. This implies that the system possesses pseudo-unitarity.

Recently, many interesting phenomena have been observed in PT symmetric non-Hermitian systems. However, most experimental systems have only a small number of elements, due to difficulty in controlling gain and loss effects. In contrast, quantum walks can overcome this difficulty. Quantum walks recently attract attentions as a versatile platform for quantum computations and quantum simulations. Quantum walks describe quantum dynamics of particles (walkers) with several internal states by a time-evolution operator, which is composed of coin operators, shift operators, and so on. The coin operator varies the internal states of walkers, and the shift operator changes the positions of walkers depending on the internal states. Quantum dynamics is described by acting the time-evolution operator to a quantum state at each time step.

In 2012, a quantum walk built by optical fiber loops was experimentally implemented, in which highly tunable gain and loss effects are included with additional optical amplifiers [1]. Effects of gain and loss make the time-evolution operator nonunitary, which means the effective Hamiltonian is non-Hermitian. It is known that, in certain parameter regions, the system has entirely real quasienergy.

In the present work, we explicitly show that the reality of quasienergy obtained in Ref [1] stems from *PT* symmetry [2]. We find that parameters of operators must have correlations not only in spatial direction but also in time direction in order to preserve *PT* symmetry of the time-evolution operator. Nevertheless, we numerically show that the system can have entirely real quasienergy, in the case parameters of the coin operators are random over the position space and the time-evolution operator does not hold *PT* symmetry in the explicit sense. This suggests that reality of quasienergy is guaranteed by pseudo-unitarity.

Abstract— We propose a fiber laser composed of coupled ring cavities with gain and loss, featuring parity-time transition between symmetry-broken single-mode and bistable symmetric regimes, controllable by static phase shifters without active modulation.

The concept of parity-time (PT) symmetry in optics attracts great deal of attention. Recently, a parity-time symmetry-breaking microring laser has been experimentally demonstrated [1, 2]. The latter paper considered two coupled microrings, one ring with losses and another one with gain. A single-mode operation in an initially multi-mode system was achieved through stronger mode discrimination close to a PT-symmetry breaking transition. Further on, a single transverse mode operation in a system of coupled microring lasers was demonstrated near the exceptional point [3]. In a pair of coupled microdisk quantum cascade lasers, the reversal of generated power dependence was identified in the vicinity of exceptional points [4]. Further on, a realization of the PT symmetry based mode-locking has been theoretically proposed [5], and PT fiber cavity laser was developed [6].

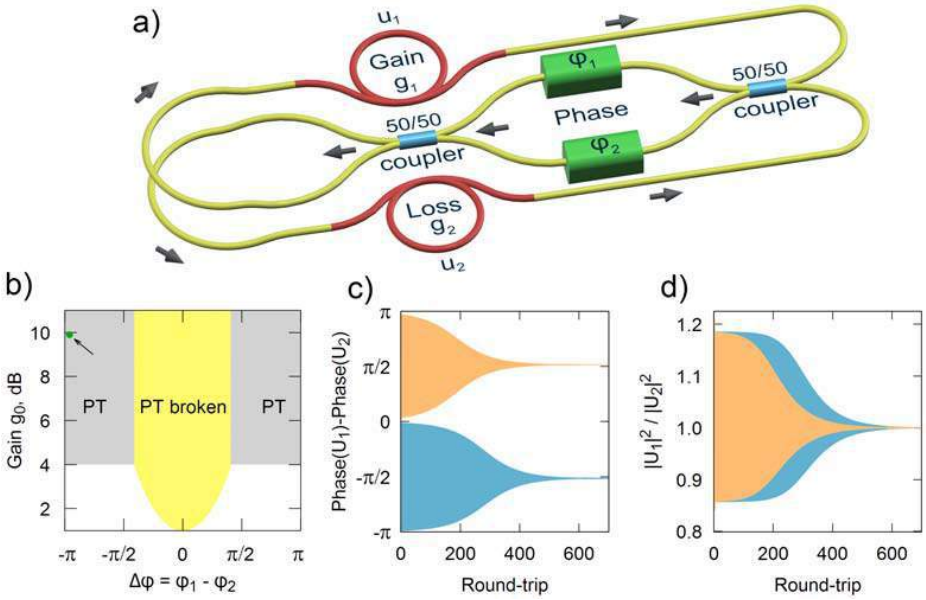

Figure 1: (a) Schematic of the PT-symmetric fiber ring, composed of two cross-coupled fiber cavities with gain and loss. (b) Parameter regions of broken and unbroken PT-symmetry, (c,d) Laser dynamics converging to one of two bistable states in PT-symmetric regime [parameters correspond to a point indicted by arrow in plot (b)] depending on the initial excitation, having (c) different phases but (d) identical intensity profiles in gain/loss regions.

In this work, we propose a design of PT-symmetric fiber ring laser. The scheme comprises two cross-coupled fiber cavities of the same length, as shown schematically in Fig. 1(a). The cavities are coupled via a set of two fiber 50:50 couplers with incorporated adjustable phase shifts (φ_1, φ_2) between them. In the case of zero phase shifts, the ring cavities are uncoupled, then the active cavity acts as a conventional ring fiber laser under appropriate pumping (operating via

Raman gain for example), while the second acts as a passive unpumped fiber cavity. We predict that by changing the phase shift difference, one can switch between PT-symmetric and PT-broken generation regimes.

To describe the system, we use the simplest discrete model governing the evolution of the field amplitudes in both fiber cavities at successive cavity round-trips. Field evolution on a cavity round-trip is modeled via multiplication by a product of matrices corresponding to the discrete cavity elements starting at the middle of gain / loss sections:

$$\mathbf{L} = \begin{pmatrix} e^{g_1/2} & 0 \\ 0 & e^{g_2/2} \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} \frac{1}{\sqrt{2}} & \frac{i}{\sqrt{2}} \\ \frac{i}{\sqrt{2}} & \frac{1}{\sqrt{2}} \end{pmatrix} \begin{pmatrix} e^{i\varphi_1} & 0 \\ 0 & e^{i\varphi_2} \end{pmatrix} \begin{pmatrix} \frac{1}{\sqrt{2}} & \frac{i}{\sqrt{2}} \\ \frac{i}{\sqrt{2}} & \frac{1}{\sqrt{2}} \end{pmatrix} \begin{pmatrix} e^{g_1/2} & 0 \\ 0 & e^{g_2/2} \end{pmatrix}, \tag{1}$$

where $g_2 < 0$ is a constant loss coefficient and $g_1 > 0$ characterizes gain.

We establish that the round-trip operator $\mathbf{L}$ possesses PT symmetry if gain and loss are balanced, $g_1 = -g_2$. The parity operator $\mathbf{P}$ swaps the two fibers, which interchanges the gain and phase coefficients: $g_1 \leftrightarrow g_2$, $\varphi_1 \leftrightarrow \varphi_2$. The time-reversal operator $\mathbf{T}$ performs complex conjugation and also swaps the propagation direction, which is expressed as $\mathbf{TL} = (\mathbf{L}^{-1})^*\mathbf{T}$. Then, it can be checked that the PT symmetry is satisfied as $\mathbf{PTL} = \mathbf{LPT}$. The optical cavity modes possess PT symmetry if the phase difference exceeds a critical value, $|\Delta\varphi| > \Delta\varphi_{PT}$, where $\exp(-g_2) = [1 + |\sin(\Delta\varphi_{PT}/2)|]\cos^{-1}(\Delta\varphi_{PT}/2)$ and $\Delta\varphi = \varphi_1 - \varphi_2$. Conversely, PT-broken modes are present for $|\Delta\varphi| < \Delta\varphi_{PT}$. It is remarkable that PT symmetry arises for a broad range of phase shifts. Importantly, cross over coupling as described by the second matrix in Eq. (1) facilitates PT symmetry with static elements, whereas active modulation was required in previous realizations of mesh lattices [7].

We model the onset of lasing by considering saturable gain as $g_1 = g_0/(1 + P_1) - g_h$, where P_1 is the normalized power at the input of the gain element at the current round-trip. The model assumes that amplifier introduces g_h loss at high power limit, whereas its amplification of weak field is $(g_0 - g_h)$. In numerical simulations, we assign $g_h = 1$ dB$=10^{-0.05}$. We find that in the PT-symmetric regime with $|\Delta\varphi| > \Delta\varphi_{PT}$ and for $g_0 - g_h + g_2 > 0$, the laser selects a stationary generation power level such that the saturated gain balances total optical losses, and condition $g_1 = -g_2$ is satisfied, see take regions marked 'PT' in Fig. 1(b). Interestingly, optical bistability appears in this regime, i.e. the laser can generate one of two stable modes. In contrast, for the phase difference below a threshold, a PT-broken regime is realized, where only single lasing mode is supported, associated with a stronger light concentration in the fiber cavity with a gain. Accordingly, such PT-broken mode has a lower lasing threshold, see a central shaded region marked 'PT broken' in Fig. 1(b).

In laser experiments, the most direct way to characterize the PT-transition is to measure generation dynamics in both active and passive fiber cavities. We show the relative phase and intensities in the middle of gain and loss sections after each round-trip in Figs. 1(c) and (d), respectively. The parameters are chosen within a PT-symmetric region, and we show the evolution for two different initial conditions with blue and green coloured lines. We observe that for all initial conditions, the intensity ratio converges to unity [Fig. 1(d)], according to PT symmetry property of the lasing mode. However, stationary modes with two different phase structures can emerge [Fig. 1(c)], which illustrates bistable laser operation.

Abstract— We theoretically study Floquet topological phases of PT symmetric non-unitary quantum walks. Especially, by considering feasibility of experiments, we focus on passive Hadamard quantum walks which have effects of only losses and whose coin operators are described by Hadamard matrices. We clarify Floquet topological phases of this quantum walk and find that after compensating the loss effect, the corrected probability corresponding to edge states exponentially increases with time due to PT symmetry breaking.

A quantum walk, that is, a synthetic quantum system mainly implemented by photonic systems, whose dynamics is described by a time-evolution operator, provides potential applications for quantum computing and information. It is further interesting that the quantum walk possesses novel topological phases akin to those of Floquet topological insulators, which are topological insulators driven by a time-periodic field[1,2]. Recently, a one-dimensional quantum walk dynamics associated with gain and loss is experimentally implemented by optical fiber loops [3]. The experiment shows that the energy of the system is kept to be real as a manifestation of PT symmetry (combined parity and time- reversal symmetry) in spite of the open quantum system. In the previous work, motivated by the above experiment, we theoretically studied Floquet topological phases driven by the PT symmetric non-unitary time evolution. We have found the presence of combined parity and chiral symmetry, in addition to PT symmetry[4]. The presence of these symmetries allows us to study Floquet topological phases in open quantum systems by using a procedure for ordinal quantum walks belonging to class BDI[5]. We have confirmed that the number of edge states originating from Floquet topological phases and topological numbers satisfy the bulk-edge correspondence, while a modification due to the imaginary energy is required due to breaking of PT symmetry.

In the present work, we extend this work to passive Hadamard quantum walks which have effects of only losses and whose coin operators are described by Hadamard matrices. This setup can be easily realized by using bulk optics. We find that, after proper treatments of the effect of losses, the fundamentally same Floquet topological phase is defined for the passive Hadamard quantum walks. We also show that, by considering the connection between the passive quantum walk and quantum walks with gain and loss, a corrected probability corresponding to edge states exponentially increases with time because only edge states break PT symmetry. This provides a way to observe effectively high probabilities originating from edge states in actual experimental setups even in quantum regime.

Abstract— A parameteric PT-coupler in which the PT-symmetry is satisfied both in transverse and longitudinal directions is presented in this summary paper. The stability of this structure resembles that of parametric amplifiers, such that the stability of the system not only depends on the gain/loss but also on the parametric parameter. This structure exhibits unique behaviour such as thresholdless lasing and stability re-emergence.

In photonics, an *ideal* PT-symmetric system translates to an optical structure with a judicious profile of complex refractive index that requires the combination of both gain and loss [1–5]. PT-symmetric photonic structures can have purely real spectra, i.e. zero net-power amplification or dissipation, despite having both gain and loss in the system. However, there exists an exceptional point defined by certain system parameters for which the PT-system undergoes a spontaneous PT-symmetry breaking. Above this point the eigenfrequencies become complex and power grows exponentially. In [1–5], we have studied the spectral properties and the dynamics of various PT-symmetric structures, and also demonstrated interesting properties of PT-photonic structures such as loss-induced invisibility and laser generation that effectively reverses the effect of loss at threshold [1–5].

In the context of PT-waveguide structures, most of the studies on PT-symmetry have been limited to systems in one-dimension, in which the PT-symmetry is satisfied either transversely (in a PT-waveguide array) or longitudinally (in a PT-grating). In this summary paper, we consider PT-waveguide arrays (see Fig. 1) which satisfies PT-symmetry both longitudinally and transversely, referred to as parametric PT-waveguide array.

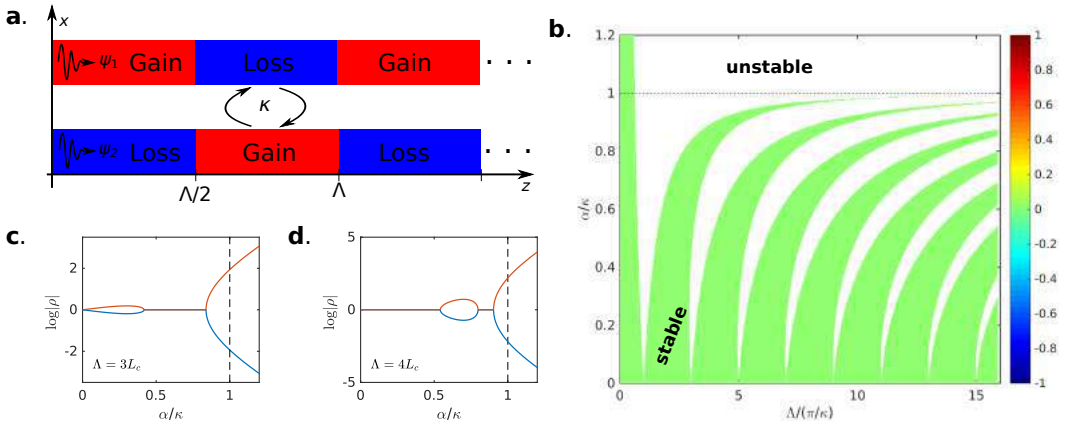

Figure 1: (a) Schematic illustration of parametric PT-coupler with gain/loss spatial modulation parameter Λ; (b) The stability criteria of the parametric PT-coupler as a function of gain/loss parameter α and Λ; (c,d) Eigenvalue ρ of the state transition matrix Φ of the parametric PT-coupler as a function of gain/loss parameter α for $\Lambda = 3L_c$ and $\Lambda = 4L_c$, where $L_c = \pi/\kappa$ denotes the coupling length of the waveguide coupler.

The parametric PT-coupler considered here is comprised of a uniform real part of refractive index with an alternating gain/loss region along the propagation direction z. Its state transition matrix, which describes the state at particular distance z for a given initial state at z_0, is given by

$$\Phi(\Lambda) = \frac{4\mathrm{e}^{j(\beta_0\Lambda+2\theta)}}{(1+\mathrm{e}^{2j\theta})^2}\begin{pmatrix} A & B \\ C & A \end{pmatrix}; \qquad \theta = \arcsin\left(\left|\frac{\alpha}{\kappa}\right|\right), \tag{1}$$

with the matrix entries being given by,

$$
\begin{aligned}
A &= \cos(\kappa\Lambda\cos\theta) + \frac{1}{2}\left(\cos(2\theta)\,!\;\;1\right), \\
B &= 2j\cos\left(\kappa\frac{\Lambda}{2}\cos\theta+\theta\right)\sin\left(\kappa\frac{\Lambda}{2}\cos\theta\right), \\
C &= 2j\cos\left(\kappa\frac{\Lambda}{2}\cos\theta\,!\;\;\theta\right)\sin\left(\kappa\frac{\Lambda}{2}\cos\theta\right).
\end{aligned}
\tag{2}
$$

In (1) and (2), β_0 denotes the phase propagation constant, α is the gain/loss parameter and κ is the coupling strength of the waveguide coupler.

The parametric PT-coupler has a stability behaviour similar to that of a parametric amplifier, as shown in Fig. 1(b), such that its stability depends not only on the gain/loss present [3] in the structure but also on the gain/loss spatial modulation Λ. There also exists a thresholdless condition at which the structure becomes unstable for an infinitesimal amount of gain/loss α. This thresholdless condition occurs on every odd-multiple of the coupling length, $\Lambda = (2n\,!\;\;1)L_c$. Furthermore, we note stability re-emergence as gain/loss increases in the system; a counter-intuitive behaviour in which stability can be attained from an unstable state by increasing gain/loss further in the system.

Abstract- The emission of light from electrons passing in proximity to periodic grating structures includes both resonant plasmonic features and Smith-Purcell collective excitations. We observe both and distinguish between them, finding surprising robustness to disorder in the Smith-Purcell radiation. We also demonstrate the emission of visible light induced by low-energy electrons (1.5 - 6 kV) from sub 60 nm pitch gratings. The experimental results compare nicely to numerical simulations.

The conventional Smith-Purcell effect [1] describes light emission by a collective excitation that is induced by a free electron when it couples through its near-field to the electromagnetic modes of a grating or a periodic structure. Advances in nanoscale fabrication techniques in recent years have created new opportunities to explore the Smith-Purcell effect in plasmonic structures and metasurfaces and new applications are possible based on the Smith-Purcell effect in modern nanophotonic structures.

Over the years, the use of free electrons has become a significant tool in studying plasmonic resonances. Localized plasmonic resonances often appear due to nanoscale disorder and roughness on metal surfaces, with surface-enhanced Raman spectroscopy being a prominent example. At the same time, the effects of disorder on collective modes in periodic structure have been widely studied through the theory of Anderson localization. However, there is no existing theory or experiment studying the effects of disorder on collective excitations of electron-photon interactions, such as the Smith-Purcell effect. Our work studies and observes physical phenomena involving localized resonances and effects of disorder co-existing with collective excitations in the coupling of free electrons with modes of light [2]. While these phenomena usually appear in completely different settings, they can occur simultaneously given the proper nanophotonic structure and the proper experimental setup.

The experimental setup is comprised of a conventional scanning electron microscope (SEM) with the sample mounted almost parallel to the electron beam. A microscope objective is placed on the SEM stage to collect and image the light emission from the surface. The light collected by the objective passes through a viewport and is sent through a series of free space optics that includes a beam splitter, allowing simultaneous measurement of the spectrum and imaging of the spatial emission pattern. The SEM is operated in spot mode, which we control precisely to align the beam so that it passes near to the surface in the desired area of the sample. The spectral

signature contains multiple mechanisms of emitted radiation – the collective effect of conventional Smith-Purcell radiation, the localized plasmonic resonance (if present) and potentially background cathodoluminescence. These signals are separated and analyzed and compared to theory.

Such periodic systems can be used as light sources that are completely tunable by changing the electron velocity. The possibility of observing shorter wavelength emission from relatively low-energy electrons (accessible with regular scanning or transmission electron microscopes, SEM or TEM) is a promising field of research, because of the numerous applications [3].

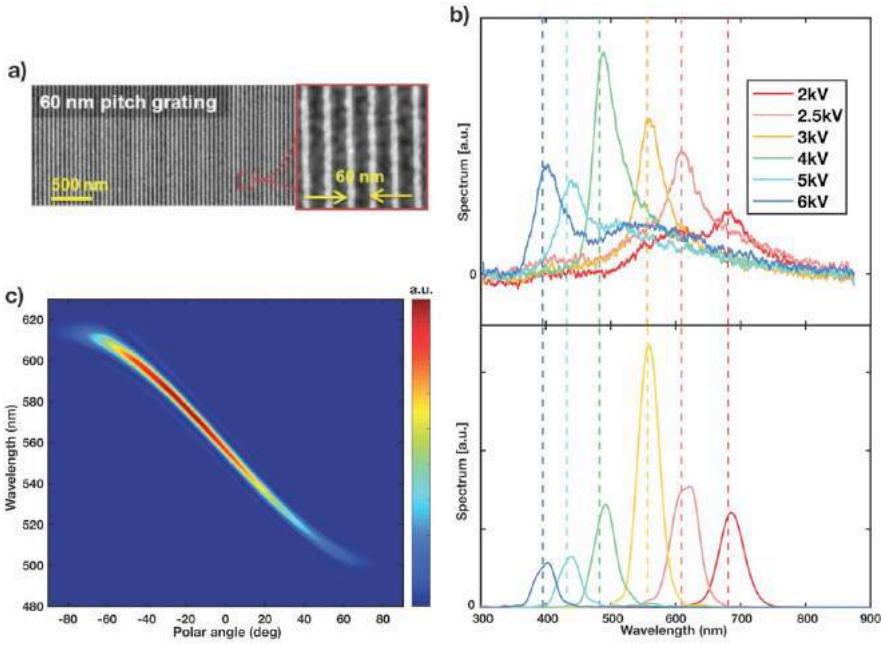

Figure 1. Measured and simulated radiation patterns. (a) SEM images of 60 nm pitch gratings. (b) Upper plot: measured spectra for different kinetic energies. Lower plot: time-domain far-field distribution computed with N = 20 unit cells and integration over an angle corresponding to the numerical aperture of the objective used in our experiment. The dashed vertical lines are calculated according to the conventional Smith-Purcell theory at normal emission, with the color corresponding to the same kinetic energies. (c) Simulation of the angular distribution for a kinetic energy of 3 keV and a grating of N = 100 unit cells. The polar angle is measured from the direction normal to the beam propagation. At each angle, we verify the wavelength radiated with maximum intensity corresponding to the theoretical prediction.

Abstract- We discuss single-sided diffraction gratings and waveguide isolators based on exceptional-point optical structures.

Synthetic optical materials having a carefully structured complex refractive index distribution, following non-Hermitian Hamiltonian analogs, have attracted significant attention because of their non-orthogonal eigensystems. Such materials enable functions such as uni-directionality, non-reciprocity, and unconventional beam dynamics. In this paper, we discuss non-Hermitian diffraction gratings formed by optical pumping, in a method offering control of the real and imaginary parts of the complex refractive index distribution defining the grating. The grating was formed by vector-field holographic interference of two elliptically polarized pump beams incident on an azobenzene-doped polymer film. We experimentally observed single-sided grating diffraction, whereby the negative diffraction order is significantly suppressed (by almost 3 orders of magnitude) relative to the positive diffraction order due to operation of the grating at an exceptional point [1].

We also show that interactions based on encircling-an-exceptional-point, which are reciprocal in the linear regime, may become nonreciprocal in the nonlinear regime over a very broad optical bandwidth (limited mainly by the bandwidth of the nonlinearity). We describe a coupled-waveguide structure that supports an encircling-an-exceptional-point parametric evolution based on a gain saturation nonlinearity [2]. The structure is capable of low-loss nonreciprocal optical transmission with an isolation greater than 10 dB over an optical bandwidth approaching 100 THz. We describe progress on the experimental realization of the proposed concept, aiming towards an integrated on-chip optical isolator.

Stable transport with nonlinear PT-broken active couplers

Sergej Flach
Center for Theoretical Physics of Complex Systems
Institute for Basic Science, Daejeon, South Korea
sflach@ibs.re.kr

Abstract

I will discuss two examples of nonlinear PT-broken active couplers. First, I consider light propagation through a pair of nonlinear optical waveguides with absorption, placed in a medium with power gain. The active medium boosts the in-phase component of the overlapping evanescent fields of the guides, while the nonlinearity of the guides couples it to the damped out-of-phase component creating a feedback loop. As a result, the structure exhibits stable stationary and oscillatory regimes in a wide range of gain-loss ratios. I show that the pair of actively coupled (AC) waveguides can act as a stationary or integrate-and-fire comparator sensitive to tiny differences in their input powers [1].

This first example is in sharp contrast to nonlinear active couplers with PT symmetry, which are known to display unstable dynamics [2]. To explore the degree of symmetry breaking needed to achieve stable propagation, I consider a slightly PT-broken system [3]. This asymmetric active coupler (AAC) consists of two coupled dissimilar waveguides with gain and loss. I show that under generic conditions, not restricted by parity-time symmetry, there exist finite-power, constant-intensity nonlinear supermodes (NS), resulting from the balance between gain, loss, nonlinearity, coupling and dissimilarity. The system is shown to possess non-reciprocal dynamics enabling directed power transport functionality and stability with respect to modulations [4].

PT systems with time-delayed gain and loss

Y.N. Joglekar[1]

[1]*Indiana University Purdue University Indianapolis (IUPUI), Indianapolis, USA*
E-mail: yojoglek@iupui.edu

In recent years, Floquet PT-symmetric systems, with time-periodic Hermitian or non-Hermitian parts, have become a topic of increasing interest. This interest is driven by their rich PT phase diagram and ability to induce PT transitions in the presence of minimal gain-loss strength. However, in all cases, the system of interest – classical or quantum – is described by a local (instantaneous) Hamiltonian.
In this talk, I will introduce the concept of PT systems with time-delayed gain and loss, where the non-Hermitian, balanced gain and loss terms depend *not on the fields at that time, but on fields at an earlier time.* Formally, such a system is described by delayed differential equations (DDE) that are commonplace in population biology and lasers with feedback. I will show that a PT system with time-delayed gain and loss undergoes transitions from a stable, off state to an unstable state that is similar to the PT broken phase, and present a theoretical phase diagram that results from analysis of DDEs with complex coefficients. I will then show that, under appropriate conditions, such a system is realized in two coupled semiconductor lasers, and that the experimental results show the signatures of these transitions.

This is joint work with Prof. Vemuri's group at IUPUI (NSF grant DMR-1054020).

Experimental realization of the manipulation of exceptional points using magnetic fields

Xu-Lin Zhang[1], **C. T. Chan**[1*]

[1] Department of Physics and Institute for Advanced Study, The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China

[*]corresponding author: phchan@ust.hk

Abstract- We study a pair of coupled ferromagnetic waveguides under an external magnetic field. We find this two-state non-Hermitian system has an exceptional point and a subsequent symmetry recovery due to the presence of accidental degeneracy points when the system has no loss. Experimental measurements on the transmission spectra and field distributions clearly demonstrate the presence of the exceptional point and symmetry recovery.

Non-Hermitian systems with parity-time (PT) symmetric complex potentials undergo a transition at an exceptional point when the degree of non-Hermiticity is increased. Such PT-symmetric systems have drawn a lot of attentions recently [1,2]. It is commonly believed that a two-state PT-symmetric system has only one exceptional point beyond which the eigenvalues become complex and eigenmodes are PT-symmetry broken. The so-called "symmetry recovery" (i.e. the eigenvalues become real again and eigenmodes become PT-symmetric again after the system parameters extend beyond the exceptional point) will not occur for a two-state system, but it can appear in multi-state systems (say three or four-state systems) [3,4].

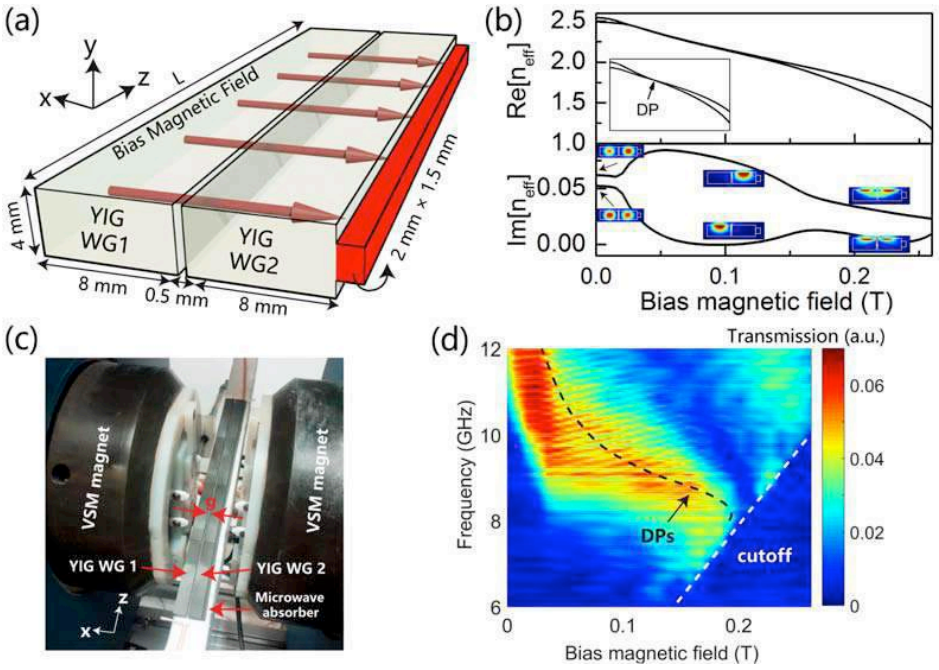

Figure 1 (a) Schematic of a passive coupled YIG waveguide system with microwave absorbers attached to the side of one waveguide. (b) Calculated real part and imaginary part of the effective mode index as a function of the bias field. (c) Experimental setup. (d) Measured transmission spectra under different bias magnetic fields.

Here, we show theoretically that a two-state non-Hermitian system can have symmetry recovery and we performed an experiment to demonstrate for the first time that such phenomena can be realized and observed in a system consisting of a pair of coupled ferromagnetic waveguides under an external magnetic field (see Fig. 1(a)). We show theoretically that the symmetry recovery is made possible by the presence of accidental degeneracy points in the Hamiltonian governing the waveguide system if it is lossless, and each degeneracy point must break up into one pair of exceptional points when loss is introduced and such a process will ensure that the system can have symmetry recovery even though it has only two internal degrees of freedom (see Fig. 1(b)). We performed microwave experiments to verify the theoretical design. The experimental set up is shown in Fig. 1(c), where a pair of yttrium iron garnet (YIG) dielectric waveguides are placed inside a vibrating sample magnetometer. We measured the transmission spectra under different bias fields and found that the transmission was enhanced at specific bias fields for different frequencies due to the presence of broken phase regions (see Fig. 1(d)).

The tuning process in this work is both adiabatic and continuous. As a result, our system serves as a good candidate to be further employed to tune system parameters to encircle an exceptional point to manifest the topological properties unique to PT-symmetric systems.

Abstract. This talk will describe how to construct novel microscale laser devices by parity-time symmetry in a non-Hermitian micro-ring cavity system.

Parity-time (PT) symmetric systems have attracted increasing attention over the past few decades for its rich physics and applications. PT symmetry was originally developed in the framework of quantum mechanics to characterize non-Hermitian systems with real eigenspectra. In optics, a system with can be considered as an analogue of a PT symmetric system in quantum mechanics. These PT symmetric optical systems exhibit numerous exotic features and functionalities, such as unidirectional invisibility, loss-induced transparency, coherent perfect absorption and lasing, and nonreciprocal light transmission. Very recently, PT symmetry has been introduced in microscale lasers as a powerful tool of mode manipulation. In a PT symmetric system, there are three phases, i.e. PT symmetric phase, exceptional point and PT symmetry broken phase. In the PT symmetric phase, the coupled modes in the system experience a balanced gain and loss, and thus no lasing can be observed. The transition from the PT symmetric phase to PT symmetry broken phase must experience a singular point, named the exceptional point at which not only eigenvalues but also the eigenstates coalesce. Novel vortex lasers that can directly emit optical beams carrying orbital angular momentum of light has been proposed based on exceptional points [1]. At the PT symmetry broken phase, the coupled modes in the system share the same eigenfrequency, but possess conjugate modal gain/loss coefficients. This phase has been utilized to make single mode microscale lasers [2].

Abstract- The concept of parity-time symmetry has inspired new switch architectures. Here, we explore a 2x2 cross/bar switch architecture that mostly works by redistributing the longitudinal gain along one of the waveguides, which then features either gain in its center or at its edges. The other guide can then be of purely loss type, as occurs in plasmonic or hybrid waveguides. The advantage is to work with more stable space- and time-averaged parameters than previous parity-time symmetric designs.

The design of new devices in optics has recently taken advantage of the parity-time symmetric concept. By implementing gain and losses in adequate fashion onto a pair of coupled waveguides, the two basic "cross" and "bar" states of a 2x2 switch can be realized [1-3].

The advantages of using gain instead of real-index modulation are clear when material such as glass or metals (in plasmonics) are used as the basis of waveguiding [1-3], with adequate care to take into account realistic parameters of real cases [4, 5]. The physics of PT-symmetry (parity-time symmetry) indicates the combination of gain, loss and coupling parameters that ensures an operation close to a conservative condition (conserved power for signals).

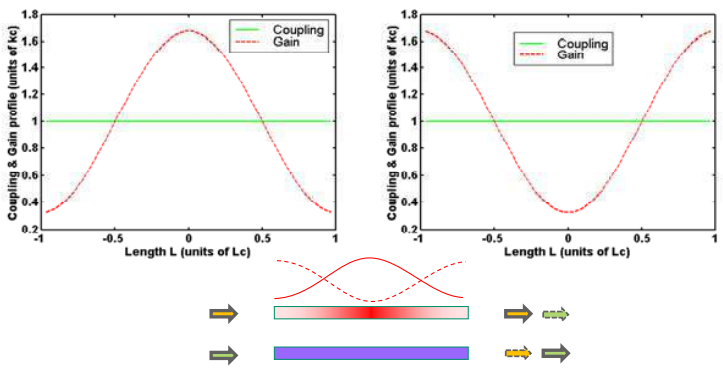

Fig.1: Two different longitudinal distribution of gain in a variant of a PT symmetric device of two coupled waveguide. The bottom scheme illustrates the two distributions and the targeted 2x2 cross/bar switching result.

Another practical quantity whose “conservation” can be interesting is the gain itself. Switching the gain entails heat dissipation and a number of inhomogeneous effects and related engineering issues that can eventually plague a device and incur severe penalties to its implementation. So it is tempting to think of switching by modifying a spatial gain distribution with a constant integral of the gain rather than switching the whole gain on or off in waveguide branches.

We will propose such a device, based on a variable cosine or anti-cosine repartition as pictured in Fig.1, whereby the gain is gently variable between a weak value and a maximum value. The overall gain is the same, but due to the longitudinal distribution change, the result will be shown to be reasonably close to the expected target. Here the other guide is purely lossy and does not undergo any tuning.

More characteristics will be studied to assess the perspectives of the proposed design approach.

Abstract— Low-symmetry photonic elements with most symmetries broken but other spatial-temporal symmetries maintained could support exceptional points separating different interesting phases, such as PT-exact and PT-broken phases. Periodic arrays of these units may also support different classifications of topological bands, where the local symmetries in unit cell including material permittivity and permeability tensors play crucial roles. In recent years, it has been found that magneto-photonic crystals can form interesting one-way bands and topological edge modes, which could be used to design compact (Lorentz) non-reciprocal devices such as one-way waveguides and optical isolators. These photonic systems require the breaking of many spatial-temporal symmetries in addition to pure spatial and temporal symmetries. Meanwhile, some other spatial-temporal symmetries can be kept to support exceptional points and different phases similar to PT phases. We aims to understand the scattering and transmission properties associated with these topological photonic bands and edge states. In this talk, we discuss our recent findings on anomalous transmission associated with topological edge modes in Lorentz non-reciprocal and non-Hermitian systems with different spatial-temporal symmetries maintained. Arrays of plasmonic, gyroelectric and gyromagnetic resonators will be used to illustrate the roles of various symmetries including Lorentz reciprocity, time-reversal symmetries, and other spatial-temporal symmetries on these effects.

Abstract-We demonstrate that adiabatic closed-loop operations on a system of damped oscillators can be used to achieve topological control and nonreciprocity.

In classical mechanics the time evolution of N coupled harmonic oscillators may be described by an $N\times N$ Hamiltonian matrix **H**. For undamped oscillators, **H** is Hermitian and has N pairs of real eigenvalues $\{\pm\omega_1, \pm\omega_2, ..., \pm\omega_N\}$ (corresponding to the normal frequencies) and N distinct orthogonal eigenvectors (corresponding to the normal modes). If **H** depends on a set of parameters λ_j which define a space V, then the ω_i are distinct except in isolated subsets of V. Even when degeneracies are present, the eigenvalue "surfaces" (i.e., the ω_i viewed as functions of the λ_j) can be represented by holomorphic functions of the λ_j.[1] These surfaces may be ordered unambiguously throughout V.[1] A smooth path defined by smoothly varying the λ_j will remain on a single surface, provided that it avoids the degeneracies. As a consequence, a closed-loop variation of the λ_j (that avoids degeneracies) will result in a path that remains on a single eigenvalue surface and returns to its starting point.

The situation is substantially different with damped oscillators, for which **H** is non-Hermitian. A system of N damped oscillators possesses N pairs of complex eigenvalues (i.e., ω_1 and $-\omega_1$*, etc.) and $2N$ distinct eigenvectors (which are not in general orthogonal).[2] Degeneracies among the ω_i still occur only for isolated subsets of V, but these degeneracies may be qualitatively different from those of undamped systems. For example, such a system may possess degeneracies (known as "exceptional points" or EPs) at which **H** cannot be diagonalized. In the vicinity of an EP the eigenvalue surfaces are represented by a Puiseux series in the λ_j. As a result the surfaces cannot be ordered unambiguously in a domain of V that contains an EP.[1] A smooth path (even one that avoids all degeneracies) need not remain on a single surface, and a closed-loop variation of the λ_j will not in general return to its starting point on the eigenvalue surfaces.

These features have important consequences for the dynamics of systems of oscillators. It was pointed out in Ref.[3] that if a system of damped coupled oscillators is prepared in one of its normal modes and then **H** is varied slowly in a loop that encloses an EP, the system will be in a different normal mode at the end of the loop. It was later pointed out that this is only true for choices of the initial normal mode and control loop that ensure that the system is in its least-damped mode for the majority of the operation; otherwise non-adiabatic effects will prevent the system from following a smooth path through the eigenvalue surfaces (regardless of how slow the control loop may be).[4,5] Thus, closed-loop operations may be used to achieve topological control *and* nonreciprocal dynamics in systems of damped oscillators.

We have demonstrated the topological control and nonreciprocal dynamics discussed in Refs.[3,4,5] by using two vibrational modes of a SiN membrane as the damped oscillators.[6] The membrane is placed in an optical cavity, and we use the optical spring effect to vary the oscillators' **H** and to carry out the loop operations. Figs.

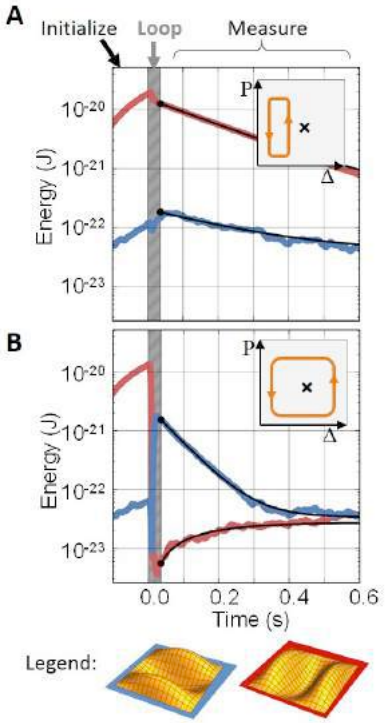

Figure 1. Amplitudes of the two modes (shown in the legend) as a function of time. Each inset shows a cartoon of the control loop in the Δ–*P* plane ("×" indicates the EP).

1(a)&(b) show typical measurements. In each case, one mode is initially driven to a large amplitude. At time t = 0 ms the drive is switched off and the control loop is executed by varying the detuning Δ and power P of a laser incident on the cavity. The control loop finishes at t = 40 ms. After the control loop is complete, the amplitude of each mode is fit (black lines) to determine the mode's energy just after the loop is complete (black dot). In Fig. 1(a) the loop does not enclose the EP, and the energy remaining after the loop is predominantly in the mode that was initially driven. In Fig. 1(b) the loop encloses the EP, and the energy remaining after the loop is predominantly in the mode that was not initially driven.

Fig. 2 shows the transfer efficiency E, defined as the fraction of the energy (after the loop) in the mode that was not initially driven. E is plotted as a function of the loop shape; in Fig. 2(a) the maximum value of Δ is varied, while in Fig. 2(a) the maximum value of P is varied. Loops that remain far from the EP without encircling it show $E \approx 0$, while loops that remain far from the EP and encircle it show $E \approx 1$. Loops passing close to the EP are less likely to result in quasi-adiabatic behavior and show intermediate values of E.

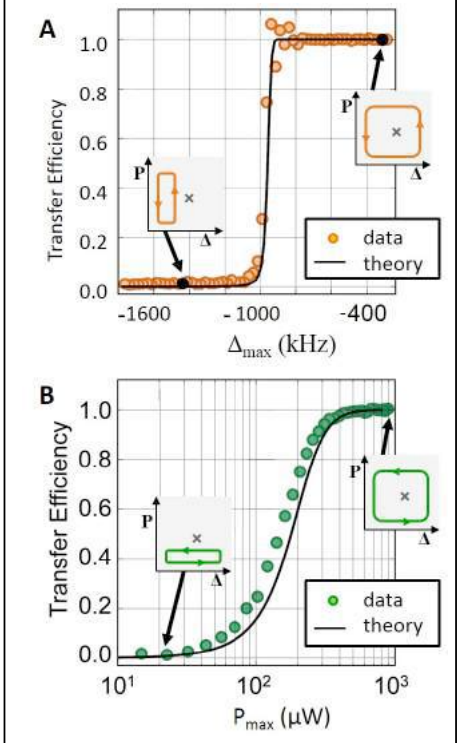

Figure 2. Dependence of the transfer efficiency E upon the control loop's shape.

Abstract- Tailoring the beam propagation is crucial in nonlinear optics. Here we will demonstrate a nonlinear meta-lens that works in a nonlinear way by simultaneously converting the collected light in a second harmonic wave while performing an imaging of the object. We demonstrate the concept by imaging fundamental beams in the infrared wavelength region into a second harmonic image.

We design and experimentally investigate a plasmonic metasurface, which can work as a lens for nonlinear imaging with simultaneous frequency conversion for the incident near-infrared light. With our approach, we take advantage of the Pancharatnam-Berry phase [1,2] in the nonlinear regime originating from the arrangement of meta-atoms with threefold rotational geometry [3]. Due to the strong light-matter interaction of the plasmonic antennas, the nonlinear metalenses have only a thickness of 30 nm. Based on the design concept the nonlinear metalens shows different operation modes, which depend on the spin angular momentum of light. By using a particular circular polarization state, the nonlinear lens can either work as a focusing or defocusing lens while simultaneously converting the illumination light to SHG light. At the same time, no imaging effect will appear for the fundamental wavelength. We investigate the beam propagation of our nonlinear metalenses and determine the evolution of the real and virtual focal planes for illumination with Gaussian beams. To underline the strength and the design flexibility we fabricated and analyzed different types of more complex nonlinear devices featured by different focusing abilities. In addition to that, we present intriguing spin angular momentum depending nonlinear imaging abilities giving rise to real and virtual SHG images of real objects as well as nonlinear Fourier transformations. The images are thereby generated at visible wavelength, which enables this device for revealing new avenues in integrated nano-optoelectronics, quantum communication technologies or other future device applications. Such nonlinear metalenses feature a symbiotic relationship between generation and modulation of frequency conversion within an ultrathin element.

Abstract-We proposed a plasmonic modulator design with a graphene covered groove-structured metasurface, which show excellent modulation performance on plamsonic waves. For comparison, several types of graphene-based modulators on dielectric waveguides, planar and wedge surface plasmons are theoretically investigated in detail. The results indicate great advantage of our proposed design and promise potential applications in compact optical circuits.

Graphene holds a great potential to provide efficient modulation in optoelectronic integrated circuits due to its excellent tunablity in conductivity, and several types of graphene-based photonic modulators have already been demonstrated [1,2]. In this work, a plasmonic modulator was proposed based on groove-structured metasurfaces covered by a graphene, in which a transverse electrical (TE) like mode is accommodated. Our design takes the advantage of field enhancement of plasmonic mode, and meanwhile overcome the mismatch of electrical field orientations of the surface plasmon polaritons (SPPs) and that required by graphene conductivity [3]. Therefore, this graphene based plasmonic modulator exhibits greatly improved modulation depth compared with the conventional SPP ones [4]. Moreover, we carried out detailed comparative investigations on different types of graphene modulated waveguides system including Si waveguide, planar SPPs, wedge SPPs. Our results show that this proposed groove-structured metasurface design holds significant advantages in modulation depth (see Fig. 1). Moreover, the theoretical results also show this modulator has a broadband property with acceptable insertion loss, indicating possible applications in nanophotonic integrations.

Abstract- In this work, we study the multimodes and their hybridization in several plasmonic nanostructures. First, we present multimodes in a plasmonic nanowire and the applications on plasmonic circuits. Second, we show the multiple hybrid polariton bands in organic-dye-doped plasmonic nanostructures. Third, we explore hybrid strong coupling between multiple photonic modes and excitons in an organic-dyeattached photonic quasicrystal. Our investigations may inspire related studies on hybrid light-matter interactions, and achieve potential applications on multimode polariton lasers and optical spectroscopy.

With the capabilities of confining light into subwavelength volumes, plasmonics has attracted much attention, due to both fundamental interests and practical applications. Here we provide several examples to show the multimodes and their hybridization in the plasmonic nanostructures, and the related applications are also discussed.

Firstly, we demonstrate that by cascading nano-corrugation gratings with different periodicities on silver nanowires atop silicon, multiple plasmonic bands are achieved in the system, and then different colors are spatially separated and chronologically released at different grating junctions [1,2]. The released light frequency depends on the grating arrangement and corrugation periodicities. Hence the nanowire acts as a spectral splitter for sorting/demultiplexing photons at different nano-scale positions with a ten-femtosecond-level interval. Such nanowires can be constructed further into compact two-dimensioanl networks or circuits. We believe that this study provides a promising approach for realizing spatiotemporal-sensitive spectral splitting and optical signal processing on nanoscales, and for general integration of nanophotonics with microelectronics.

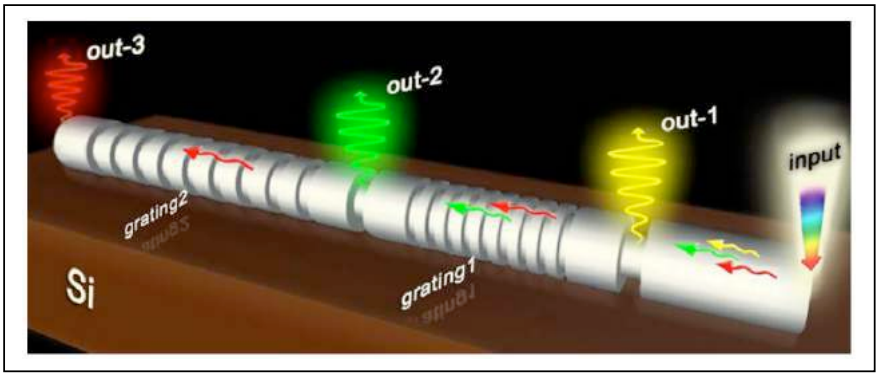

Figure 1. The principle of the wavelength division multiplexing with a plasmonic nanowire.

In the second, we present the possibilities to realize hybrid light-matter interactions, which can effectively achieve multiple hybrid polariton bands in organic-dye-doped nanostructures. We demonstrate experimentally the hybrid coupling among molecular excitons, surface plasmon polaritons (SPPs), and Fabry-Perot (FP) mode in a nanostructured cavity [3], where a J-aggregates doped PVA (polyvinyl alcohol) layer is inserted between a silver grating and a thick silver film. By tuning the thickness of the doped PVA layer, the FP cavity mode efficiently couples with the molecular excitons, forming two nearly dispersion-free modes. The dispersive SPPs interact with these two modes while increasing the incident angle, leading to the formation of three hybrid polariton bands. By retrieving the mixing fractions of the polariton band components from the measured angular reflection spectra, we find all these three bands result from the strong coupling among SPPs, FP mode, and excitons.

Thirdly, we have also experimentally explored multimode photon-exciton coupling in an organic-dye-attached photonic quasicrystal [4]. We show hybrid strong coupling between multiple photonic modes and excitons in an organic-dyeattached photonic quasicrystal. The excitons effectively interact with the photonic modes offered by the photonic quasicrystal, and multiple hybrid polariton bands are verified in both experiments and calculations. Our investigations may inspire related studies on hybrid light-matter interactions, and achieve potential applications on multimode polariton lasers and optical spectroscopy.

Abstract- We report here the plasmon-based chiroptical nanosensors for (1) discriminating the enantiomeric pair of chiral molecules; (2) quantifying enantiomeric purity of the chiral analytes; and (3) recognizing homo/heterochiral zwitterionic interactions in solutions with different pH values (Figure 1). Self-assemblies of gold nanoparticles were designed to achieve chiral or achiral nanostructures with remarkable circular dichroism (CD) responses at plasmon resonance wavelengths[1-5]. Their chiroplasmon spectral responses to chiral molecules provide a new strategy of chiral analyses, which may find important applications in bioscience and biomedicine.

Surface-assisted carrier excitation in plasmonic nanostructures

Tigran V. Shahbazyan
Department of Physics, Jackson State University, Jackson, MS 39217 USA
shahbazyan@jsums.edu

We present a quantum-mechanical model for surface-assisted plasmon decay into electron-hole pairs (Landau damping) in metal nanostructures of arbitrary shape. The surface absorbed power and scattering rate are highly sensitive to local field polarization relative to the surface. Our model can be used for efficient calculations of plasmon-induced hot carrier generation rates in photovoltaics.

Plasmon-assisted hot carrier excitation and transfer across the interfaces has recently attracted intense interest due to wide-ranging applications in photovoltaics and photochemistry [1]. In metal nanostructures with characteristic size below the diffraction limit, excitation of hot carriers is enhanced due to resonant plasmon absorption followed by plasmon decay into electron-hole pairs. In small nanostructures, the dominant decay mechanism is Landau damping facilitated by carrier scattering from the metal-dielectric interface [2].

We developed a quantum-mechanical model for surface-assisted carrier excitation by alternating electric field **E** in metal nanostructures of arbitrary geometry. We found that the power absorbed in the metal due to carrier surface scattering has the form

$$Q_s = \frac{e^2}{2\pi^2\hbar}\frac{E_F^2}{(\hbar\omega)^2}\int dS\,|E_n|^2$$

where E_n is the normal field component, E_F is the Fermi energy, and integration takes place over the metal surface. We provide simple expressions for surface enhancement factors for plasmon-assisted carrier excitation in terms of surface scattering rates γ_s, which are highly sensitive to field polarization relative to the metal-dielectric interface and can be tuned in a wide range with an appropriate choice of system geometry [3]. In Fig. 1, the surface scattering rates are plotted for nanorods and nanodiscs modeled by prolate and oblate spheroids. The rates for longitudinal and transverse modes exhibit dramatic differences in behavior with changing the system geometry.

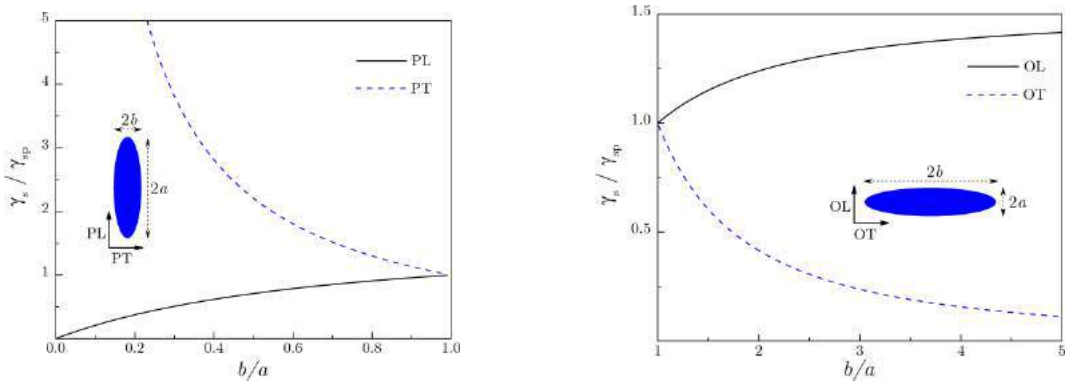

Fig. 1. Surface scattering rates for nanorods (left panel) and nanodisks (right panel) are plotted vs. aspect ratio for longitudinal (PL and OL) and transverse (PR and OR) polarizations.

Abstract-We demonstrate the nonmonotonous surface plasmom resonance (SPR) red-shift caused by resonant electron transitions and photocatalytic activity enhanced by the quantum plasmon resonance of colloidal gold nanoparticles. A maximal SPR wavelength and the largest photocatalytic activity are observed in the quantum regime for the first time for the gold nanoparticles with a diameter of 3.6 nm. Theoretical analysis based on a quantum-corrected model reveals the evolution of SPR with quantized electron transitions and well explains the observations.

The surface plasmom resonance (SPR) of metal nanoparticles is strongly influenced by their size, morphology, composition, surface chemistry, and surrounding environment. In the nanometer size regime, SPR is more sensitive to the quantum nature of conduction electrons and surface composition. A blue-shift of SPR has been observed in individual and aggregate silver nanospheres with sizes ranging from 20 nm to 2.0 nm.[1,2] This SPR blue-shift has been attributed to the quantum transitions of the conduction electrons of silver particles. Different theoretical approaches have been developed to describe the size-dependent SPR of quantum-sized metal nanostructures; different SPR shifting behaviors are revealed when the finite or infinite barriers and spill out effect are taken into account. But the understanding of quantum plasmon resonance, in particular its size-dependent energy shift in the classical-to-quantum transition regime, remains limited.

Here, colloidal Au nanoparticles have been synthesized by a hydrothermal etching technique.[3] The nanoparticle size is tuned by controlling the etching temperature. Double-reversed size-dependence of the SPR wavelength is observed in the classical and quantum size regimes at the diameter of 20.0 nm and 3.6 nm. The theoretical calculations from the quantum-corrected model reveal that the maximum SPR wavelength at 3.6 nm corresponds to the quantum limits of the SPR of colloidal Au nanoparticles, which is attributed to the competition and the collaboration of surface scattering and resonant quantum transitions of free electrons. The SPR of colloidal Au nanoparticles with diameters smaller than 2.2 nm is substantially broadened and difficult to observe owing to the strong damping by the *d* electrons and the strong individual quantum transitions of conduction electrons. Moreover, the photocatalytic activity reaches a maximum at the diameter of 3.6 nm, and there is no enhancement of reaction rate as the plasmon resonance disappears. This result indicates that the photocatalytic activity is enhanced by the quantum plasmon resonance of Au nanoparticles. These observations offer insight into the nature of the optical responses of quantum-sized Au nanoparticles and have general significance for their prospective applications in photophysics and photochemistry.

Control of Emission Photon Statistics from a Single Quantum Dot Using Plasmonic Nanostructures

S. Masuo*

Department of Applied Chemistry for Environment, Kwansei Gakuin University, Japan

*corresponding author: masuo@kwansei.ac.jp

Abstract-One of the important emission behavior of semiconductor nanocrystal quantum dots (NQDs) is the emission photon statistics, i.e., single-photon and multiphoton emission. Generally, the emission photon statistics of the NQDs are governed by the multiexciton dynamics based on the quantum confinement depending on the size, shape, and atomic composition of NQDs themselves. We demonstrated that the emission photon statistics from a single NQD could be controlled by the interaction with the plasmonic nanostructures.

The emission photon statistics, i.e., single-photon and multiphoton emission from a single semiconductor quantum dot (NQD) are one of the important emission behavior. Generally, the emission photon statistics of the NQD are governed by the multiexciton dynamics based on the quantum confinement depending on the size, shape, and atomic composition of NQDs themselves. We have recently demonstrated that the emission photon statistics from single NQDs could be controlled by the interaction with the plasmonic nanostructures.[1-7] To elucidate the possibility of the control of the photon statistics using the plasmonic nanostructure, the best way is the direct observation of the emission behavior accompanying the interaction with the plasmonic nanostructure. In this work, the enhancement of multiphoton emission from a NQD interacting with a plasmonic nanostructure was investigated using a silver-coated atomic force microscopy tip (AgTip) as the plasmonic nanostructure.[3] Using the AgTip, which exhibited a well-defined localized surface plasmon (LSP) resonance band, we controlled the spectral overlap and the distance between the single NQD and the AgTip. The emission behavior of the single NQD when approaching the AgTip at the nanometer scale was measured using off-resonance (405 nm) and resonance (465 nm) excitation of the LSP (Fig.1).

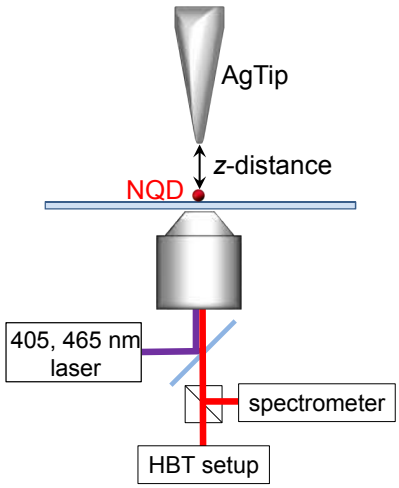

Figure 1. Schematic of the experimental setup for the observation of emission behavior of a single NQD by approaching the AgTip.

We directly observed the conversion of the single-photon emission from a single NQD to multiphoton emission with reduction of the emission lifetime at both excitation wavelengths as the NQD-AgTip distance decreased, whereas a decrease and increase in the emission intensity were observed at 405 nm and 465 nm excitation, respectively. By combining theoretical analysis and the numerical simulation of the AgTip, we deduced that the enhancement of the multiphoton emission was caused by the quenching of the single-exciton

state due to the energy transfer from the NQD to the AgTip and that the emission intensity was increased by enhancement of the excitation rate due to the electric field of the LSP on the AgTip. These results provide evidence that the photon statistics and the photon flux from the single NQD can be manipulated by the plasmonic nanostructure through control of the spectral overlap and the distance.

Towards atto-Joule efficient Electro-optic Modulators

Z. Ma[1], R. Armin[1], V. J. Sorger[1*]

[1]Department of Electrical and Computer Engineering, George Washington University, Washington, D.C. 20052, USA

[*]corresponding author: sorger@gwu.edu

Abstract- Here we report the optical and electrical concepts to achieve atto-joule per bit efficient and compact on-chip electro-optic modulators. We show that the interplay between the active material and the optical mode properties define the modulator performance. Based on physical tradeoffs, we find combinations of bias, material, and optical-mode that yield efficient phase or amplitude modulation with acceptable insertion loss. Furthermore, we show how material properties in the epsilon near zero (ENZ) regime enable reduction of device-length by 15x.

Photonic integrated circuits (PIC's) are an important enabling technology in today's communication networks and in future chip-to-chip and potentially on-chip interconnects for information processing. The development of PIC has been historically hindered by the inherently weak interaction of light and matter, which requires fundamental size (footprint), speed, and power (S^2P) limits for photonic-based information processing technologies. Among the active PIC components, the high-efficiency, low-noise sources (lasers) and detectors have seen rapid improvement in their performance in the last decade, but the third key active PIC component, light modulators, still remain far from achieving S^2P characteristics. While for a long time there has been no shortage of speculations about achieving all-optical control of signals in PIC's, in the foreseeable future the electrical control of optical signals or, in short, electro-optic (EO) conversion remains the only practical option. Efficient light–matter interaction (LMI) within the active material is key to any optical modulation and strong modulation requires active material that exhibits adequate interaction with the light [1-5]. EO modulation can be enabled by either changing the real part (n) of the modal refractive index leading to phase shifting-based interferometer-like devices termed electro-optic modulators (EOM), or by modulating the imaginary part (k) of the modal index of linear electro-absorptive modulators (EAM). In both types, the

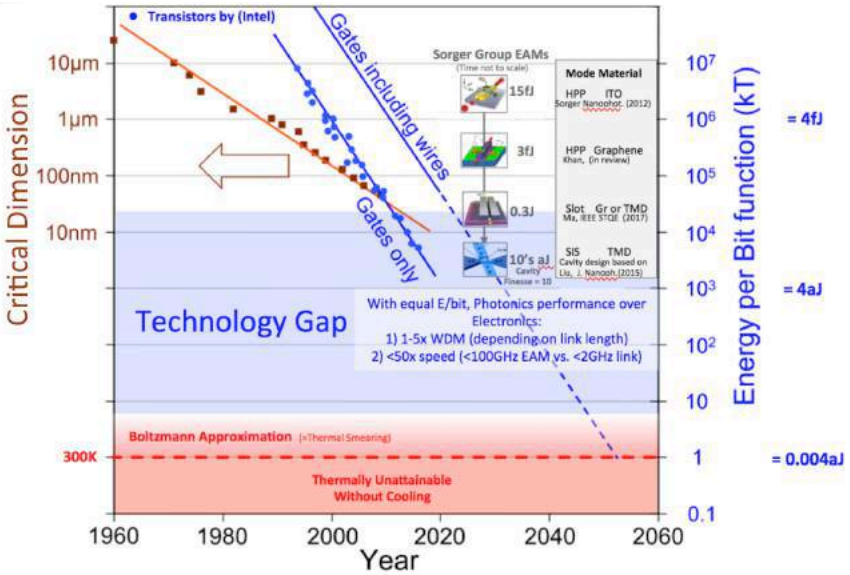

Figure 1. The other Moore's Law: Energy/bit vs. time. Optoelectronics, however, is classically limited to 10-100+ fJ/bit efficiencies, dramatically lagging electronic transistors performance. This illustratively highlights the weak light-matter-interaction. A holistic approach including material choice, optical mode, and cavity feedback enables possible sub-100aJbit EOM performance, as shown by the Sorger group.

fundamental complex index of refraction is altered electrically inside the active material, which in turn modifies the propagation constant of the mode inside the respective waveguide. Electrically driven modulators are classified by the physical mechanism responsible for the change of the complex index. One can distinguish between the current-driven and voltage-driven modulators [1-3]. In the current driven modulators, the change in index is achieved when carriers are injected in (removed from) the active region thus enabling (disabling) the optical transitions and therefore adding (subtracting) to the oscillators strength. Silicon, ITO and graphene modulators are current-driven. In contrast voltage-driven EO modulators no conductivity current flows in/out of the active region, and the change in index is engendered by the energy level shifts and oscillator strength change caused by the electric field (Stark effect), such as in lithium niobate modulators based on Pockels effect and III-V semiconductor based quantum-confined Stark effect. The performance characteristics of current-driven and voltage driven modulators are essentially similar, except that the voltage-driven devices by their nature require active regions capable of avoiding electrical breakdown at high fields which is difficult to achieve in the active regions that are only a few hundred nanometers thick. Given the present state of technology, almost all novel miniaturized modulators appeared over the last few years have been current-driven. The challenge facing EOMs is fundamental in nature; the Kramers–Kronig relations dictate that changing the real part of the complex index independent from simultaneously altering the imaginary part is impossible, unless one operates far from the resonance with any optical transition as is the case when the photon energy is deeply inside the bandgap of modulator material. Yet, both real and imaginary index changes are enhanced near the resonance and any attempt to increase the efficiency of modulation inevitably leads to the increased insertion loss [xxx]. We recently showed that the switching E/bit of EO modulators are able to approach that of electronic transistors of about 10^3-10^4 in fundamental units of k_BT **(Fig. 1)**. For a polaritonic mode, high-index changing material, and cavity enhancement (Finesse = 10), 10's to 100 aJ/bit are possible, matching our earlier optoelectronics scaling law study [4]. Such switching energy is comparable to <10nm scaled FETs is enabling since the performance improvement over electronic links using WDM and medium fast EOM drivers (10's GHz) can approach 250x, depending on link details such as length [6].

Phase Control and Nonlinear Holography in Composite 3d Metamaterials

Yehiam Prior and Euclides Almeida
Department of Chemical Physics, Weizmann Institute of Science, Rehovot 76100, Israel
*corresponding author: yehiam.prior@weizmann.ac.il

Abstract –The accurate control over the phase and amplitude response of nanoantennas, individual and in arrays, offers a wide range of opportunities for linear and nonlinear shaping of light beams. Optimization of the nonlinear response has been demonstrated, as well as generation of nonlinear holograms at the third harmonic frequency. More recently we introduced a new methodology for the fabrication of three dimensional multilayer metamaterials. Implementation of the 3D materials for phase controlled holography will be discussed, as well as composite multispectral elements such as an RGB lens which is chromatic-aberration-corrected over the visible range.

Metamaterials provide a platform for the study of light-matter interaction in the subwavelength regime, where the material properties can be tailored to give rise to exotic optical phenomena, such as negative refraction, electromagnetic cloaking and superlensing. The current generation metasurfaces rely mostly on quasi 2D structures for the control of amplitude, phase and polarization, and operate mostly in the linear regime. Here we discuss full local phase control of the nonlinear susceptibility tensor in 3D multilayer metasurfaces and show how this control can lead to functional metamaterials operating in the nonlinear regime.

Directional emission of electromagnetic radiation can be achieved from a properly shaped single antenna or from a phased array of individual antennas. Control of the individual phases within an array enables scanning or other manipulations of the emission, and it is this property of the phased arrays that makes them attractive in modern systems. Likewise, the propagation of Surface Plasmons at the interface between metal films and dielectric materials can be controlled by similar approaches. The generic situation of plasmonic surface propagation that is different on both sides of a metal film provides a unique opportunity for such control: plasmons propagating on the slower side feed into the side with the faster propagation, creating a phased array of interfering antennas, and thus controlling the directionality of the wake fields. We show that by shaping the individual nanoantennas we can generate asymmetric propagation geometry as well.

The amplitude and phase control of nonlinear signals in wave mixing experiments can be achieved by tuning the resonance of dipolar nanoantennas. By changing the geometry of these plasmonic elements, the cavity plasmonic resonances are tuned and a continuous, nearly 2π radians, relative phase among nonlinear signals can be attained. This continuous phase-span enables the fabrication of nonlinear metasurface optical elements, such as beam deflector or nonlinear lenses.

The approach for nonlinear phase control described above can be extended to other nonlinear processes and to three dimensions. Polarization dependent 3D metamaterial holograms were fabricated. When illuminated by an

infrared beam, they generate holographic images at the third-harmonic frequency in the blue. The phase information of the nonlinear susceptibility is encoded in nanometric gold antennas (this time V-shaped), fabricated by e-Beam lithography, with stamping accuracy of 10 nm between layers. Because the hologram is generated at a new frequency (the third harmonic), these multilayer metamaterial holograms are background-free and enable high density storage of optical information.

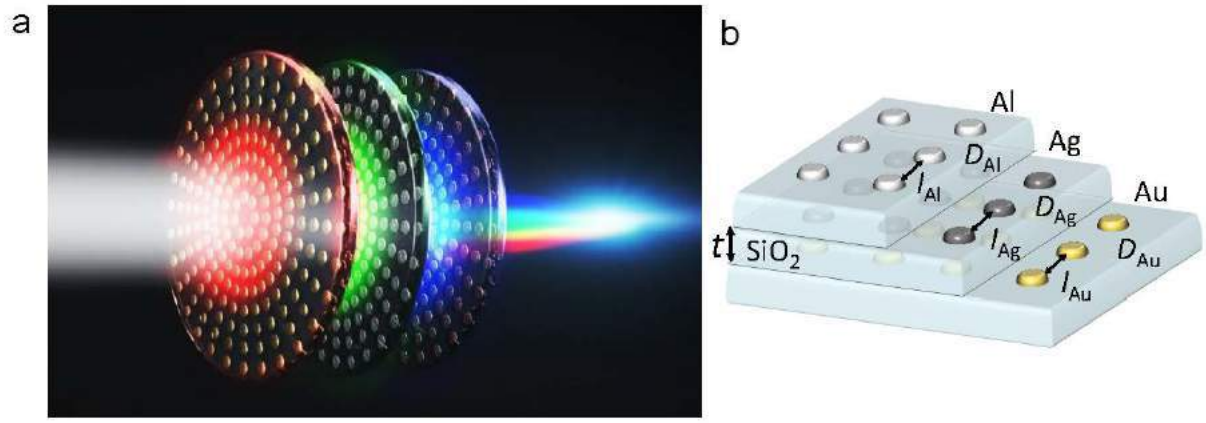

Figure 1. Multilayered RGB lens. A three layers lens, consisting of three different metals each individually designed for a specific wavelength, delivering achromatic operation over the visible range.

Last but not least, based on the ability to assemble multilayer structures, where each layer consists of different metal particles and is separately controlled, Figure 1, we fabricated functional 3D elements, including an aberration free RGB lens and STED elements where different color beams are manipulated differently by the same thin nano element.

Photonic noise in deep-subwavelength plasmonic structures with gain and fundamental limitations on data transfer rates

A. A. Vyshnevyy and D. Yu. Fedyanin*
Laboratory of Nanooptics and Plasmonics, Moscow Institute of Physics and Technology, Russian Federation
*corresponding author: dmitry.fedyanin@phystech.edu

Abstract – Surface plasmon amplification by stimulated emission of radiation gives the possibility to compensate for high ohmic losses in the metal and design virtually losses devices. However, stimulated emission is inevitably accompanied by spontaneous emission, which greatly reduces the signal-to-noise ratio and impairs the performance characteristics. Here, we present a comprehensive framework to evaluate noise in plasmonic structures with gain and present a strategy for noise reduction to a level sufficient for practical applications in high-density on-chip optical interconnects.

The main obstacle currently faced by plasmonics is strong signal attenuation due to absorption in the metal. High ohmic losses can be compensated by optical gain in an adjacent medium. At the same time, the process of stimulated emission is accompanied by spontaneous emission [1]. If the spectral linewidth of the optical signal is narrow, spontaneous emission can be filtered out. However, according to the laws of thermodynamics, signal amplification unavoidably reduces the signal-to-noise ratio. The higher the material gain, the higher the power of spontaneous emission, which goes into the plasmonic mode, and therefore the stronger the noise. In deep-subwavelength plasmonic structures, where an extremely high optical gain is needed to compensate for high ohmic losses, the spontaneous emission power can significantly exceed the signal power. This greatly affects the noise characteristics.

Here, we develop a comprehensive framework to study photonic noise produced by spontaneous emission [2]. We present our results in a ready-to-use form, which can be immediately applied with no change to different plasmonic and nanophotonic systems, such as optical amplifiers based on semiconductors, quantum dots and dye molecules. Using the developed approaches and comprehensive numerical simulations, we study the influence of spontaneous emission on the performance of truly nanoscale active plasmonic waveguides, which simultaneously provide deep-subwavelength (˜λ2/100) mode confinement and full compensation of the propagation loss (Figure 1). We find that the power of spontaneous emission at the end of the 1-mm-long waveguide exceeds 100 μW and the role of the spontaneous-spontaneous beat noise is crucial due to the relatively large bandwidth of the spontaneous emission spectrum in the semiconductor gain medium. We show that similar to the spontaneous emission power, the spontaneous-spontaneous beat noise can be suppressed using optical filtering. At the same time, the signal-spontaneous beat noise can not be affected by optical filtering, since its spectral properties are determined by the bandwidth of the photodetector [2]. Nevertheless, we demonstrate that deep-subwavelength plasmonic waveguides with gain can be efficiently used for data transfer at distances below ˜1 mm, which is a typical distance for on-chip interconnects, while longer communication distances could be problematic due to the strong photonic noise (Figure 1).

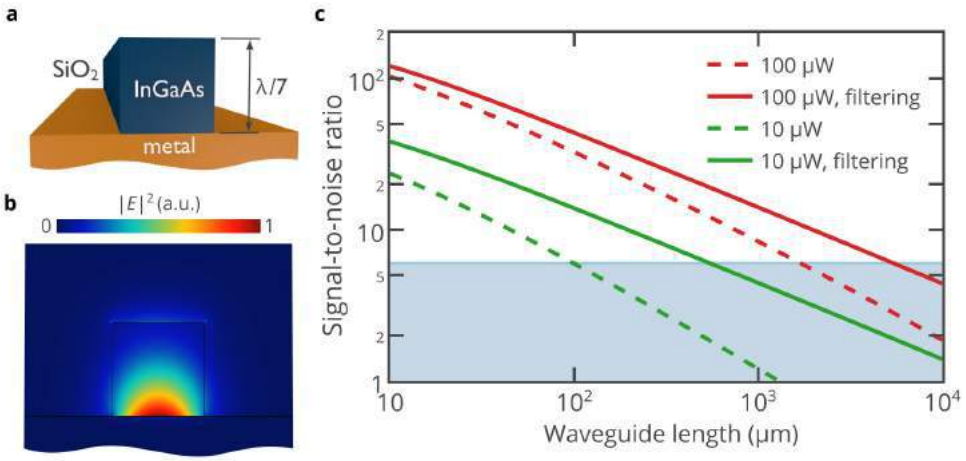

Figure 1. (a) Schematic of the single-mode subwavelength plasmonic waveguide with the InGaAs active medium. (b) Electric field distribution of the plasmonic mode at a light wavelength of 1550 nm. (c) Signal-to-noise ratio versus waveguide length for two different signal powers. The solid curves correspond to the system with a narrow bandpass optical filter, and the dashed curves correspond to the systems without optical filters. The blue area shows the region of high bit error ratios, where high-speed communication is complicated.

Chiral Plasmonic Nanoparticles with Chiroptical Activity Engineerable in the UV-visible region

Z. F. Huang[1*]

[1]Department of Physics, Hong Kong Baptist University, Kowloon Tong, Kowloon, Hong Kong SAR, China

[*]corresponding author: zfhuang@hkbu.edu.hk

Abstract-Chiral plasmon is expected to markedly enhance the optical chirality of the electromagnetic field on the nanostructure surfaces. An accessibility of chiral molecules to the irradiation with enhanced optical chirality will give rise to a wide range of vital chirality-related applications. To develop these applications, it is a prerequisite to understand and control the chiroptical activity of chiral plasmonic nanostructures, which is generally characterized by circular dichroism (CD) monitoring the differential absorption of left- and right-handed circularly polarized light. However, the understanding of the chiroptical activity is ambiguous currently. In this talk, the author will present that when plasmonic nanoparticles (NPs) are sculptured in a (hidden) helical shape using, e.g. glancing angle deposition, the NPs exhibit chiroptical activity intrinsically originating from the spiral structures. The chiroptical activity can be flexibly controlled in terms of the CD amplitude and CD resonance wavelength in the UV-visible regime, by engineering the plasmonic material, handedness, and helical dimensions. Numerical and analytical simulations are operated to understand the chiroptical activity of the chiral plasmonic NPs.

Integrated graphene waveguide modulators based on low-loss plasmonic slot waveguides

Sanshui Xiao*
DTU Fotonik, Department of Photonics Engineering, Center for Nanostructured Graphene,
Technical University of Denmark, 2800, Kgs. Lyngby, Denmark
saxi@fotonik.dtu.dk

Abstract- Graphene based electro-absorption modulators involving dielectric optical waveguides have been recently explored, suffering however from weak graphene-light interaction. Surface plasmon polaritons enable light concentration within subwavelength regions opening thereby new avenues for strengthening graphene-light interactions. I present novel integrated graphene plasmonic waveguide modulator showing high modulation depth and low insertion loss, thus giving a promising way to miniaturize the device without jeopardizing the performance of the device.

In recent years, the unique optical and electronic properties of graphene attracts wide interest, ranging from light-emitting devices to photodetectors, and touch screen [1]. In particular, the opportunity to control optoelectronic properties through Fermi-level tuning enables electro-optical modulation, optical-optical switching, and other optoelectronics applications. The deployment of graphene on top of a silicon waveguide is an efficient mean to make graphene−silicon hybrid devices [2-3]. However, it remains a big challenge to achieve high modulation depth because of the modest graphene light interaction in the graphene-silicon waveguide hybrid systems. Surface plasmon polaritons are broadband with the ability to manipulate light on the subwavelength scale [4], while at the same time giving possibility to direct more optical energy to the material interface where graphene could reside. Here I present novel graphene plasmonic waveguide modulators that are interfaced with silicon waveguides and are thus fully integrated in the silicon-on-insulator platform [5],

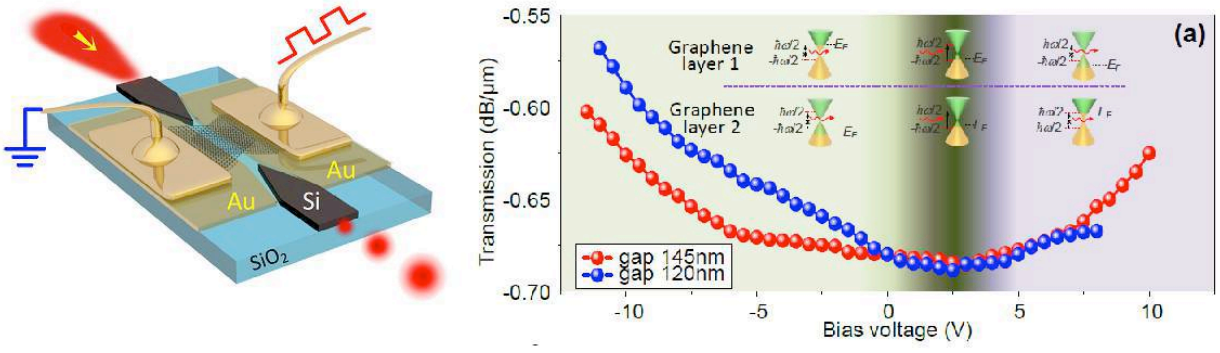

Figure 1. (a) 3D schematic of the graphene plasmonic waveguide modulator; (b) Modulated transmission for 20um-long graphene plasmonic hybrid slot waveguides.

Figure 1(a) shows the illustration of proposed graphene plasmonic waveguide modulator, where the plasmonic slot waveguide is coupled in/out by silicon waveguides with inverse tapering tips. The plasmonic waveguide can confine modes beyond diffraction limit, while at the same time suffering with large propagation loss. Here we propose plasmonic slot waveguides relying on the concept of leaky mode, giving us extremely low loss of 0.25dB/μm. The good alignment of the coupling part (between the silicon and plasmonic waveguide) leads to high in/out coupling efficiency of 1.45 dB.

Transmissions of the light at 1.55 μm through 20 μm-long leaky-mode graphene-plasmonic waveguides at different bias voltages are presented in Fig. 1(b) for two slot widths of 120 nm and 145 nm. One can find that the transmission through the graphene-plasmonic hybrid waveguides is effectively tuned by applying bias voltages on the graphene. An efficient attenuation tunability of 0.13 dB/μm is achieved for the plasmonic slot width of 120 nm at low gating voltages. The modulation depth of 0.13 dB/μm achieved here exceeds that for reported graphene-plasmonic hybrid device [6].

The Center for Nanostructured Graphene is sponsored by the Danish National Research Foundation, Project DNRF103.

Abstract— Analytical expression for fourth-order autocorrelation function of laser field shows strong influence of collective effects to laser coherency and helps to identify parameters for coherent, incoherent (thermal), sub- and associated with superradiance super-thermal lasing. Below-, above- and thresholdless lasing of micro- and nano-lasers are analyzed in the model without adiabatic elimination of active medium polarization. We show that collective effects reduce beta-factor and number of photons below the threshold.

Our model includes two sequences of Heisenberg equations. The first one – for mean values of binary products of operators, describing dynamics of total energy in the system: emitter populations, cavity mode photon number, dipole interaction of emitters with the cavity mode and with each other. Quantum mechanical relations between operators of emitters lead to terms responsible for spontaneous emission into lasing mode. Thus we can describe lasing below, at and above the threshold. The second sequence of equations is for mean value products of four operators, beginning with $\langle a^+a^+aa\rangle$, where a is Bose-operator of the cavity mode, $\langle ...\rangle$ means quantum-mechanical averaging. We break some mean value products of four operators in products of mean values of two operators and arrive to closed set of equations. We approximately neglect by fluctuations in populations of states of emitters, that is good approximation in a weak coupling limit. From the first and the second sets we found, respectively, the stationary photon number $n = \langle a^+a\rangle$ and the normalized autocorrelation function $g_2 = \langle a^+a^+aa\rangle / n^2$.

The model takes into account and shows explicitly the contribution of collective radiation from emitters. A part of the energy from the pump goes to collective radiation, reducing the incoherent spontaneous emission to the lasing mode. As a result, we found a reduction of β-factor respectively to one calculated in the rate equation approach [1] without taking into account collective radiation from emitters. The competition between collective and "individual" (incoherent) spontaneous emission causes the decrease in the number of photons below the threshold, which correlates with results of numerical analysis, for example, in [2]. We also found a feature of two-level active medium corresponding, for example, to q-dots: it permits "thresholdless" lasing even at $\beta \ll 1$ – if the number of emitters is small, that the threshold population inversion per emitter is close to 1.

The approach beyond limits of laser rate equations allows us carefully take into account up to fourth-order correlations between the cavity mode and the active medium polarization. We analytically calculate autocorrelation function g_2 for cavity mode field and identify conditions and laser parameters for various photon statistics. In particular, how large the photon number n must be for $g_2 \to 1$ – coherent field generation; when we obtain $g_2 = 2$ – for thermal field, or $g_2 > 2$ - for super-thermal field and $1 < g_2 < 2$ – for sub-thermal field generation.

Super-thermal field generation $g_2 > 2$ clearly appears below the lasing threshold, when the threshold population inversion per emitter is small: $\Delta_{th} \ll 1$, and for relatively low polarization relaxation (de-phasing) rate γ_h: $\gamma_h/2\kappa < 1$, where κ is the lasing cavity mode damping rate. $g_2 > 2$ means photon bunching because of collective spontaneous emission into lasing mode, which has been shown numerically in [3, 4]. We also see, that lasers with low threshold $\Delta_{th} \ll 1$ and low de-phasing $\gamma_h/2\kappa < 1$ easily demonstrate collective nature not only in spontaneous emission below, but also in stimulated emission above the threshold: there the coherency $g_2 \to 1$ appears at relatively small number of photons.

Abstract-This paper describes highly efficient plasmonic-electronic transducers based on tunneling. The plasmons are excited and detected via plasmon assisted tunneling. By electrically detecting the plasmon, the plasmon excitation efficiencies can be estimated which are 1000 times higher than estimates based on photon out coupling efficiencies.

Recently, the use of tunnel junctions as plasmon sources have regained interest [1,2]. In these devices, currents are directly converted to plasmons in a single step. The reverse process is also possible – optical rectification – and plasmons can couple to tunneling currents also in a single step (i.e., without the need of free photons or excitons). Therefore, tunnel junctions may find applications in plasmonic-electronic circuitry. Till date, it is unclear whether tunnel junctions can excite and detect plasmons efficiently enough for practical applications. From a fundamental point of view, the exact mechanisms of plasmon-electron coupling are not clear in these junction [3].

During the talk I will discuss our recent progress in the development of molecular tunnel junctions based on self-assembled monolayers (SAMs) and how we apply them as electrical excitation sources of plasmons [4-7]. The bottom-electrode is made of gold which also serves as the plasmonic waveguide. By simply applying a bias between the top and bottom electrode, a tunnelling current will flow. The tunnelling charges carriers that reach the gold electrode excite plasmons. Since the tunnelling rate and the tunnelling direction can be controlled by simply changing the chemical structure of the SAM, we have the ability to control the plasmonic properties of the devices and launch plasmons [8,9]. Our experiments indicate that these plasmon sources behave as point sources whose blinking properties can also be controlled by simply changing the molecular structure. Finally, by integrating two tunnel junctions with one wave-guide, we demonstrate that the tunnel junctions are also promising as plasmon detectors [9]. The latter devices make it possible to estimate the plasmon-electron coupling efficiency. Our results indicate that the plasmon-electron coupling efficiency is 1000 times higher than previously estimates based on photon out coupling rates [1-3]. Our results show that molecular electronics combined with plasmonics makes it possible to control plasmonic properties and to study new phenomena at the molecular length-scales and the tunnel junctions are interesting for applications in plasmonic-electronics in more general.

Plasmofluidic assembly of nanometallic structures: from single-molecule SERS to dynamic lithography

Partha Pratim Patra, Junsuk Rho
Department of Mechanical Engineering, POSTECH, South Korea
ppptra@gmail.com

Sub-wavelength control and manipulation of light is one of the most desirable issues in science and technology. To destine this, surface plasmon polariton (SPP) plays a significant role and to harness SPP, the nanometallic architectures have unprecedented ability to concentrate and transport light. The sophisticated and versatile applications of SPPs mostly rely on the geometry and the arrangement of the nanostructures. Thus innovative 'preparation and assembly' of nanometallic architectures is crucial. Especially, by assembling the nanostructures in a controlled way, one can deploy the plasmon-coupling for subtle modulation of light wave. Recently, the assembly of nanostructures has opened up a promising field of research which is directly linked to many other important subjects, e.g. biophotonic sensing, metamaterials, optical nanoscopy, thermoplasmonics, nonlinear plasmonics, photovoltaics, catalysis etc.

Herein we present how to harness plasmofluidic field (plasmonic field in fluid) to create efficient electromagnetic hot-spots by assembling colloidal nanoparticles to detect single-molecule SERS signals[1]. Also we shall discuss how the extension of this technique can lead to a preamble of reconfigurable dynamic lithography of plasmonic nanostructures at metal-fluid interface[2].

Abstract-Two dimensional colloidal plasmonic cavities spatially and spectrally shape the near-field. By designing these two degres of freedom, transduction function can be implemented in single cavities that perform Boolean logic functions. The wealth of available plasmonic modes allow to implement complex logic funcitons without the need of concatenating building blocks but rather by redesigning the ransfer function.

2D plasmonic systems with mesoscopic sizes sustain higher order plasmonic modes and combine the properties of surface plasmon polaritons (SPP) and localized surface plasmon (LSP). Such multimodal plasmonic systems open a new realm in which the modal behavior is better described by the Surface Plasmon local density of states (SP-LDOS), which is solely governed by the material properties and the boundary conditions set by the structure shape, but is independent of the illumination parameters. SP-LDOS can be rationally designed to tailor the local spatial and spectral characteristics of the SP modes, while allowing information transfer over micrometer-sized distances.

The next level of information processing consists in performing Boolean logic from the incoming signal. Here again, the tailoring of the modal properties of confined plasmonic cavities can be exploited to designing reconfigurable universal logic gates that can be converted into one another, this opens the way to the integration of complex functions at the nanoscale.

Abstract-Synthesizing the optical response of material through photonic band engineering is a means of slowing down light, in effort to achieve enhanced light-matter interaction or optical buffering. State-of-the-art, photonic crystal (PhC)-based slow light devices however suffer from limited bandwidth, group velocity dispersion, and non-flat transmission. Here, we report on the experimental measurements on structures, based on genetically optimized PhC coupled cavity waveguide (CCW) design, with largest bandwidth and the highest group-index bandwidth product. CCWs of length ranging between 50 and 800 cavities were measured with a very homogeneous flat-top transmission profile and losses value below 67 dB/ns.

Slow light propagation through engineered band dispersion in photonic structures is a highly promising tool for realizing integrated optical delay lines and efficient photonic devices through enhanced optical nonlinearities [1,2]. A primary goal is to achieve devices over the largest possible bandwidth with large group index and minimal dispersion (*i.e.* approximately constant group index), flat transmission spectrum, which otherwise would hinders their use for pulse propagation, with setbacks such as pulse distortion and generation of echoes, thus enabling multimode and pulsed operation [2].

We present an experimental proof of record-high group-index bandwidth product (GBP = $n_g \Delta\omega/\omega$) [2] in genetically optimized coupled-cavity waveguides (CCWs) made of staggered modified L3 photonic crystal cavities (Fig.1(a) and (b)). The optimization procedure [3] was applied to the unit cell (Fig. 1(a)) to achieve maximal GBP combined with low losses. The resulting designs [4] were realized in Si slabs (Fig. 1(b)), where CCWs of length ranging between 50 and 800 cavities were fabricated. The samples were characterized by measuring the CCW transmission (Fig. 1(c) and (d)), the mode dispersion through Fourier-space imaging (FSI), and the group index n_g independently with FSI and Mach-Zehnder interferometry (Fig. 1(e)).

Various cavity designs were investigated, with theoretical group index ranging from $n_g = 37$ to $n_g > 100$. Record-high GBP = 0.45 was demonstrated over a bandwidth approaching 20 nm (Fig. 1(e)), with $n_g = 37$, a very homogeneous flat-top transmission profile (Fig. 1(c) and (d), exhibiting variations lower than 10 dB) and losses value below 67 dB/ns. On a different design [3], an average $n_g = 107$ with 15 % variation over 7.4 nm was measured. These values range among the best ever demonstrated for a silicon device.

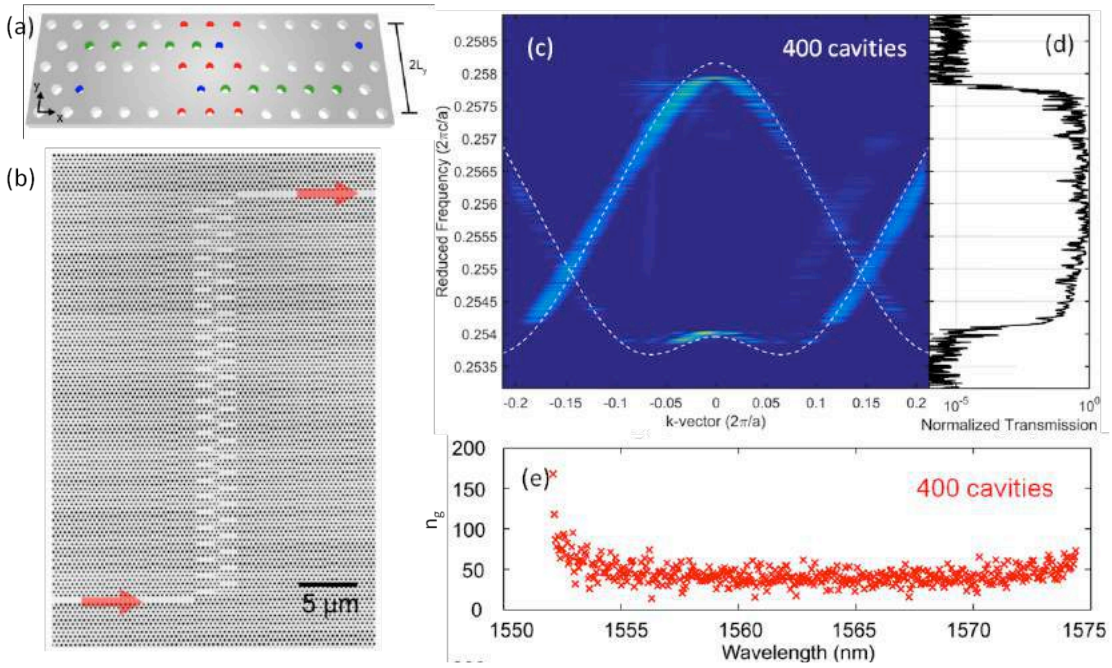

Fig. 1 *: (a) Sketch of the unit cell of the CCW. The radii of the red and green holes, and the radius and x-position of the blue holes, were used as variational parameters to optimize the GBP and the loss rate of the CCW. Soliton pulse propagation in the presence of disorder-induced multiple scattering in slow-light photonic crystal waveguides

N. Mann and S. Hughes

Department of Physics, Queen's University, Kingston, Ontario, Canada K7L 3N6

Abstract— We describe a new coupled mode theory to model nonlinear Schrödinger equations for counter-propagating Bloch modes that include disorder-induced multiple scattering effects on nonlinear soliton propagation in photonic crystal waveguides. Our numerical simulations of nonlinear pulse propagation are in excellent qualitative agreement with recent experiments and provide fresh insight into how disorder inhibits soliton propagation and other nonlinear propagation effects in photonic crystal waveguides.

Slow light in photonic crystal waveguides (PCWs) can be exploited for enhancing nonlinear optical (NLO) interactions [1]. For example, self phase modulation (SPM) in the presence of two photon absorption (2PA) and free carrier effects was observed by Monat *et al.* [2], while non-trivial scaling of SPM and three-photon absorption (3PA) was investigated by Husko *et al.* [3]. Colman *et al.* [4] utilized dispersion engineered PCWs to suppress 3PA which was critical in the demonstration of temporal pulse compression of higher order solitons. Other demonstrated NLO effects include third harmonic generation and highly efficient four wave mixing [5–7].

Despite these successes, one of the major limiting factors for exploiting NLO effects in PCWs is disorder-induced multiple scattering which roughly scales as n_g^2, where n_g is the group index [8]. This limitation is somewhat suppressed through dispersion-engineering [9, 10] or by reducing the length of the PCW to less than 500 unit cells which lowers losses but typically increases the required pump power [2]. Regardless, in the slow light regime, coupling to disorder is unavoidable and any realistic model must include such effects. The theory of disorder on linear propagation in PCWs is well developed [8, 11–13]. For modelling NLO effects in PCs, Bhat and Sipe [14] used multiple scales analysis and $k{\cdot}p$ theory to derive a *dynamical* nonlinear Schrödinger equation (NLSE), which is first-order in time, and their nonlinear coefficients use unit-cell averaged Bloch modes; however, the previously mentioned NLO works use the NLSE model adapted from the nonlinear fiber optics literature [15], where the NLSE is *first-order in space* and the nonlinear coefficients are generalized by a unit cell integration involving only the *periodic part* of the Bloch mode.

A severe shortcoming of current NLSEs applied to PCWs is their naive modelling of disorder-induced losses (if at all) as an effective loss parameter α, which follows the Beer-Lambert law, known to breakdown in the regime of multiple scattering, arising from coupling between contra-propagating modes [16]. The effect of multiple scattering on soliton propagation is shown schematically in Fig. 1 (though the pulse profiles are from actual calculations for 2 ps pulses). Although some works have partly studied coupling between contra-propagating modes in the context of examining nonlinear

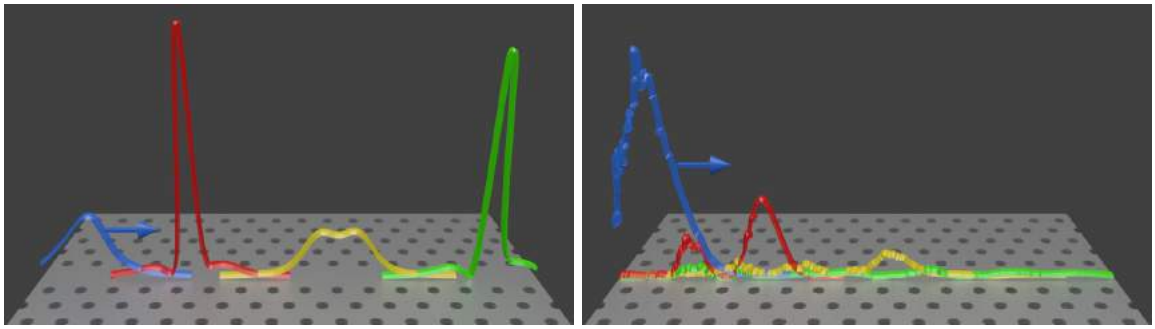

Figure 1: Spatial profiles at various times of a soliton injected from the left side of a W1 PCW in the absence (left) and presence (right) of disorder-induced multiple scattering and localization. For comparing the two schematics, the two leftmost pulses (blue) are of the same magnitude.

bistability in finite periodic media [17, 18], it was for weak scattering and in the *absence* of group velocity dispersion (GVD). For PCWs, neither of these assumptions holds true.

In this work, we will describe our recently developed coupled-mode theory (CMT) to model two coupled NLSEs for counter-propagating Bloch modes, including the effects of GVD, disorder-induced multiple scattering, SPM and cross-phase modulation (XPM) [20]. Unlike previous works, our nonlinear coupling coefficients are positional dependent because they involve an integration over the cross-section of the PCW and utilize the full 3D vectorial Bloch modes. We also introduce a characteristic length scale corresponding to each coupling coefficient, including a length scale associated with multiple scattering, which denotes the spatial extent associated with a disorder-induced localized mode. Using the W1 PCW, we model solitons propagating in the presence of multiple scattering for several n_g ranging from fast light to the slow light regime, and connect to a range of experimental observables. When nonlinearities dominate over multiple scattering, the soliton's spectra shows a random fine peak structure, whereas when multiple scattering dominates, the soliton's spectra exhibits narrow spectral peaks indicative of disorder-induced photon localization. Our numerical results are able to capture hitherto unexplained experimental features related to multiple scattering [2, 3, 19]. Moreover, our formalism can be generalized to assess the impact of multiple scattering on other nonlinearities such as 2PA, 3PA, and four-wave mixing.

Abstract-Slow-light photonic crystal waveguide designs that support chiral C-point polarisation singularities are shown. Using FDTD simulations, we have confirmed spin-photon entanglement with a correlation >99% for a quantum dot placed at a C-point. Photonic crystal waveguide designs that optimise the chiral light-matter interaction are provided, with a factor 8.6 enhancement of the local optical density of states found. The existence and location of C-points in the waveguide is confirmed to be remarkably robust to disorder in the waveguide.

Photonic crystal waveguides support polarisation singularities such as C-points, which are expected to be useful in future quantum information applications for several reasons. Firstly, thanks to the ability to tailor their dispersion properties [1], photonic crystal waveguides provide a flexible, integrated and miniaturised technology platform for quantum information applications. Secondly, quantum emitters such as quantum dots can be coupled on-chip and in-plane. And thanks to the very tight mode confinement and high density of optical states in the slow-light waveguide mode, the photon emission into the waveguide can be made near-deterministic – e.g. coupling with $\beta > 98\%$ between a slow-light mode and an quantum dot has been demonstrated [2]. Thirdly, the existence of C-points allows the waveguide to display local chirality. The global chirality is zero, as the C-points occur in pairs of left- and right-handed points. The local chirality has consequences for the photons emitted by quantum dots positioned at a C-point. The photons emitted by quantum dot transitions possess an angular momentum which is dependent on the spin state of the electrons. At a C-point, this angular momentum interacts with the chirality to give unidirectional emission dependent on the spin of the electron. The propagation direction of the light is what gives rise to the symmetry breaking needed. Such spin-dependent unidirectional emission is an attractive property for quantum information applications [3].

Here we report on the use of C-points in photonic crystal waveguides for quantum information applications. We use FDTD simulations to show that C-points can be used to entangle spin-encoded static qubits with path-encoded flying qubits [4] – see Fig. 1 – and we have optimised the waveguide design to use slow-light to enhance the local density of optical states at the C-point by a factor of 8.6 [5]. Further increases are constrained by temporal symmetry and the reciprocal nature of light. We find that C-points cannot exist at the bandedge due to the symmetry of the forward and backward modes found there, and this places limits on the use of C-points for unidirectional emission in the slow-light regime [6].

We also investigated the effect that disorder in the waveguide has on the existence and position of the C-points (see Fig. 2), and find that the C-points are remarkably robust to the introduction of disorder [7].

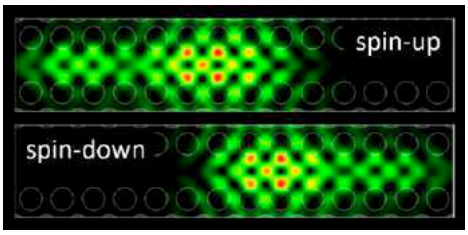

Figure 1. Spin-dependent unidirectional emission from a quantum dot at a C-point. There is >99% correlation between electron spin and emission direction: spin-up electrons always emit photons to the left and spin-down to the right.

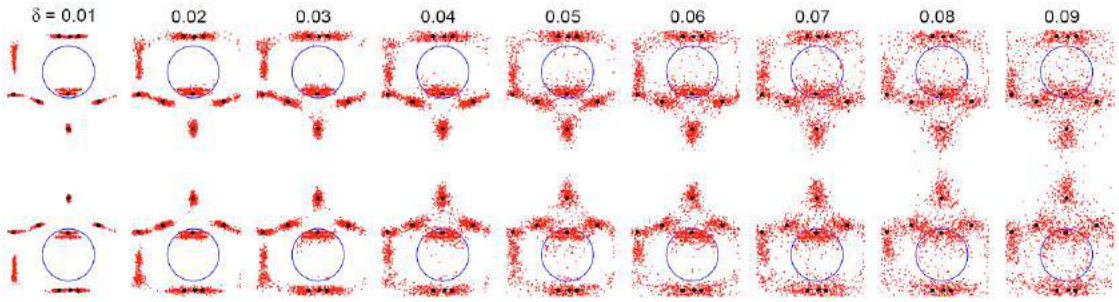

Figure 2. C-points are robust to disorder. Red dots show the calculated positions of C-points in a statistical ensemble of disordered waveguides for increasing values of the disorder parameter δ (indicated). Black dots show positions of C-points in the ideal waveguide.

Cavityless plasmonic nanoresonator

I. M. Fradkin* **and D. Yu. Fedyanin**
Laboratory of Nanooptics and Plasmonics, Moscow Institute of Physics and Technology, Russian Federation
*corresponding author: fradkin@phystech.edu

Abstract-Optical resonators are one of the most critical components in optoelectronics owing to their ability to strengthen light-matter interaction. Here, we demonstrate a cavityless nanoresonator based on an extremely slow mode of the metal-insulator-metal plasmonic waveguide. Its operating principle does not rely on the geometric resonances, and thus the device characteristics are almost independent of the structure dimensions. This feature makes such a resonator attractive for diverse applications at the deep-subwavelength scale, where accurate fabrication is still a challenge.

Development of highly efficient nanophotonic devices requires the ability to localize light in order to strengthen the light-matter interaction. This can be achieved with optical cavities, which store the electromagnetic energy in the form of standing waves. The resonance frequencies are determined by the geometry of the cavity, which discretizes the possible dimensions of such a resonator. Here, we discuss and demonstrate a fundamentally different type of resonators: a cavityless resonator, - which paves the way to a whole new approach for the electromagnetic field enhancement. The operating principle of such a resonator is not based on reflection from the cavity boundaries and, therefore, the resonant modes almost do not depend on the geometrical parameters [1,2]. This gives the possibility to reduce the fabrication tolerance and makes this type of resonators highly attractive for nanoscale LEDs [3], lasers [4], detectors and other active nanophotonic devices. The cavityless resonator can be realized using an optical waveguide, in which the energy velocity is close to zero, i.e. light is almost stopped. If the electromagnetic energy dissipates faster than it flows out of the small region of the waveguide, the decay time does not depend on the waveguide length. In this work, we present a cavityless nanoresonator based on the metal-insulator-metal (MIM) plasmonic waveguide (Fig. 1). Its operating frequency can be easily adjusted by choosing the insulator material. We show that even in the presence of Joule heating losses the MIM structure is able to decrease the energy velocity to near zero, which gives the possibility to achieve a high quality factor of the cavityless plasmonic resonator.

Abstract- Here we present an on-chip photonic memory based on a coherent transfer of optical data pulses to acoustic phonons and vice versa. We show that this process is fully coherent by encoding different phase states. The ultra large Brillouin gain in our photonic chips allows us to reach GHz bandwidth. We furthermore show storage of different amplitude levels, which increases the capacity of our memory even further.

Optical communication techniques are the only way to deliver the necessary speed and bandwidth to cope with the exponential increasing amount of data transferred today. The fast speed of light allows to send large amounts of data over long distances, however imposes a challenge when processing, rerouting or synchronising signals. Therefore, it is required to reduce the speed of optical data packets, or in some cases even completely stop the signal stream in a controlled way to enable processing, buffering or rerouting. Achieving this challenging goal in an integrated platform at room temperature has attracted a lot of interest, in particular slow-light in photonic crystals[1], [2] and stimulated Brillouin scattering (SBS) based slow-light in optical fibers [3]. The latter harnesses a change in the group velocity due to the resonant Stokes amplification and is a direct consequence of the Kramers-Kronig relation.

Here, we show a different way to use stimulated Brillouin scattering to delay light signals by storing optical data pulses as acoustic phonons for a certain amount of time and subsequently convert the stored information back to the optical domain [4], [5]. The optical data pulses at frequency ω_{Data} are resonantly transferred to an acoustic wave Ω via a counter-propagating write pulse at frequency $\omega_{W/R}$ that is frequency offset to the data pulse ω_{Data} by the Brillouin frequency shift Ω. The acoustic wave travels 5-orders of magnitude slower than the optical data pulses therefore efficiently delaying the optical signal. Afterwards the optical signals are retrieved by a second counter propagating optical pulse $\omega_{W/R}$, in this case depleting the acoustic wave and retrieving the original data pulse ω_{Data}.

This concept was first demonstrated in highly nonlinear fiber [6], showing, in a proof-of-principle experiment, that several nanosecond long pulses can be stored and retrieved afterwards. However, the potential of this memory greatly exceeds this early demonstration. In our work, we show that the transfer photon-phonon-photon is fully coherent by encoding different phase levels. We also show that we can store and retrieve several amplitude levels and the strict phase-matching condition of stimulated Brillouin scattering allows multi-wavelength operation. As a storage medium we use ultra-high Brillouin gain chalcogenide spiral waveguides. The on-chip waveguides not only greatly reduce the form factor of our memory but also enable to store pulses with much wider bandwidth, i.e. much shorter pulses. As a consequence, the Brillouin gain is spread out over a wide bandwidth, hence ultra-high Brillouin gain in the overlap region of the pulses is required.

In conclusion we demonstrated an optical memory based on a coherent transfer of photons to phonons and vice versa. The optical information is stored in a small-footprint spiral waveguide at room temperature. The ultra-high Brillouin gain of these waveguides allows us to store pulses with sub-ns length. We demonstrate that our Brillouin based memory is fully coherent and show storage and retrieval of multiple phase and amplitude levels.

Abstract-Optical nonlinearity allows various control of light, while their effects is usually small. Si photonic crystal waveguides enhance the nonlinearity on a chip, thanks to the strong optical confinement and slow-light effect. Here, we present co-/counter-propagating slow-light systems, in which two slow-light pulses propagate simultaneously and exhibit unique interactions. The enhanced nonlinearity as well as engineered group-delay and dispersion in slow light gives unique functions such as adiabatic wavelength conversion, fast delay tuning, pulse compression, Doppler shift and auto-correlation.

Abstract— A reconfigurable multi-tap microwave filter is demonstrated on a silicon-on-insulator platform. Compactness and low-power operation are achieved owing to slow-light in photonic crystals. As an example, a microwave band-pass and a stop-band filters are obtained. Channel equalization is also demonstrated on an unitary filter cell.

1. INTRODUCTION

The use of optical technology brings unprecedented advantages to manipulate and process microwave signals. Initially mainly reserved to the distribution of signals over long distance, microwave photonics, which exploits optics to process high-speed analog signals, is quickly advancing thanks to the development of photonic integrated circuits (PIC), promising compact, robust, low-power, lightweight devices which can be mass produced. This will have a tremendous impact in wireless and space communication and radar.
In this context, filtering is considered as the most relevant function [1], as superior agility and broadband operation, in addition to immunity to electromagnetic interference, are expected to be an obvious advantage of a photonic microwave device, compared to its electronic counterpart. Our microwave photonic filter implements a finite impulse response owing to the interference of 4 delayed and weighted replicas of the signal in the optical domain. The coherent summation of the fields allows to cover a broader range of response functions. In this architecture, reconfigurability and tunability is provided by adjustable switches and optical delay lines. As the size of these devices is constrained by the dispersion of the waveguide, dispersion engineering and slow light are crucial assets [2].

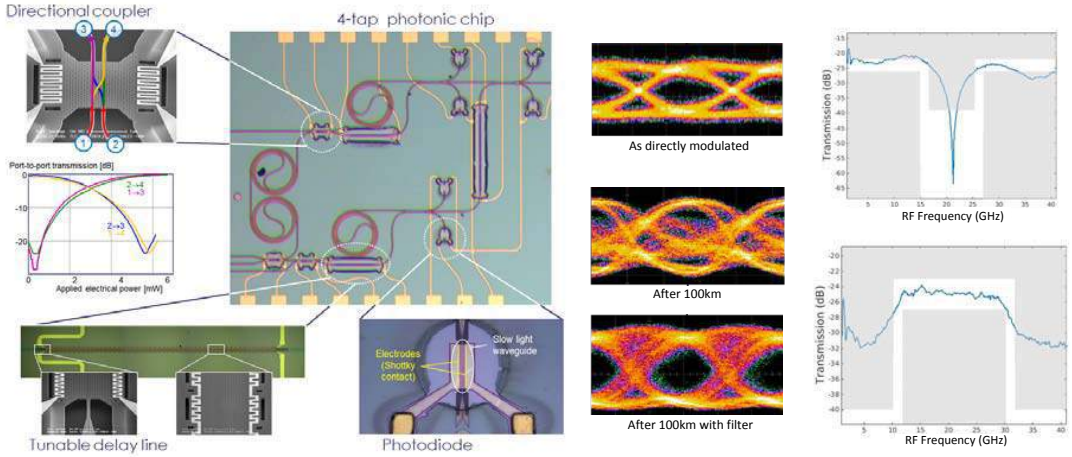

Figure 1: On the left, image of a 4-tap photonic integrated microwave filter and magnified images (SEM) of its constitutive elements: PhC photodetector, PhC tunable delay-line and PhC directional coupler. Signal processing using the device (right): eye diagram before and after dispersion compensation and example of synthesised transfer functions.

2. IMPLEMENTATION OF A SLOW-LIGHT BASED MICROWAVE FILTER

The architecture of the filter (figure 1) is based on nested cells consisting of a Mach-Zehnder (MZ) interferometer formed with a PhC directional coupler (DC), a tunable PhC delay-line (DL) and a 250 μm-long fixed spiral delay ($\sim$ 25 ps) and a multi-mode interferometer (MMI). The device shown here uses two lower level cells nested in a third one. The performances of the filter depends largely on the properties of the tunable delay line, which is a photonic crystal waveguide operating in the so-called slow light regime [5]. The range of the delay determines the central frequency and the free spectral range. The dispersion is tailored to provide a very steep change of the delay as the temperature of the PhC suspended slab is modified. A different design of the dispersion is exploited to reduce the size of the directional coupler [3] at the heart of the 2×2 switch to $10\mu m$ (figure). Because of the tiny active volume and the large thermal resistance of the suspended slabs, the switch provides a large contrast ($> 20dB$) by consuming only (3 mW) of electric power, and its thermal tunability is fairly fast ($1\mu s$). Similarly, the delay line covers a range of 80 ps with a maximum of 80 mW.

The two arms of each interferometer are recombined by a 2x3 MMI interferometer, allowing the use of two photodetectors to measure the state of the interferometer, which is crucial to set the desired parameters of the filter. We use germanium-free photodetectors [4] based on nonlinear and surface absorption, which are remarkably effective in silicon photonic nanostructures in telecom spectral range. Under the operating condition, the responsivity is $\sim$ 0.1 A/W, which is sufficient for our purpose. The structures were fabricated in a standard clean room environment, on a silicon-on-insulator (SOI) platform.

3. DEVICE OPERATION

Each interferometer is stabilized using a small amplitude and low frequency modulation of the current applied to the heaters of the delay lines. Using a standard lock-in technique, the resulting phase modulation of the optical signal is used to unambiguously measure and stabilize the optical phase. The residual phase error of the stability loop is as low as $\lambda/80$ rms . Using a single stabilized filter cell, we have demonstrated [6] the compensation of the dispersion in an optical link based on a directly modulated laser diode. This is apparent in the eye diagram in figure 1.

The transfer function of the 4-tap filter is measured using a modulator, a detector and a vector network analyser (VNA). This is shown in figure 1(right), where a variety of responses are obtained by setting the currents applied to the heaters suitably. As an example, a "stop band" or "bandpass" function are obtained. The slope of the filter edges will increase with the number of coefficients (hence taps), which is allowed by the inherently scalable architecture used here. This opens the way to structures with larger number of taps thanks to silicon photonics capabilities in terms of integration.

Abstract- Optical non-classical states are fundamental resources for applications in quantum information processing. We show that integrated frequency comb sources, operating in the quantum regime, can provide a scalable and versatile platform for non-classical state generation.

With recent advances in optical quantum information processing (e.g. the realization of quantum cryptography systems), it is foreseeable that reliable, low-cost, and scalable on-chip sources of complex optical quantum states will represent a key enabling technology for quantum applications [1-4]. The requirements of such sources vary for different applications, but typically include long-term operational stability and insensitivity to environmental perturbations, compatibility with quantum memories, operation at telecomm wavelengths (around 1550 nm), and compatibility with mass-producible electronic chip fabrication standards (CMOS). More importantly, source characteristics, such as frequency multiplexing to enable multi-user/channel operation, polarization diversity to implement polarization-based operations, and the generation of more complex quantum states are necessary to enable new functionalities in the fields of quantum information science. Therefore, the realization of integrated quantum sources has attracted considerable attention from the scientific community [1]. However, major difficulties arise when sources need to satisfy several requirements at the same time, i.e. a narrow spectral bandwidth, high-purity single-mode generation, high production rates, multiplexed broadband operation, and / or entanglement shared between several photons.

We demonstrate that integrated quantum frequency combs (based on on-chip, high-Q micro-ring resonators [5]) can address these requirements and enable the generation of *pure heralded single photons, cross-polarized photon pairs,* as well as *bi- and multi-photon entangled qubit states* over a broad frequency comb covering the full S, C, and L telecommunication bands.

2. Heralded single photon source

Exploiting a self-locked, intra-cavity excitation configuration [6], a highly stable integrated source of frequency-multiplexed heralded single photons is demonstrated without the need for active stabilization (of e.g. excitation frequency) [6]. The photons are generated though four-wave mixing (FWM) within an integrated micro-ring resonator. The measured photon bandwidth of 110 MHz is compatible with state-of-the-art quantum memories and repeaters, and the high purity of the emitted photons was confirmed through single-photon auto-correlation measurements [6,7]. We report nearly single-frequency-mode operation and demonstrate

heralded single photons with an anti-bunching dip as low as 0.144.

3. Cross-polarized photon pair source

By simultaneously exciting two resonances corresponding to orthogonal polarization modes, while suppressing stimulated degenerate four-wave mixing (FWM) through a mode family frequency offset, we introduce a new type of spontaneous FWM to the toolbox of integrated photonics [7]. In particular, we demonstrate the first realization of type-II spontaneous FWM (in analogy to type-II spontaneous parametric down-conversion in second-order media), which enables the direct generation of orthogonally-polarized photon pairs on a chip [7]. The measured photon bandwidths (320 MHz), excellent coincidence-to-accidental ratios, and high purity single-frequency-mode operation in the single-photon regime underline the source utility.

4. Two- and multi-photon entangled state source

Through the double-pulse excitation of a high-Q micro-resonator, we demonstrate the generation of time-bin entangled photon pairs [8] over the entire frequency comb spectrum. We measure qubit entanglement with fidelities above 90% both on co- as well as cross-polarized photon pairs. The measured density matrix of the two-photon state also agrees very well with the expected ideal state, confirmed by a measured fidelity of 96%.

Finally, the generation of multi-photon states [9] is experimentally very challenging. In our quantum comb, the excitation field and the generated photons are intrinsically bandwidth-matched due to the resonant characteristics of the ring cavity, enabling the multiplication of Bell states and the generation of a four-photon time-bin entangled state. We confirm the generation of this four-photon entangled state through four-photon quantum interference [10]. The measured density matrix of the four-photon entangled qubit state exhibits a fidelity of 64%, comparable in quality four-photon states generated in other, non-integrated platforms.

3. Conclusion

Integrated quantum frequency combs based on third-order nonlinearities are shown to be a scalable and versatile platform for quantum state generation and a practical technology towards optical quantum information processing.

Abstract – Efficient single-photon source is a key milestone in the development of optical quantum computers and secure communication lines. Color centers in diamond and related materials are considered to be the best candidates for practical single-photon sources. However, the low quantum yield and poor collection efficiency of these emitters are a serious obstacle. Here, we present a plasmonic nanoantenna for single-photon sources on diamond which increases the radiation efficiency about 30 times and enhances the collection efficiency up to 90%.

The ability to generate single photons on demand is the key to the development of quantum communications and quantum computing technologies. Color centers in diamond give a unique opportunity to design single-photon sources that operate at room and higher temperatures [1–4]. However, it is still a challenge to achieve a high quantum yield and efficiently collect light emitted by these defects in the crystal lattice of diamond. For example, the silicon-vacancy (SiV) center demonstrates a very narrow emission spectrum, but the quantum efficiency is only of the order of 5% [5]. In addition, due to the high refractive index of diamond, it is possible to collect only a few percent of emitted photons [5]. This problem can be solved using an optical antenna.

In our work, we demonstrate a plasmonic nanoantenna, which is simultaneously used to increase the quantum yield and improve the directivity of photon emission. Remarkable is that the proposed relatively simple design (see Figure 1) enables to substantially reduce the dimensions of the single-photon source and greatly improves its efficiency. This approach can be efficiently used for both optically and electrically pumped single-photon sources. Our results show that the Purcell factor is as high as 30, which increases the quantum efficiency of the SiV center more than tenfold. Moreover, the highly directional far-field emission pattern gives the possibility to achieve an ultrahigh collection efficiency of more than 85% using a conventional immersion objective with a numerical aperture of 1.25. These numbers can be further improved by optimizing the materials and geometry. We believe that our findings pave the way towards the development of highly efficient room-temperature practical single-photon sources.

Engineering quantum light on micro/nanophotonic chips

Qiang Lin[1]

[1]Department of Electrical and Computer Engineering, University of Rochester, Rochester, NY 14627, USA
qiang.lin@rochester.edu

Abstract— In this talk, we will discuss our recent progress in engineering micro/nanophotonic device structures for producing and manipulating photonic quantum states on chip.

Recent advances in quantum photonics have resulted in broad applications ranging from secure communication, metrology, sensing, to advanced computing. Chip-scale implementation would not only enhance the complexity and capacity of information processing, but also enable novel functionalities which are otherwise inaccessible in room-wide/table-top experiments.

Lying in the heart of these applications is the capability of generating versatile high-purity entangled photonic quantum states. In this talk, we will discuss our recent effort in engineering micro/nanophotonic device structures for producing and manipulating photonic quantum states on various chip-scale device platforms, by taking advantage of enhanced four-wave mixing and parametric down conversion processes, via the second-order and third-order optical nonlinearities.

Improved single-photon sources for quantum photonic integrated circuits

Abstract- Large-scale quantum photonic circuits require deterministic sources of indistinguishable single photons exhibiting very high efficiency. Single semiconductor quantum dots embedded in nanophotonic cavities and coupled to waveguide circuits can provide the required efficiency. We will discuss our recent progress in improving these integrated sources, including advanced tuning schemes and electrical injection into photonic crystal cavities

Single photons can be efficiently generated from the recombination of single excitons in quantum dots embedded inside photonic crystal (PhCs) cavities [1] and then coupled to waveguides in quantum photonic integrated circuits [2]. The applicability of these sources is however limited by practical problems such as their relative energy detuning and the complexity of optical pumping. In this talk, after reviewing our approach to fully-tuneable on-chip single-photon sources using nano-opto-electromechanical actuation, we will discuss recent progress in their electrical injection.

Electrical injection in PhCs is difficult due to the need of combining a low-resistance electrical path and low optical loss. Here we report the first demonstration of electroluminescence from single QD lines within PhC cavities. A double-membrane electromechanically tuneable [3] PhC structure was used (Fig 1, top), where the top membrane hosts an additional vertical p-i-n junction in order to inject current in the embedded QD layer. The cavity resonance can be reversibly tuned over almost 20 nm by electrostatically actuating the intermembrane distance. Low-temperature electroluminescence spectra clearly show single QD lines, which become enhanced when they cross the cavity mode. The measurement of the second-order autocorrelation function from a cavity-enhanced line (Fig. 1, bottom) proves the antibunched character of the emitted light, and allows deducing a Purcell enhancement of a factor of 3.5 in its emission rate.

As electrical injection does not require focusing a pump spot on the cavity and does not involve stray pump photons, it makes the implementation of large arrays of single-photon sources much more feasible. The large-scale integration of such tuneable single-photon sources, passive optics and waveguide detectors [4] may enable the implementation of boson sampling circuits [5] able to process tens of photons.

Quantum photonics for novel quantum computing and testing quantum physics foundations

Philip Walther

University of Vienna, Faculty of Physics Quantum Optics, Austria

Abstract- The advantages of the photons makes optical quantum system ideally suited for fundamental quantum physics experiments and a variety of applications in quantum information processing. Here I will discuss multi-photon processing using integrated waveguides as well as experimental benchmark values for hyper-complex extensions of quantum mechanics (such as quaternions) that exploited a metamaterial. As outlook I will briefly discuss the scale-up of photonic quantum information processing by using high-efficient detectors and solid-state single-photon sources.

Photonic circuitry with quantum dots

L. Midolo[1*] and **P. Lodahl**[1]

Abstract-The recent advances in building scalable photonic quantum devices based on semiconductor quantum dots in Gallium Arsenide are reported. The excellent properties of quantum dots as efficient and coherent single-photon resources in this platform allows us to explore novel functionalities by combining them with photonic integrated circuits. Recent results include methods for the efficient out coupling of single photons to optical fibers using tapered waveguides with 80% efficiency, and the on-chip electro-optical routing of single quantum dot emission with sub-μs speed.

Semiconductor quantum dots are excellent sources of single photons for quantum-information processing [1]. The integration with planar photonic nanostructures such as photonic crystal waveguides, nano-beams, and electrically gated devices, provides an exciting platform to perform solid-state quantum optics experiments. We have recently demonstrated near-unity emitter-mode coupling efficiency [2], single-photon nonlinearity [3], directional emission [4], and indistinguishable photon generation [5]. With the proliferation of photonic integrated technologies it is becoming more and more attractive to combine quantum dot sources with passive and active optical elements such as beam-splitters, phase shifters, and input-output couplers. Such integration would open up new possibilities to implement low-loss and scalable photonic quantum devices with embedded capabilities for signal routing. In particular, such capabilities would enable de-multiplexing a single-photon source into an Nx1-photon resource for multi-qubit experiments [6].

A major challenge in this direction is to efficiently couple photons from an optical chip to a fiber without incurring in high losses. We have demonstrated different out-coupling strategies including gratings, inverted tapers [5], and evanescent coupling to nanofibers [7]. The latter method resulted in chip-to-fiber efficiencies exceeding 80% and a total source efficiency of 10.9%.

Another outstanding problem for single-photon de-multiplexing is to realize fast (sub-μs) and low-loss optical switches operating at cryogenic temperatures, i.e. without resorting to thermo-optic effects. We have devised a method for integrating a phase-shifter based on the electro-optic effect in a compact (<250x250 μm^2) Mach-Zehnder interferometer built with free-standing GaAs waveguides. The electric field is applied across a p-i-n junction embedded in the waveguide itself [5]. Switching of quantum dot emission spectra has been demonstrated by a series of electro-optical measurements performed at 10 K, at a <500 ns modulation speed.

Abstract— Integrated quantum photonics is now drawing attention as a way to realize scalable quantum information systems using photons. We review the recent progress of integrated photonic devices based on silica, silicon and lithium niobate waveguides for quantum information and communication systems based on time-bin qubits and qudits.

Integrated quantum photonics is a promising approach to realize scalable quantum information systems using photons. Since most optical waveguides for integrated photonic circuits shows polarization dependence, polarization qubits are not suitable for integrated quantum photonics systems. A time-bin qubit is a promising candidate of a quantum information carrier for such systems, because of its polarization insensitivity and seamless connectivity with quantum communication systems over optical fiber networks.

Our group has employed planar lightwave circuits (PLC), which are optical waveguides fabricated using silica (SiO_2), to construct 1-bit delayed interferometers for phase difference measurement of time-bin qubits. The PLC interferometers have been key components in various quantum communication experiments such as a quantum key distribution [1, 2], time-bin entanglement generation [3], and quantum teleportation of time-bin qubit [4]. Recently, we applied the PLC interferometers to high-dimensional time-bin quantum states. Using cascaded PLC interferometers, we demonstrated a violation of Collins-Gisin-Linden-Massar-Popescu inequality for four-dimensional time-bin entangled photons [5], and also showed that a resource-efficient quantum state tomography for high-dimensional time-bin states could be implemented [6].

We have also been studying silicon (Si) waveguides as a promising platform to realize active functions on photonic chips [7]. In nanoscale silicon waveguides, the nonlinear effect is significantly enhanced by the tight confinement of light inside the very small effective area. Using this enhanced nonlinearity, we demonstrated the first entanglement generation experiment using SFWM in a 1-cm silicon waveguide, where a time-bin qubit was used to encode quantum information [8]. To enhance the nonlinearity further, we employed a slow-light device based on a coupled resonator optical waveguide (CROW) consisted of silicon photonic crystal (PhC) cavities [9]. We realized on-chip time-bin entangled photon pair source using a silicon PhC CROW whose length was as short as 420 μm [10]. We also showed that the silicon PhC CROW could be used as an on-chip single-photon buffer with a tunable temporal delay [11].

A lithium niobate (LN) waveguide is another important platform for integrated quantum photonics since it can be used as an electro-optic device for manipulating single photons. We proposed and demonstrated that a 2-input, 2-output LN switch could be used as two-qubit gate for time-bin qubits [12]. In our most recent experiment, we used an optical single sideband modulator based on an LN waveguide to erase the frequency distinguishability between two single photons [13]. This technology enables us to tune the frequency of single photons with the precision of the frequency of an RF signal that drives the modulator.

Frequency conversion in the single photon regime in silicon waveguides

Abstract-Four-wave mixing Bragg scattering in silicon waveguides is demonstrated as a low-noise frequency converter for single photon level signals. The limits to conversion efficiency due to nonlinear losses and parasitic processes are considered. Stable interference between separate input frequencies is observed, and it is shown that a birefringent phase-matching scheme can provide additional control over the unwanted processes and could lead to higher conversion efficiencies.

Four-wave mixing Bragg scattering (FWM-BS) is a $\chi^{(3)}$ nonlinear process which enables the frequency conversion of weak signals using two strong pump lasers [1], as illustrated in Fig.1(a). In particular, the signal can be translated by the frequency difference between the pumps, and this is in principle a noiseless process – unlike other four-wave mixing processes such as parametric amplification or phase conjugation, no excess noise photons are introduced into the signal. For this reason, FWM-BS can be applied to single photon level or quantum signals, and could be used in quantum communications, either for routing signals across a network with wavelength division multiplexing or for aligning a photon with the operating wavelength of a particular quantum memory or matter qubit.

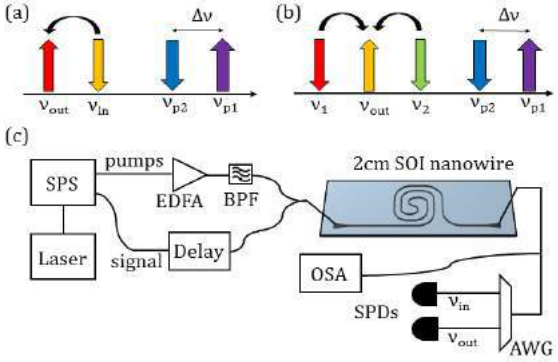

Figure 1. (a) Four-wave mixing Bragg scattering for frequency translation of a weak signal from ν_{in} to ν_{out} using two pump lasers. (b) Two input frequencies at ν_1 and ν_2 are coherently combined at ν_{out} giving rise to stable interference. (c) Experimental setup: a broadband mode-locked laser is filtered into two pumps and a signal using a spectral pulse shaper (SPS). The pumps are amplified by an erbium doped fibre amplifier (EDFA) then a band-pass filter (BPF) removes spontaneous emission from the EDFA. A delay line is used to resynchronize the signal with the pumps in a silicon waveguide. The output is measured with an optical spectrum analyzer (OSA) for classical characterization or filtered by an arrayed waveguide grating (AWG) and measured with single photon detectors.

Here, FWM-BS is demonstrated in silicon waveguides, with the experimental setup shown in Fig. 1(c). Silicon has the advantages of a high $\chi^{(3)}$ nonlinearity and a narrow Raman gain peak, compared to silica fibres [2] or silicon nitride waveguides [3], where the broad Raman spectrum created by the pumps is a source of noise for the signal. First, a 2cm silicon nanowire is used to apply up and down-shifts of 200GHz to a laser attenuated to the single photon regime, within the telecommunications C-band. Maximum internal conversion efficiencies of 11% for up-shifting and 12% for down-shifting are largely limited by nonlinear loss in the waveguide, which increases with the pump power. When this loss is normalized out, up to 32% of the signal power can be transferred to a particular shifted frequency; this limitation is due to the fact that FWM-BS in a short waveguide with relatively small frequency shifts is almost unconstrained by phase-matching, so a photon is equally likely to be up- or down-shifted, and can be shifted multiple times at higher pump powers. This reduces the proportion of the signal which ends up at the intended output frequency.

Despite the limited conversion efficiency, this technique can be used to investigate interference effects between different frequencies. When the input contains two frequencies, they can be overlapped and measured at a single output frequency as in Fig. 1(b). A stable interference fringe is observed with 80% visibility, demonstrating the coherence of the FWM-BS, and this could be useful in some quantum key distribution schemes as a test of frequency-time entanglement. Finally, an example of FWM-BS where the pumps are orthogonally polarized to one another is shown, in a silicon waveguide with a much larger cross-section and a weak birefringence. It is found that the birefringence is useful in controlling the phase-matching of the different FWM-BS processes, so that up-shifting or down-shifting in frequency can be selected using the input polarization of the signal, and the unwanted process is suppressed.

Silicon photonic sources of nonclassical states of light.

Daniele Bajoni[1,*]

[1]Dipartimento di Ingegneria Industriale e dell'Informazione, Università di Pavia, Italy
[*]corresponding author: daniele.bajoni@unipv.it

Abstract-We review recent advances in silicon integrated quantum photonics, with particular emphasis on integrated sources of nonclassical states of light. We show how the third optical nonlinearity of silicon and silicon compatible materials can be enhanced via the use of resonators, and how this can be exploited to generate entangled states of the electromagnetic field as well as heralded single photons.

Quantum technologies offer compelling new ways to improve creation, manipulation and transmission of information [1]. Quantum cryptography, for instance, leverages on the properties of single photon states to improve data security in telecommunication networks [2], one of the most critical challenges in communication technologies. Quantum imaging techniques use correlations between photons to improve resolution and signal to noise ratio [3]. Quantum computing protocols point to the use of the laws of quantum mechanics to perform tasks like factorisation or searches in large random databases in a much more efficient way than what can be obtained for classical computers [4].

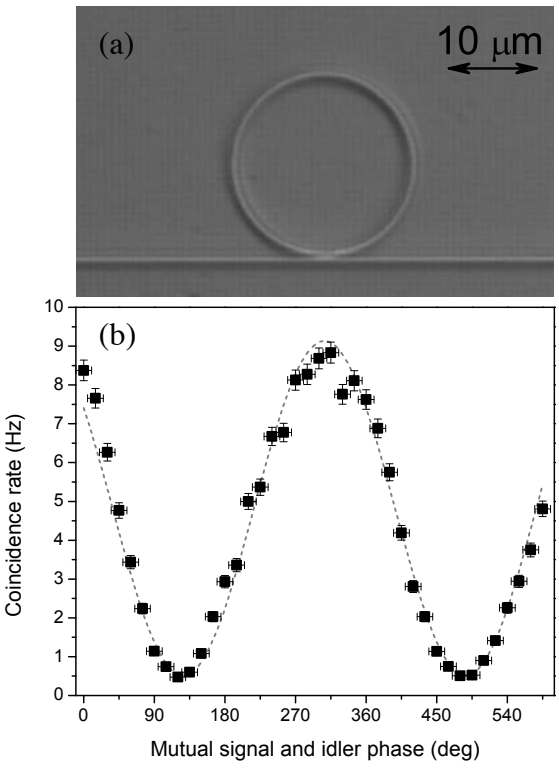

Figure 1: (a) Optical image of a 10 micron radius silicon ring resonator. (b)Dependence of coincidences on the mutual signal and idler phase in a time energy entanglement experiment performed on the ring in (a). The data are taken from ref. [8]. The grey line is the best fit to the experimental data and corresponds to a visibility of about 90% implying a violation of Bell's inequality by 7.1 standard deviations.

Many different systems are being researched as substrates for quantum information protocols, ranging from cold atomic systems, to superconductors, to semiconductor quantum dots. Photons offer an attractive medium for quantum information technologies due to their long coherence times even at room temperature, and can be easily manipulated using the tools of photonics [5]. Photons are also the mostly used medium for the transmission of information via fiber networks. Silicon photonics devices have seen a dramatic development in recent years as Multi Project Wafer (MPW) and application-specific integrated circuit (ASIC) design are becoming increasingly widespread [6]. This offers an unprecedented opportunity to bridge quantum technologies from laboratory environments to actual industrial applications.

In this presentation we review recent advances on the integration of one of the fundamental components of quantum photonics: sources of nonclassical states of light. We start discussing Four Wave Mixing, the most widely used process to achieve emission of quantum states in silicon samples, and how it can be enhanced via the use of resonators. We will in particular describe ring resonators, which are among the most efficient and most used silicon integrated sources reported so far. We will review recent results on silicon integrated sources of photon pairs [7], heralded single photons and entangled photon pairs [8], both in silicon and silicon compatible high band-gap

materials [9,10]. Finally, we will discuss how sources can be integrated with other photonic components on a chip and review promising alternatives and perspectives.

Femtosecond laser writing of 3D integrated quantum photonic circuits.

R. Osellame
Institute for Photonics and Nanotechnologies – National Research Council (IFN-CNR), Italy
corresponding author: roberto.osellame@polimi.it

Abstract The use of integrated photonics in quantum optics experiments has introduced dramatic improvements in terms of stability and scalability of the experiments. In particular, femtosecond laser direct writing of photonic circuits enabled the manipulation of polarization-encoded single photons and the realization of 3D photonic circuits. These unique capabilities opened the door to advanced quantum simulation and computation tasks.

Femtosecond laser waveguide writing is a recently developed technology to fabricate integrated photonic circuits. It exploits focused ultrafast laser pulses for the direct inscription of waveguides in the bulk of dielectric substrates [1]: the laser beam can be indeed used as an optical pen, able to draw in the three dimensions an optical circuit with arbitrary geometry.

This technology presents several advantages and potentials, with respect to conventional planar lithographic processes. One of its distinctive features is the possibility to produce circuits with arbitrary three-dimensional design inside the substrate. In addition, no lithographic masks are needed and this allows to produce devices with novel design and unique flexibility, rapid turnaround and cost-effective process.

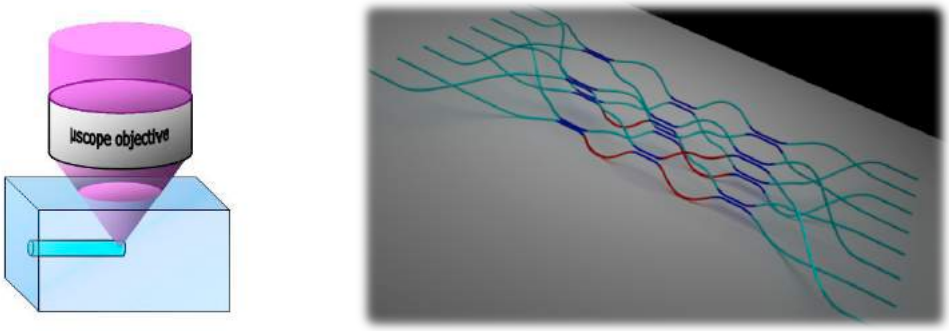

Figure 1. Schematic of the direct laser writing process (left). Example of a 3D layout for a photonic circuit performing the Fourier transform over the optical modes (right).

Femtosecond-laser written circuits have also shown specific advantages in the flourishing field of integrated quantum photonics. In fact, femtosecond-laser written waveguides have typically low birefringence, which enables the propagation and manipulation of polarization encoded qubits [2]. Several components have been reported for the integrated manipulation of the polarization degree of freedom, such as polarization sensitive or insensitive integrated beam splitters [3, 4], and rotated waveplates [5].

A remarkable control in the circuit fabrication has been demonstrated, enabling the realization of complex

circuits for quantum simulation [6, 7] or to implement arbitrary unitary transformations over the optical modes [8, 9, 10], useful e.g. for boson sampling applications.

A further capability of this technology is the possibility to process different materials besides glasses, for example crystals. We have demonstrated the possibility to write waveguides in Pr:YSO [11], implementing an integrated waveguide memory, as well as in diamond [12], where it can be combined with the laser generation of NV centers [13,14].

Abstract- In this work we develop a high-time-resolution double π-pulse resonance fluorescence technique, allowing observation of a record-high Purcell factor of 35 in a low-Q (677) waveguide-coupled photonic crystal cavity. The short radiative lifetime (27 ps) leads to coherent single photon emission regardless of significant dephasing processes and an enhanced photon generation rate. Combining the strong Purcell effect with resonant coherent excitation and electrical tuning, we demonstrate an on-chip, on-demand tunable single photon source that exhibits high purity and indistinguishability without any spectral filtering.

Integrated quantum circuits are an exciting architecture for compact and scalable Quantum Information Processing (QIP). Silicon-on-insulator devices have demonstrated the concept [1], but rely on four-wave mixing sources which have low brightness (kHz) and large space and optical power requirements. It is thus desirable to consider a source based on a single quantum emitter such as a quantum dot (QD) instead. Single photon emission has been observed from continuous resonant excitation of an InGaAs QD coupled to a nanobeam waveguide [2,3]. However, in this work and others [4] poor coherence times ($T_2 < T_1$) have been observed, possibly due to charge noise from the presence of nearby surfaces. An ideal single photon source requires high coherence and thus should operate close to the radiative limit of $T_2 = 2T_1$.

To overcome this issue and demonstrate a near-ideal on-chip single photon source, a waveguide-coupled Photonic Crystal Cavity (PCC) is used to strongly reduce the radiative lifetime (T_1 = 27 ps) of the QD in this work. In addition to the coherence benefits, the cavity also significantly enhances the source emission rate whilst reducing the optical excitation power required. On demand operation is achieved by resonant driving with π-pulses.

The device studied consists of a waveguide-coupled H1 PhCC. InGaAs QDs are embedded in a *p-i-n* diode and may be electrically tuned across the cavity resonance. As the radiative lifetime (T_1) is too fast to resolve with conventional detectors, we develop a double π-pulse resonance fluorescence (DPRF) technique. As the inter-pulse separation is scanned, the RF signal recovers exponentially with T_1. When the QD is resonant with the cavity, T_1 is 27 ps (Fig. 1(a)), corresponding to a record-high F_P of 35. The short T_1 and near-radiatively-limited coherence ($T_2 = 2T_1$) are verified by a large (~95 %) sub-natural linewidth resonant Rayleigh scattering (RRS) [5] component under weak continuous excitation (Fig. 1(b)). Whilst this super-natural linewidth indicates excellent coherence of the emission, the weak excitation limit means that the process is fundamentally inefficient and cannot operate "on-demand".

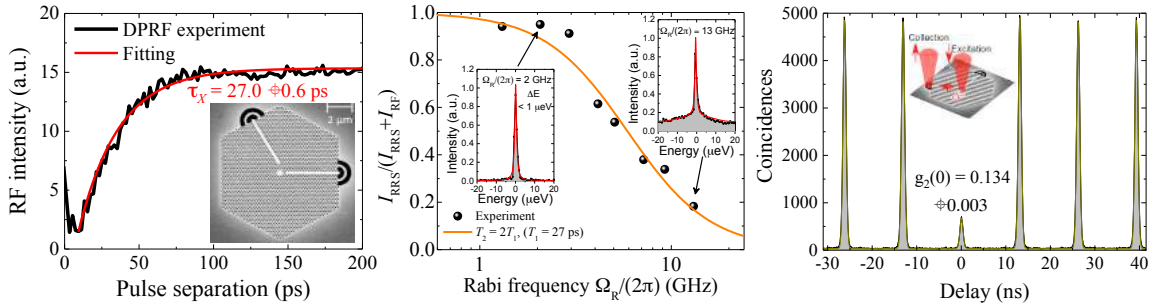

Figure 1. (a) DPRF signal versus pulse separation. An exponential fit (red line) gives T1 of 27 ps. Inset: SEM image of an H1 PhCC coupled to W1 waveguides. (b) Plot of the ratio of the coherently scattered laser photons (I_{RRS}) over the total QD emission ($I_{total} = I_{RRS} + I_{RF}$) versus Rabi frequency. Orange line: Fitting with $T_2 = 2T_1$, ($T_1 = 27$ ps). Insets: QD emission under weak (left) and strong (right) continuous resonant driving. (c) $g^{(2)}(t)$ of the waveguide-coupled QD emission measured with resonant π-pulse excitation and no spectral filtering. Inset: Spatially separated excitation and collection scheme.

To demonstrate an efficient, on-demand single photon source, we perform correlation measurements on the waveguide emission under resonant π-pulse excitation. Unlike most studies to date, no spectral filtering is used, as such these measurements represent a lower-bound to the true on-chip performance of the device. A Hanbury-Brown-Twiss measurement (Fig. 1(c)) yields $g^{(2)}(0) = 0.134$ whilst Hong-ou-Mandel interference gives a two-photon interference visibility of $V = 78$ % at a delay of 2 ns, corresponding to 25 excitation cycles of the source at pulsed RF saturation. This indistinguishability exceeds all QD-based on-chip sources to date, indicating a clear path toward fully-integrated chip devices for QIP. In addition, the short radiative lifetime demonstrated here also lends itself to other important QIP proposals such as fast single photon switching and photonic cluster state generation.

Quantum Emitters in Flatland

Igor Aharonovich
School of Mathematical and Physical Sciences, University of Technology, Sydney
corresponding author: igor.aharonovich@uts.edu.au

Abstract - Engineering solid state quantum systems is amongst grand challenges in engineering quantum information processing systems. While several 3D systems (such as diamond, silicon carbide, zinc oxide) have been thoroughly studied, solid state emitters in two dimensional (2D) materials have not been observed. 2D materials are becoming major players in modern nanophotonics technologies and engineering quantum emitters in these systems is a vital goal.

In this talk I will discuss the recently discovered single photon emitters in 2D hexagonal boron nitride (hBN). I will present several avenues to engineer these emitters in large exfoliated sheets using ion and electron beam techniques. Density functional theory calculations suggest that that the studied defects are the antisite nitrogen vacancy in hBN. The formed emitters in 2D hBN flakes have extremely promising properties – including high brightness (~ millions counts/s), stability up to high temperatuers and linear polarization at excitation and absorption. Those properties make these emitters extremely attractive for their integration with optical resonators and waveguides. Finally, I will discuss several challenges and promising directions in the field of quantum emitters and nanophotonics with 2D materials and other wide band gap materials.

Infrared single-photon detection with superconducting nanowires

Abstract- Single photon detectors based on superconducting nanowires have emerged as a highly promising alternative for single-photon detection. These devices offer single photon sensitivity from visible to mid infrared wavelengths with high efficiency, low dark counts and tens of picoseconds timing resolution. We discuss recent advances in device design, integration and miniaturized cooling. We give an overview of applications where these devices are now being deployed, including optical quantum information processing, single photon remote sensing and dosimetry for laser medicine.

The ability to detect single photons underpins a host of emerging 21st century scientific and technological applications. Over the past decade, superconducting nanowire single photon detectors (SNSPDs) [1] have emerged as a practical alternative to off-the-shelf photon counting technologies such as photomultipliers (PMTs) semiconductor single-photon avalanche diodes (SPADs). The canonical SNSPD device consists of a narrow superconducting wire patterned via electron beam lithography in a thin superconducting film. The device is cooled below the superconducting transition temperature and biased close to the critical current. When an infrared photon (energy ~1eV or even lower) strikes the wire, the current distribution is perturbed triggering a fast voltage pulse which can be rapidly read out with room temperature electronics. Major avenues of development include scale up from single pixel SNSPDs to large area arrays [2], integration with optical waveguides [3] and nanoantennas [4]. At the University of Glasgow we are employing novel superconducting materials and advanced nanofabrication techniques to realize these designs [figure 1 (a),(b)]. We are using a suite of advanced characterization tools, including low temperature photoresponse mapping to characterize these devices from near to mid infrared wavelengths. In tandem our group are addressing the challenge of practical device operation at cryogenic temperatures. We have recently partnered with STFC Rutherford Appleton Laboratory to realize a miniaturized 4 K cooling platform for SNSPDs [figure 1 (c)].

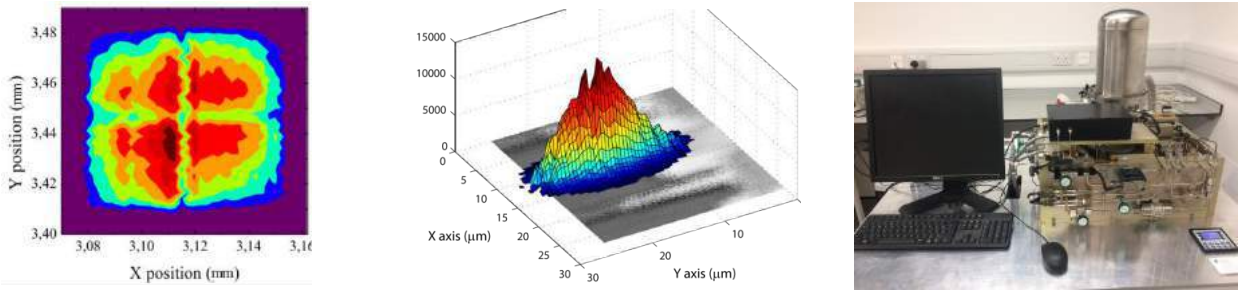

Figure 1 SNSPD development at the University of Glasgow (a) photoresponse map of 60 μm x 60 μm area four-pixel SNSPD array with peak detection efficiency >40%. (b) waveguide integrated SNSPD (c) miniaturized 4 K cooler for SNSPDs

In collaboration with UK and international partners we are deploying SNSPDs in a wide range of advanced photon counting applications. Recent examples of groundbreaking implementations include quantum communication networks [5], on-chip quantum information processing [6], single photon remote sensing [7] and singlet oxygen luminescence dosimetry for photodynamic therapy in the treatment of cancer [8].

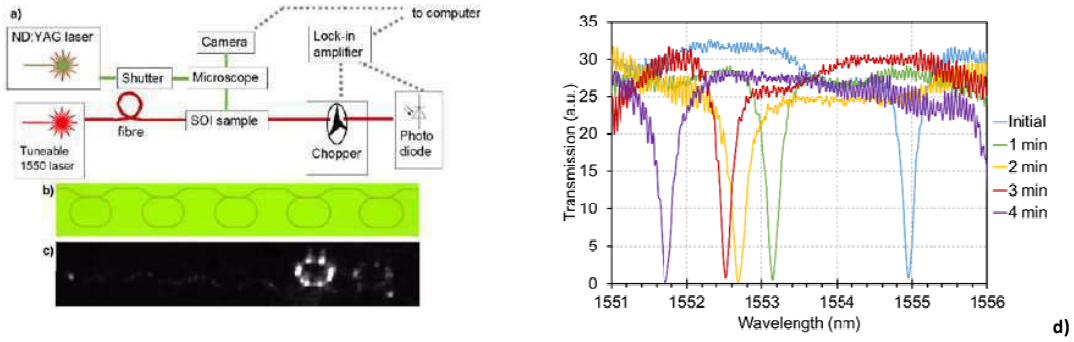
Abstract-Future photonic integrated chips for quantum experiments will demand several thousand of components and a number of diverse functionalities integrated on the same chip. We will discuss some of the challenges faced by the up-scaling of photonic integrated chips with a particular emphasis on robust component trimming and heterogeneous integration of III-V devices on a silicon-on-insulator platform.

The rapid increase in the complexity of quantum experiments demands a shift from bulk optics experiments to integrated circuits that can offer larger stability, compactness and low cost. Amongst the various material platforms, silicon-on-insulator (SOI) is of particular interest thanks to its large third-order nonlinearity, technological maturity and potential for large scale manufacturing. Moreover, its large index contrast allows for the design of very small bend radii that translates into high component density, with figures already exceeding thousands of components per chip[1,2].

However, component numbers and functionalities cannot indefinitely scale up if a number of issues are not effectively addressed. These include the development of algorithms, technologies and designs to mitigate the fabrication process variability, as well as manufacturing processes that allow wafer scale heterogeneous integration. The latter is of particular relevance to all those applications that require components such as optical sources, which cannot be provided by silicon. Here, we will focus on recent advances on trimming of silicon photonic components in complex circuits and on back-end integration of III-V membrane lasers by transfer printing.

An effective way to trim optical components is to thermally cure a cladding layer on top of the silicon waveguide as a means to permanently change the effective index of the optical mode. We will discuss trimming techniques that offer long-term stability and wide tuning range through localised laser irradiation of the upper cladding (see Fig. 1).



Figures 1 a) Schematic of experimental set-up for localised trimming of SOI components using a frequency-doubled

ND:YAG laser. b) Micrograph of a racetrack resonator array and c) Racetrack array viewed in the infra-red while light is scattered from rings at resonance. d) Transmission spectra of a SOI racetrack resonator following thermal curing at 250℃ at 1 minute increments.

We will also present results on the transfer printing of III-V membrane devices onto silicon substrate with sub-micrometer positioning accuracy[3]. A notable advantage of this method, other than its scalability and precise alignment is the flexibility of the process. In fact, the bonding occurs after device fabrication, thus allowing independent fabrication processing of III-V and SOI wafers. Also, many different III-V membrane devices can be printed onto the SOI host substrate, with the potential for a wide range of heterogeneously integrated photonic devices. One such example is the integration of membrane materials with large Pockels coefficients for the development of ultra-fast electro-optic modulators.

Abstract The future of information processing relies on the rapid manipulation of spin states. Thereupon, we present a novel, non-invasive way to change the spin order of the model ferrimagnet Yttrium Iron Garnet on ultrafast time scales, while keeping its electronic ground state unperturbed. Here, the resonant excitation of high-frequency optical phonons reveals a coupling of lattice vibrations to the spin order within few picoseconds, leading to a novel quasi-equilibrium state of the magnetization that survives for several nanoseconds.

One of the goals of contemporary research is to unveil the fundamental interaction mechanisms of electrons, spins and lattice degrees of freedom in condensed matter. Among them, spin-lattice interaction determines how fast energy and angular momentum is transferred between electron spins and ionic motion. It plays a central role in ultrafast magnetization switching where the crystal lattice acts as the ultimate sink of spin angular momentum[1]. In addition, it is highly relevant for the spin Seebeck effect[2]. The remarkable attention also arises from an application point of view for magnetic data storage technology or future spintronic devices. Surprisingly, despite such wide-area importance, spin-lattice interaction in magnetic solids is still not completely understood.

To reveal the essence of spin-lattice coupling, we reduce the complexity of interactions in a magnetically ordered solid by selectively exciting few optical lattice modes of an insulator in which the electronic degrees of freedom are frozen out. More precisely, we resonantly pump the high-frequency oxygen-iron phonon modes (at ~17 THz) of the insulating two-sublattice ferrimagnet $Y_3Fe_5O_{12}$ (YIG) using intense THz pump pulses (fluence of ~50 mJ/cm , duration of ~200 fs). As the pump photon energy (80 meV) is much smaller than the electronic band gap (2.85 eV), such pumping enables the exclusive excitation of phonons, while leaving the electrons unaffected in their ground state. A subsequent weak probe pulse (duration of 8 fs, photon energy of 1.6 eV) interrogates the transient magnetization change by means of Faraday rotation and ellipticity, on time scales ranging from tens of femtoseconds to hundreds of microseconds.

We find an unexpectedly fast quenching of the transient Faraday signal with a time constant as short as (1.4±0.2) ps. The resulting novel magnetization state persists over a timescale of nanoseconds. Given the long spin-lattice relaxation times in YIG (nanoseconds to microseconds)[3], the observation of such fast phonon-mediated spin dynamics is highly surprising, and indicates a highly efficient energy transfer between ion lattice and spins. Additional temperature dependent measurements suggest distinctively different time scales for

energy and angular momentum transfer between the major part of phonons and the spins. We also present atomistic spin dynamics simulations[4], confirming the scenario of ultrafast inter-sublattice angular momentum transfer. Furthermore, a comprehensive thermodynamic model is presented in order to describe a novel quasi-equilibrium state of the magnetic order accessible via phonon excitation.

Our findings not only give insights to energy and angular momentum transfer between crystal lattice and spins, they also pave the way for spin Seebeck effect based devices operating at THz frequencies and provide implications for the emerging field of antiferromagnetic spintronics[5].

Ellipsometric analysis of magneto-optical effects in thin films, nanostructures and spin transport devices

P. Riego[1,2], J. A. Arregi[1], and A. Berger[1*]
[1]CIC nanoGUNE, E-20018 Donostia-San Sebastian, Spain
[2]Departamento de Física de la Materia Condensada, Universidad del País Vasco, E-48080 Bilbao, Spain

Abstract - We investigate experimentally in how far optical property modifications change magneto-optical responses in films, multilayers and nano-structures. For this purpose, we utilize Generalized Magneto-optical Ellipsometry (GME), a technique that combines high sensitivity of small magneto-optical signal detection with the ability to simultaneously determine both optical and magneto-optical properties by means of a simple experimental setup. Application examples include the detection of magneto-optical anisotropy, optical anisotropy, including in artificial meta-materials, and the investigation of spin transport effects.

Over the last decades, the magneto-optical Kerr effect (MOKE) has gained widespread popularity as a characterization tool for the study of magnetic materials, films and nanostructures [1], and more recently it has been applied also in conjunction with plasmonic structures and devices, for which it allows a magnetic field induced signal modulation [2]. Reasons for its increased popularity are hereby the rather low cost of experimental setups as well as its non-destructive nature and the compatibility with almost any environment. In most experimental approaches, the magneto-optical Kerr effect is measured by using a polarization sensitive detection scheme that is tuned to achieve an optimized sensitivity to at least one MOKE impacted optical property, such as polarization rotation, for instance [1]. While such setups generally achieve excellent sensitivity, they do not track the entirety of available information in reflection experiments and thus, they can be susceptible to data misinterpretation. This is especially relevant in highly excited optical states, such as pump-probe experiments or nano-structured materials, in which temporal or structural modifications lead to variations of not only the magneto-optical effect but also the purely optical response.

Under such circumstances, it is crucially important to fully characterize the optical and magneto-optical properties of the object under investigation, which is possible by means of Generalized Magneto-optical Ellipsometry (GME). This technique combines a high sensitivity of small magneto-optical signal detection with the ability to determine full reflection or diffraction matrices by means of a simple experimental setup [3]. Several examples of its successful application include the detection of magneto-optical anisotropy in films, the detection of optical anisotropy in ferromagnetic grids, and the analysis of Spin Hall Effect induced signals in non-ferromagnetic materials [4-7].

Extending Magneto-Plasmonics to the Mid IR by the use of the Magneto Refractive effect.

Alfonso Cebollada*, Fernando García, and Gaspar Armelles
IMM-Instituto de Microelectrónica de Madrid (CNM-CSIC), Isaac Newton 8, PTM, E-28760 Tres Cantos, Madrid, Spain

Abstract- Magnetoplasmonics combines plasmonic and magneto optic effects, making them to interact and finding great potential in sensing and telecom applications. While this has been so far restricted to the visible and Near IR, here we extend this concept to the Mid IR by substituting the magnetooptic by the magnetorefractive effect (change of refractive index due to magnetic field induced change in electrical resistivity), most effective in the 5-10 microns range. Possible applications of this idea will be introduced.

Plasmonics has proven as a powerful tool to improve the performance of mid-IR devices, resulting in plasmon assited quantum cascade lasers, plasmon enhanced light detection, plasmonic beam steering, plasmonic thermal emiters or plasmonic nanoantenas for vibrational spectroscopy. In this scenario, the possibility of modulating the emission, propagation and/or detection of mid-IR radiation constitutes a promising aspect to expand the limits of the currently used technologies. In this sense, fast and contactless actuation on plasmon resonances via the Magneto-Optical (MO) effect has been put forward by the inclusion of ferromagnetic components into noble metal layers and nanostructures. This magneto-plasmonic concept so far has been restricted to the visible and near-infrared spectral ranges.

Here we present our proposal and initial results on the magnetic field control of plasmon resonances in the mid IR region by the use of the Magneto-Refractive (MR) effect, i.e., a change in the optical properties of the system by magnetic field controlled electrical resistivity. For this we select a Giant Magneto Resistance model system (a Au/Permalloy multilayer), which exhibits changes in resisitivity of the order of 10% by the application of small (of the order of 20 Oe) magnetic fields.

The experiments are carried out in a dedicated FTIR spectrometer with magnetic field capabilities. Due to the low magnetic fields required for the selected GMR structures, it is conceivable to devise potential and easy to implement applications with magnetic field modulation character, improving for example current Mid IR sensing schemes.

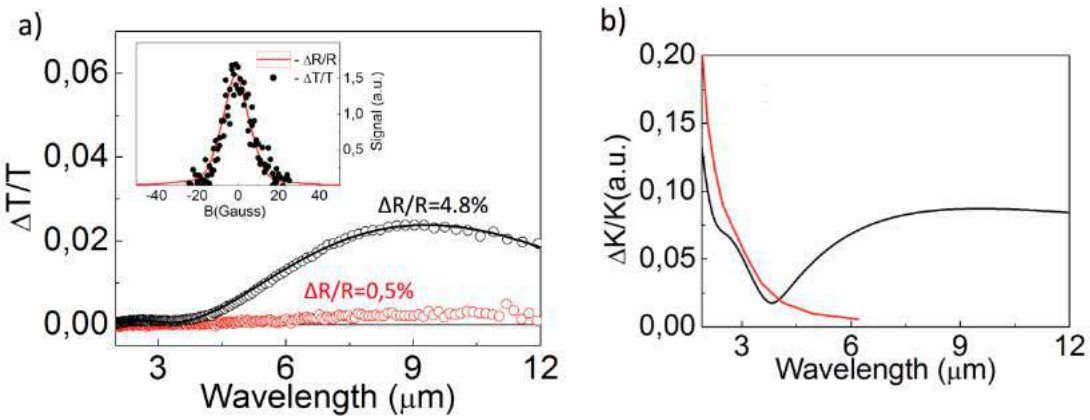

Figure 1: (a) Transmission spectra for two samples with different GMR values (4.8% and 0.5%). INSET: Magnetic field dependence of electrical resistance and integrated transmission in the mid IR region for the 4.8% GMR structure. (b) Calculated magnetic field modulation of propagating plasmons via MO effect (red) and MR effect (black). The modulation is similar for both MO and MR effects up to 3.5 μm, but it is much larger for the MR effect in the whole mid IR range.

Abstract-We report on magnetic properties of a new class of inherently nanolaminated materials: magnetic MAX phases. Hexagonal atomically layered MAX phases show exclusive mechanical properties and anisotropic thermal and electrical conductivities. These systems are parent materials of graphene-like transition metal carbides, known as MXenes, which are predicted to be future 2D magnetic materials extending the unique properties of graphene. Magnetic properties of new magnetic MAX phases are presented: magnetic ordering temperature, spin structure, saturation magnetization, magnetocrystalline anisotropy and magnetoresistance.

MAX phases are a family of hexagonal, nanolaminated compounds with the chemical formula $M_{n+1}AX_n$ (n = 1-3) composed of early transition metals *M* (Ti, V, Cr …), *A*-group elements (Al, Ga, Ge …) and *X* (C or N) [1]. Due to their unique structure these materials share properties of ceramics such as high structural stiffness and metals such as good electrical and thermal conductivity [1]. The new class of magnetic MAX phases has been recently discovered substituting or composing the *M*-element by/with Mn in quaternary solid solutions. Also ternary Mn_2GaC magnetic compounds have been synthesized as hetero-epitaxial films containing Mn as the exclusive *M*-element [2]. Significant interest in these systems is rising due to a recently discovered possibility of delamination of layered MAX phase structures leading to 2D graphene-like transition metal carbides and nitrides $M_{n+1}X_n$, known as MXenes [3]. Mn-based MXenes are predicted theoretically to be intrinsic half-metals with full spin polarization and above room temperature ferromagnetism [4].

We report on magnetic and electrical transport properties of recently synthesized magnetic MAX phases. Magnetometry and ferromagnetic resonance (FMR) reveal ferromagnetic (FM) properties of $(Cr_{0.5}Mn_{0.5})_2GaC$ and $(Mo_{0.5}Mn_{0.5})_2GaC$ at temperatures below 220 K. The saturation magnetization is on the order of 0.7 μ_B per M-atom. Both compounds behave as soft magnetic materials possessing small *c*-axis magnetocrystalline anisotropy energy density (MAE) below 5 kJ/m^3 [5-6]. Mn_2GaC at room temperature is antiferromagnetic (AFM) with a Néel temperature of approximately 600 K. At T = 240 K the system undergoes a phase transition to a canted noncollinear spin state [2]. This state is characterized as a metamagnetic state, in which the magnetic field causes a change of the lattice parameters and FM spin alignment. FM Mn_2GaC has a MAE of 40 ± 10 kJ/m^3 with the easy axis perpendicular to the *c*-axis and saturation magnetization of 1.7 μ_B per Mn atom at T = 5 K. All compounds show negative magnetoresistance of about 5% originating from spin-dependent scattering of electrical charge carriers.

Functionalized Hybrid Nanomagnets: New Materials for Innovations in Energy Storage and Medical Theranostics

Imagine a future in which food is used to activate specific immune reactions in a human body based on an external noninvasive magnetic stimulus. Dream of a material that stores and releases energy reversibly by temperature changes between day and night. These visions may be realized by using magnetic nanoparticles that are functionalized to be biocompatible, environmentally stable and recyclable, self-healing, and low-cost.

In this presentation I will discuss the basic concepts of magnetic nanomaterials and their magnetic properties with a focus on how to tune specific parameters in a controlled fashion to achieve the dreams of the future. I will highlight state-of-the-art experimental technologies that allow us to understand microscopic properties and interactions in relation to electronic structure changes caused by changes in size, shape, and composition of nanomaterials. Then I will discuss how this understanding is used when nanomagnets are functionalized for targeted drug delivery or composed to form macroscopic materials for new energetic applications like magnetic refrigeration. I will demonstrate that the seemingly complex behavior of hybrid metal/metal, metal/oxide, or oxide/oxide interface materials can be understood from the three fundamental interactions in magnetism: magnetic exchange interaction due to orbital overlap, spin-orbit interaction due to inner- and intra-atomic relativistic corrections (e.g., crystal field effects) and the long-range magnetic dipolar interaction. Several examples will be presented, including the formation of above-room-temperature ferromagnetic interface layers between low-temperature antiferromagnetic layers and the evolution of lattices of magnetic textures (skyrmions) in confined dimensions. The talk will end with an episode in the life of an imaginary golf-playing couple in the year 2040 who use their "Smart Magnet" (SMAG) phone to energize and heal their bodies on the green.

Nach Vortrag Diskussion bei Bier und Brezeln. Eine mögliche Nachsitzung wird mündlich angekündigt.

Abstract-Long range dipole-dipole correlation in a ferrimagnetic sample can be treated in terms of collective excitations of the system as a whole. Ferrite samples with linear dimensions smaller than the dephasing length, but still much larger than the exchange-interaction scales, are mesoscopic structures with magneto-dipolar-mode (MDM) oscillations. Recently, it was shown that thin-film yttrium-iron-garnet (YIG) disks, distinguishing by multiresonance MDM spectra, demonstrate unique properties of artificial atomic structures: energy eigenstates and eigen power-flow vortices. Because of these properties, MDMs in a quasi-2D ferrite disk enable strong confinement of microwave radiation to subwavelength scales. In microwave structures with embedded MDM ferrite samples, one can observe quantized fields with topologically distinctive characteristics. These fields are termed magnetoelectric (ME) fields. ME fields are characterized by the helicity parameter which is a pseudoscalar. Newly developed capabilities in microwave sensing using ME probing fields originated the MDM ferrite samples, provide a potential for unprecedented measurements of chiral materials and biological objects with chiral structures.

Subwavelength confinement of light via electrostatic plasmonic resonances has found more demand and has become an important issue in many research fields including integrated photonics, spectroscopy, biological photonics, chemical studies, and so on. In microwaves, however, the effects of the electromagnetic subwavelength confinement due to quasistatic oscillations have not been studied sufficiently. In a series of recent publications [1 – 5], it was shown that small ferrite-disk particles may have unique spectral properties of MDM oscillations and the near fields originated from such particles are microwave chiral fields with strong subwavelength localization of electromagnetic energy.

At microwave frequencies, the spectral properties of the MDM resonances are analyzed based on the Walker equation for magnetostatic-potential wave function. In a normally magnetized quasi-2D ferrite disk, one has real-eigenvalue spectra for scalar wave functions. For such a quasi-Hermitian eigenvalue problem, the analytical spectral solutions can be obtained. Because of special dynamics of the magnetization motion in a ferrite disk, characterizing by symmetry breakings, small ferrite particles with MDM spectra originate near fields with unique topological properties. We term these fields magnetoelectric (ME) fields. The ME fields are characterized by helical structures and power-flow vortices. For incident EM waves, the vortex topological singularities act as traps, providing strong subwavelength confinement of the microwave fields. It appears that a vortex may turn out to generate a “radius of no return", beyond which the incident EM fields falls inevitably towards the vortex singularity. In such a case, the MDM vortex becomes an EM “black hole" in microwaves.

It was shown [6] that at MDM resonances, RF magnetization in a quasi-2D ferrite disk is distinguished by nonzero product $\vec{m}\cdot\left(\nabla\times\vec{m}\right)^{*}$. This pseudoscalar parameter, characterizing the way in which the field lines of magnetization curl themselves, we call magnetization helicity parameter. The magnetization helicity parameter defines the helicity parameters of the ME near fields: $F=\frac{\varepsilon_0}{4}\mathrm{Im}\left[\vec{E}\cdot\left(\nabla\times\vec{E}\right)^{*}\right]=\frac{\omega\varepsilon_0\mu_0}{4}\mathrm{Re}\left(\vec{E}\cdot\vec{H}^{*}\right)$. This gives evidence for the presence of mutually parallel components of the electric and magnetic fields in the ME-field structure. The ME fields, being originated from magnetization dynamics at MDM resonances, appear as the fields of axion electrodynamics. In axion electrodynamics, the coupling between an axion field and the electromagnetic field is expressed by an additional term in the ordinary Maxwell Lagrangian $L_{\vartheta}=\kappa\vartheta\vec{E}\cdot\vec{B}$, where ϑ is an axion field and κ is a coupling constant. The axion field ϑ transforms as a pseudoscalars under space reflection *P* and it is odd under time reversal *T*. MDMs in a quasi-2D ferrite disk are microwave energy-eigenstate oscillations with topologically distinct structures of rotating fields and unidirectional power-flow circulations. The active power flow $\vec{P}=\frac{1}{2}\mathrm{Re}\left(\vec{E}\times\vec{H}^{*}\right)$ has vortex topology. The orbital angular-momentum density of the field is expressed as $\vec{L}=\frac{1}{2}\mathrm{Re}\left[\vec{r}\times\left(\vec{E}\times\vec{H}^{*}\right)\right]$, where $\vec{r}$ is a radius from the disk axis. For a given direction of a bias magnetic field, the power-flow circulations are the same inside a ferrite and in the vacuum near-field regions above and below the disk.

Newly developed capabilities in microwave sensing using ME probing fields originated from multiresonance magnetic-dipolar-mode (MDM) oscillations in quasi-2D YIG disks, provide a potential for unprecedented measurements of chemical and biological objects. Recently, microwave sensors based on ME fields were effectively used for chirality discrimination in enantiomeric liquids [7].

Abstract The manipulation of the magnetization with sub-picosecond laser pulses is attractive for potential information storage device applications. Some magnetic materials can already be switched solely by the effect of a laser pulse, without any external magnetic field involved. First, such effects were demonstrated for ferrimagnets but recently also for layered, synthetic ferrimagnets and even for ferromagnets. In this talk we investigate all-optical switching theoretically. We employ multi-scale models linking *ab initio* methods with spin models and mesoscopic theories to explore the spin dynamics, which is triggered by the laser pulse, and to distinguish thermal heating effects from opto-magnetic effects, such as the inverse Faraday effect.

The term all-optical switching (AOS) refers to the fact that some magnetic materials can be switched solely by the effect of a femtosecond laser pulse, without any applied magnetic field involved. Experimentally, such effects were demonstrated for ferrimagnets [1-3] but later also for layered, synthetic ferrimagnets [4] and recently even for ferromagnets [5].

We use a multi-scale approach linking ab-initio calculation for the parameterization of an atomistic spin model with spin dynamics simulations based on the stochastic Landau-Lifshitz-Gilbert equation, to investigate the spin dynamics of the ferrimagnets FeGd and $DyCo_5$, synthetic ferrimagnets consisting of antiferromagnetically coupled bilayers of Fe and Gd, as well as the ferromagnet FePt.

While many aspects of the thermally induced switching in FeGd have been uncovered [1, 2, 3, 6] alternative materials are less understood. In this context, $DyCo_5$ is a very interesting material displaying a reorientation transition. With our model, we are able to compute the complex temperature dependence of the magnetization. The simulations yield a Curie temperature of 1040K and a compensation point at 115K. The spin-reorientation transition is a consequence of competing magneto-crystalline anisotropies in connection with different degrees of thermal demagnetization in the Dy and Co sublattices. We explore the dynamics of the reorientation transition on ultra-fast time scales and in how far this transition affects the thermally induced switching.

For synthetic ferrimagnets we demonstrate and investigate thermally induced magnetic switching. Our findings show that deterministic magnetization reversal occurs above a certain threshold temperature if the ratio of transition metal atoms to rear-earth atoms is sufficiently large. Surprisingly, the total thickness of the multilayer system has little effect on switching. We further provide a simple argument to explain the temperature dependence of the reversal process.

Furthermore, we investigate helicity dependent AOS in FePt. We employ ab initio methods to calculate the laser-power and photon frequency dependence of the inverse Faraday field [7] and the magnetic dichroism and calculate the magnetization dynamics triggered by the laser pulse via the thermal heating effect and the inverse Faraday field based on the Landau-Lifshitz-Bloch equation of

motion for high-temperature magnetization dynamics. Closer analysis suggests the inverse Faraday effect to be strong enough to serve as mechanism for helicity dependent AOS in a multi-shot experiment. Our results are verified by a comparison to recent experiments [8].

Abstract- The thermal emission and the radiative heat transfer between finite objects of arbitrary shape that exhibit magneto-optical activity, is studied using a generalization of the thermal discrete dipole approximation (TDDA).

There is an increasing interest in the study of the radiative heat transfer between nearby objects[1]. This is motivated by the experimental verification of a large enhancement when the objects are placed within the near-filed regime [2-9].

On the other hand, MO objects are of great interest in the context of near field radiative heat transfer. In particular, doped semiconductors under a magnetic field present a sizable MO activity, that can be further controlled by changing the magnitude and the direction of the field. Thus for instance, it has been demonstrated that the radiative heat transfer between two parallel plates made of doped semiconductors can be largely tuned by applying a static external magnetic field [10].

Here, we present the radiative heat transfer between finite objects of arbitrary shape that exhibit magneto-optical activity, using a generalization of the thermal discrete dipole approximation (TDDA). We also describe the thermal emission of a finite object with and without magneto-optical activity, within the same TDDA approach. We will show that employing our TDDA approach one can rigorously demonstrate Kirchhoff's radiation law relating the emissivity and absorptivity of an arbitrary magneto-optical object. Our work paves the way for the theoretical study of the active control of emission and radiative heat transfer between magneto-optical systems of arbitrary size and shape [11].

Light induced magnetization dynamics

M. Aeschlimann
Department of Physics and Research Center OPTIMAS, University of Kaiserslautern, Germany
ma@physik.uni-kl.de

Abstract- New developments in laser-based femtosecond x-ray and extreme-ultraviolet sources make it possible to probe element-specific spin dynamics in multispecies magnetic systems. These nascent optical tools therefore provide new and detailed information that is mostly not accessible by using visible light, and allow for the design of experiments that can help to identify the microscopic mechanisms of ultrafast spin dynamics. Using femtosecond soft X-ray pulses we were able to investigate the ultrafast breakdown of the magnetic coupling in heterogeneous magnetic materials.

The study of magnetism, magnetic materials, and dynamics in magnetic systems is a topic of fundamental interest in our understanding of correlated systems, as well as being directly relevant to technology and information storage. In recent years, magnetism at the ultrafast timescale has been a topic of increasing interest. A thorough understanding of femtosecond magnetism will address the important questions of how fast the magnetization can be reoriented in a material and what physical processes present fundamental limits to this speed. In the spatial domain, magnetism at nanometer length is a topic directly relevant to data storage, since future advances in this technology will require further reduction in device dimensions to increase the storage density. These considerations have motivated a variety of studies using magneto-optic effects in conjunction with ultrafast light pulses to explore these fundamental limits.

Magneto-optical dynamic studies currently make use either of visible-wavelength light from ultrafast lasers, or x-rays from large-scale synchrotron x-ray facilities. Ultrafast lasers produce short pulses (≈10fs), making possible femtosecond time resolution [1,2], but with a spatial resolution that is generally limited by the wavelength of the probe light. Femtosecond X-rays pulses, on the other hand, allow for high spatial resolution and high contrast at the elemental absorption edges of ferromagnetic materials. This is a challenging proposition, but one that can be addressed using newly developed tabletop-scale coherent light sources based on high-harmonic upconversion (HHG) of a femtosecond laser. HHG is an extreme nonlinear process that produces coherent short wavelength beams with the shortest pulse durations demonstrated to date for any light source – in the 0.1 fs to 10 fs range [3,4]. The generated harmonics extend from 10 eV to greater than 2 keV, and retain the polarization and coherence properties of the driving laser under phase-matched generation conditions. Bright HHG beams with sufficient flux for experimental applications can currently be generated with photon energies of up to ≈330 eV [4]. Past 'static' synchrotron measurements have shown that the magnetization can be probed at the M-edges of Fe, Co, and Ni, at photon energies around 55 eV to 65 eV [5]. This is an energy range that is easily accessible using HHG.

In this work, we demonstrate that ultrafast (≈10 fs), coherent, HHG beams can serve as an elementally-sensitive probe of magnetization orientation and demagnetization dynamics [6]. We also show that our measurements are sensitive to the presence of capping layers, making it possible to probe the magnetization state of buried layers and multilayer structures [7,8,9]. The significance of this work is that the ultrafast time-resolution provides a clear pathway for addressing a controversy concerning the timescales and

mechanisms associated with the ultrafast (possibly even attosecond [10]) dynamics of magnetization. The extremely short pulses provided by HHG can address both electron and spin dynamics on an equal footing, which is the prerequisite to studying the mechanisms governing coupling between the electron, spin and lattice subsystems [11]. Finally, the high harmonic source uses a tabletop femtosecond laser that is available in many laboratories worldwide. Therefore, this work represents an accessible new experimental capability for magnetic materials research. The review concludes with a summary and an outlook to the feasibility of laser control of magnetism.

Abstract- The rapidly developing field of magnetoplasmonics merges concepts from plasmonics and magnetism to realize novel and unexpected phenomena and functionalities for the manipulation of light at the nanoscale. Such new functionalities arise from the intertwined optical and magneto-optical properties displayed by magneto-plasmonic nanostructured surfaces. This talk will cover recent advances in the investigation and development of magneto-plasmonic nanostrucutres and crystals, which contributed to broaden the understanding and control of optics at the nanoscale. Applications of such multifunctional optical surfaces and metamaterials to a variety of emerging technologies are presented as an example of their broad scientific and technological perspectives.

Plasmons play a large role in the optical properties of metals. Magnetoplasmonics combines strong local enhancements of electromagnetic fields in surface plasmon excitations with magneto-optically active ferromagnetic materials, which optical properties can be controlled by external magnetic fields.

Owing to the intertwined optical and magneto-optical properties, magnetoplasmonics may offer a smart toolbox for actively tuneable optical ultrathin surfaces and metasurfaces. Here we review recent advances in the research on magnetoplasmonic nanoantennas and two-dimensional magnetoplasmonic crystals. From the one side, they contributed to broaden the understanding and control of optics at the nanoscale. From the other side, magnetoplasmonic nanoantennas and surfaces have already shown a clear path towards applications to variety of emerging technologies as, e.g., ultrasensitive molecular sensing and ultrathin optical devices.

The fundamentals aspects of the physics underlying the optical behavior of magnetoplasmonic metamaterials are first briefly introduced [1-3].

A brief survey of applications to a variety of emerging technologies are presented as an example of their broad scientific and technological perspectives, namely:

- magnetoplasmonic nanoantennas based surfaces allowing for ultra-sensitive and label-free molecular detection, which are expected to have a clear impact on biochemistry and biomedicine and are therefore subject to intense investigation [4-6];
- systems allowing for the control of non-reciprocal light propagation relying on magnetoplasmonic nanoantennas ability to tailor the amplitude and sign of light polarization over a broad spectral range [7-10];
- ultra-thin chiroptical surfaces, built on 2D magnetoplasmonic bimetallic meta-atoms, where the chiral light transmission is modulated by the externally applied magnetic field [11];
- 2D magnetoplasmonic crystals, namely plasmonic crystals made of a periodic array of holes in a ferromagnetic layer, which support surface plasmon polariton modes and display a two-dimensional photonic band structure that can be engineered to obtain tailored and enhanced magneto-optical response [12].

Thin film magnetic metamaterials

Vassilios Kapaklis

Abstract-*Lithographically nano-patterned magnetic materials can result in fascinating behaviour exploiting the interactions between individual elements creating novel functionality. The emergent properties in such systems are distinctly different from those of their constituent components, driven by the collective dynamics of the interacting elements and respond to external stimuli such as magnetic or temperature. Further functionality can be realised exploiting the fact that the periodicity and element size in such nano-patterned magnetic arrays matches well the wavelengths of visible light.*

Magnetism has for long been a fertile playground for the study of *phase transitions and dynamics*, as well as the development of elaborate theoretical tools used to describe and explain related experimental observations. This very successful approach has so far mainly focused on properties at the atomic scale and how these result in macroscopic observations, such as magnetic order and magnetization dynamics. Here *we propose a paradigm shift and the study of magnetic phase transitions and dynamics at mesoscopic length-scales*, using interacting ferromagnetic nanostructures of size inferior to the magnetic domain in two-dimensional nanopatterned arrays. These systems exhibit similar phase transitions and dynamics but on different length- and energy-scales, providing also the possibility for direct real-space characterization using a variety of modern magnetic imaging techniques[1]. Furthermore, the mesoscopic length-scales involved, matching well the wavelengths of visible light, present an unprecedented opportunity for the development of new routes to manipulate light with magnetism or vice versa, through plasmons.

Novel functionality can appear in nature from the combination of a large number of interacting elemental building blocks[1]. An example of this are solid materials, where atoms through bonding interactions crystallise in a variety of different structures that define their mechanical, thermal, electronic, magnetic and optical properties. Physicists have attempted to describe and predict such phenomena using models, such as the famous Ising model, where the geometry, interactions and temperature are taken into account providing a route for the identification of phase transitions in real materials. Using the basic concepts of such models, it is possible to engineer condensed matter systems based on thin films that are patterned and consist of a large number of ferroic components that interact (with magnetic dipolar interactions) with each other and result in new functions and properties. The studies of these artificial model systems and their many- particle interactions have grown exponentially in the last few years. It has been demonstrated that these interactions dictate the magnetic order and switching of individual building blocks on surprisingly large length-scales[2-4]. This approach benefits from a further advantage: all the parameters in the Hamiltonian that describes the system can be varied at will during fabrication, resulting in the epithet '*designer matter*'.

Out of the variety of systems that can be designed in this meta-material approach, one of particular interest is *artificial spin ice*, named after their real material analogue, spin ice. Artificial spin ices are lattices of nanomagnets, mimicking the proton arrangement around oxygen atoms in crystalline water ice and arranged

such that their mutual interactions are frustrated, leading to a rich phenomenology associated with the fact they can take up a huge number of reconfigurable metastable states. Artificial spin ice structures can furthermore be directly imaged using real-space techniques. This facilitates the direct determination of their microscopic states experimentally and comparison to well established statistical mechanical models. These systems therefore provide an ideal platform for the investigation of ground state ordering in the presence of frustration[4] and excitations[4,5]. In addition excited states in artificial spin ice possess effective magnetic charges ('monopoles') which might be useful as a new carrier of information[5].

Furthermore, such 2D patterned surfaces (metasurfaces) can affect the polarization/phase of free propagating light – just as the magneto-optical (MO) effects in magnetic materials[6]. The combination of plasmonics, metasurfaces and magnetic materials allows for new perspectives in the long-sought functionality for waveguiding and light manipulation[6-8]. Our developed far-field methodologies already allow for the control of plasmons and their propagation using low magnetic fields and enhancement of the magneto-optic activity due to plasmons[9]. Furthermore, it might also be a possible route for controlling the magnetic state and excitations in material using light that has been "trapped" on metasurfaces through plasmons.

Abstract- We experimentally demonstrate all-optical helicity-dependent switching (AO-HDS) of magnetization in hybrid metal-ferromagnet thin films, showing very robust AO-HDS effect for a wide range of laser repetition rates and peak powers. The hybrid metal-ferromagnet structures exhibit smaller coercivity and smaller remanent magnetization compared with the bare ferromagnet film, which may facilitate the pronounced HD-AOS feature. This work paves a critical step towards future high-speed, low-power and high-density memory and storage technologies.

The emerging Big Data Era demands the ever increasing speed and capacity of processing and storing information. Recent research has shown that it is possible to use femtosecond circularly polarized laser to switch the magnetization in certain magnetic materials. This helicity-dependent all-optical switching (HD-AOS) was initially discovered in ferrimagnetic systems involving rare-earth elements [1-5], and very recently extended to ferromagnetic materials such as CoPt multilayers [6-7]. Most remarkably, such an extremely fast and novel reversal mechanism does not require an external magnetic field existing in conventional magnetic storage devices such as hard disk drives, and potentially could increase the data storage speed by three orders of magnitude. However, the fundamental mechanism of HD-AOS is still not fully understood [8,9]. In addition, nanoscale optical control of magnetization for high-density storage remains very challenging because of the diffraction limit in classical optics.

Plasmonic nanostructures made of noble metals, such as gold and silver, enable to confine light into deep subwavelength scales and meanwhile significantly increase the local field intensity [10,11]. In order to realize all-optical magnetic switching with lower power and higher density for future memory and storage devices, it has been proposed to combine plasmonic structures with advanced magnetic materials [12,13]. Towards this goal, in this talk we present the HD-AOS effect of CoPt multilayers coated with an additional gold thin film. We demonstrate that this hybrid metal-ferromagnet system exhibits pronounced HD-AOS. We have conducted systematic optical characterizations to explore the dependence of HD-AOS on different repetition rates and peak powers. It is found that better HD-AOS results can be observed for higher repetition rates. By varying the laser power, we have observed the CoPtAu thin films exhibit HD-AOS with a wide range of the threshold fluence (estimated to be larger than 360.5%). This is a significant increase compared with the previous reported results in GdFeCo alloy films [14], which shows HD-AOS only for a narrow window of threshold fluence (estimated to be 1.5%). To reveal the underlying mechanism, we have measured and compared the hysteresis curves of different samples. The hybrid magneto-plasmonic structures show smaller coercivity and smaller remanent magnetization compared with CoPt multilayers, which may be the cause of the pronounced HD-AOS feature [15]. Leveraging

these findings, we have also integrated plasmonic nanostructures with CoPt multilayers. Preliminary results of the plasmonic effect on HD-AOS are obtained.

Abstract-The magneto-plasmonic interaction is revealed in 0D, 1D- and 2D magnetic nanostructures. The magneto-optic response is examined in the presence of localized surface plasmons, of propagating surface plasmons and in the geometrical percolation limit. The role of the thickness of the magnetic layer is clarified. Finally, the influence of surface plasmons on the magnetization dynamics is discussed.

The field of magneto-plasmonics is an emergent research field that aims to explore the combination of magnetic and plasmonic functionalities in patterned nanostructures [1, 2]. The presence of magnetic materials in plasmonic structures offers the possibility to influence plasmonic resonances with the magnetization and an external magnetic field. The presence of surface plasmons in magnetic nanostructures on the other side, can boost the magneto-optic response [3].

In this work we show the evolution of the magneto-optic enhancement in zero, one and two dimensions (0D, 1D and 2D) magneto-plasmonic structures. We use Au nanoparticles, Au gratings and Au antidot structures in combination with magnetic films to study the enhancement factor of the polar, longitudinal and transverse Kerr effect. As magnetic films, Yttrium Iron Garnet (YIG) and Co layers are used.

We demonstrate the different degree of magneto-plasmonic interaction when localized surface plasmons (LSPs) or propagating surface plasmons (SPPs) are excited. Furthermore, we reveal the effect on the magneto-optical effects around the dimensionality crossover from 0D to 2D. The transition from LSPs to SPPs is achieved close to the geometrical percolation limit.

We correlate the magneto-optic interaction not only with respect to the transition from LSPs to SPPs but also to the dimensionality of the magnetic layer. The thickness of the magnetic layer plays a decisive role [4]. We present that the spectral features of the magneto-optic enhancement does not only depend on the in-plane structuring of the sample but also on the out-of-plane geometrical parameters, such as the thickness of the magnetic layer.

We furthermore explore how the presence of LSPs and SPPs is modifying the magnetization dynamics of the magnetic layer.

Abstract-We have investigated surface plasmon-polaritons in graphene-antiferromagnet layered structure. We show the possibility of resonant interaction of the graphene surface plasmon-polaritons with the magnons of antiferromagnet.

Nowadays, in plasmonics great researchers attention is paid to investigation of graphene-based nanostructures and perspectives of its applications in data processing and storage devices[1]. In our recent works we have considered some graphene-containing structures. Some interesting results on speckle-pattern rotation in graphene-coated optical fibers[2], surface plasmon manipulation by magnetic field in the planar gyrotropic waveguide formed by two graphene layers[3], plasmonically induced magnetic field and Faraday rotation of high order modes in graphene-covered nanowires[4, 5] have been obtained.

In this work surface plasmon-polaritons in dielectric – graphene – antiferromagnet structure is investigated. We assume that dielectric is non-dispersive one, antiferromagnet is centrosymmetric few-sublattice magnet (of rhombic symmetry) with exchange spin excitations of electroactive type. Eigen frequencies of exchange modes correspond to infrared and visible spectrum ranges (for example, $YBa_2Cu_3O_{6+x}$, α-Fe_2O_3). Frequency-dependence of graphene conductivity is taken into account.

Calculations are carried out in assumption of decaying length of surface electromagnetic wave is much greater than the lattice constant and phenomenological method may be used. Properties of the structure are depending on dielectric permittivity tensor of antiferromagnet and graphene conductivity.

Different propagation directions of electromagnetic wave with respect to antiferromagnet crystal orientation are considered. Dispersion equations and conditions of excitation of TM- and TE- waves and components of electromagnetic field are obtained. It is shown, that TE- waves, which are non-existing without graphene, may propagates in the structure when some relations between parameters of mediums are satisfied in frequency ranges of exchange modes of antiferromagnet.

Abstract-In order to explore the non-reciprocal effects, we investigate topological magnetic nanostructures covered with graphene-based meta-surfaces, which consist of a periodic pattern of sub-wavelength stripes of graphene winding around magnetic (meta-)tube or (meta-)torus. We establish the relation between the topological and plasmonic properties in these structures. Elliptical and hyperbolic magneto-plasmonic Fabry-Perot resonances in meta-structures not only manifest the non-reciprocity but display the giant mode splitting.

In recent years, enormous attention of researchers has been paid to metasurfaces, i.e. an artificially created one-layer lattice consisting of sub-wavelength size elements (so-called "meta-atoms") [1-4]. Recently, we have shown that cylindrical graphene-based waveguide filled by gyrotropic (or magnetized) medium demonstrate the giant Faraday rotation of high-order plasmonic modes spiraling around the nanowire axis [5]. Here work we focus on the non-reciprocal cylindrical magneto-plasmonic waveguides based on rolled graphene meta-surfaces (meta-tubes) as well as the finite-length structures serving as meta-cavities (see Fig. 1).

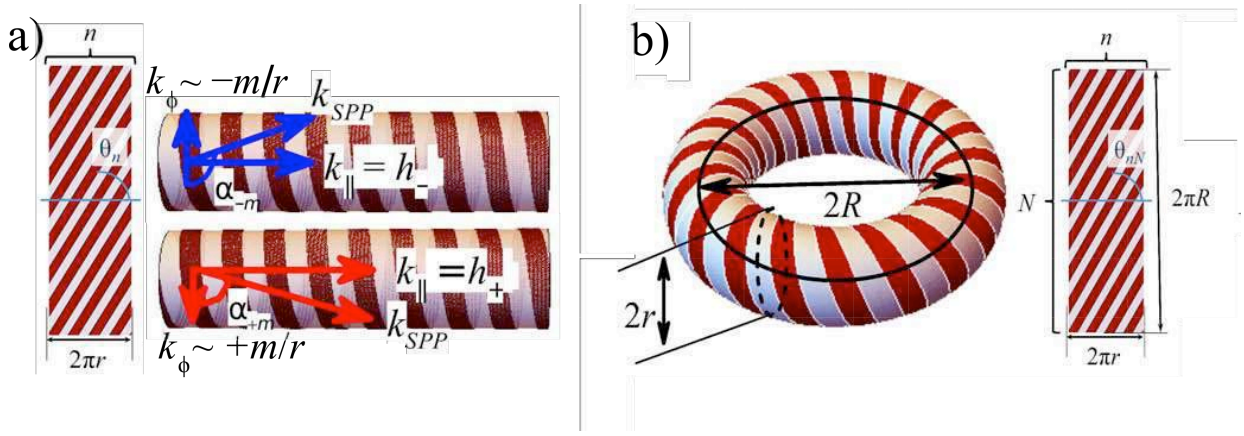

Figure 1. A graphene-based meta-tube (a) is obtained by winding a bunch of n identical graphene stripes around the cylindrical core under the fixed angle θ_n. A meta-torus (b) is characterized of the pair of topological indices of the structure n and N.

A graphene meta-tube may display a giant rotation of azimuthal magneto-plasmonic modes. This structure is

intrinsically non-reciprocal, which plays a crucial role for design of plasmonic devices with one-way propagation resulting in the disappearance of the Fabry-Perot resonances in finite-length meta-tubes. A piece of meta-tube rolled in a torus, possesses a distinct spectrum of azimuthal cavity modes with a large splitting for clock- and counterclockwise propagation directions. Interestingly, the electromagnetic, magnetic and geometrical topological indices of the structure obey simple analytical expressions. Therefore, our results are not limited for graphene-based structures and pave the way for topological non-reciprocal magneto-plasmonics.

Abstract— We present a versatile magneto-optical diffractometer, with ellipsometric capabilities, designed for investigating changes mediated by nano-engineered magnetoplasmonic crystals on the polarization state of the incident light. This facilitates a detailed characterization of metasurface light-tailoring as a function of wavelength and incidence angle, further enabling fundamental studies as well as exploring avenues for potential applications within the flat-optics framework.

The combination between plasmonic resonances, magnetism and nano-scale structuring has opened up exciting possibilities, by which the interplay between these three ingredients can enable an enhanced tailoring of the polarization state of light[1]. This active magnetoplasmonic framework can lead to numerous applications within the flat-optics playground[2]. However, in order to fully capture, quantify and understand the effects of this interplay, an in-depth characterization of the properties of the light scattered from such magnetoplasmonic metasurfaces is necessary. Of a particular interest are periodic arrangements of ferromagnetic nanostructures, for which well-defined grating-coupled plasmonic resonances can arise, given that a Laue-like momentum-matching condition is fulfilled. Such resonances have proven to enhance optical and magneto-optical activities[3] and are characterized by specific dispersion relations within the wavelength-incidence angle parameter space, which can be engineered by the choice of the materials and lattice geometry. For an experimental investigation, however, high-precision angular and wavelength-dependent measurements are required in order to properly identify and further quantify the effects of these plasmonic excitations.

We have developed a modular magneto-optical diffractometer designed to excite such plasmonic resonances while simultaneously characterizing, within a far-field picture, their impact on the polarization state of the incident light[4, 5]. Through the combined use of a high-precision goniometer stage and a supercontinuum laser source, the state of the reflected or transmitted light can be monitored as a function of incidence angle and wavelength, covering the visible and near-infrared ranges. This setup is highly versatile, capable of functioning in different operation modes and it can be regarded as a generalized diffractometer with ellipsometric capabilities. The reflectivity[6], transmission, rotation and ellipticity of the light can thus be recorded and the dispersion relations of effectively propagating plasmonic resonances or surface plasmon polaritons can be directly measured. The effects of complex unit cell geometries and phase gradients can also be investigated. Furthermore, the sample holder is equipped with a quadrupole coil system, enabling measurements under applied magnetic field. This option brings in the possibility of measuring the magneto-optical activity, such as the Transverse Magneto-Optical Kerr Effect (TMOKE) asymmetry[7], as well as exploring the potential for active magnetic tuning of the state of the light.

By using of this instrument, we have been able to experimentally highlight the fingerprints of these network-mediated plasmonic resonances on the optical and magneto-optical properties of different types of two-dimensional magnetoplasmonic crystals. Specifically, we've been able to track and quantify the dispersion relations of grating-coupled plasmonic modes, for both collinear and non-collinear alignments[4, 5, 6], in good agreement with theoretical predictions[8](see Figure1). Furthermore, the role played by the geometry of the lattice element in defining the overall behavior as well as the shape of the plasmonic resonances can been examined and quantified.

In conclusion, this versatile setup allows for an in-depth characterization of light scattered from magnetoplasmonic metasurfaces, incorporating both ellipsometric and magneto-optical functionalities, and can provide a detailed understanding of the underlying plasmonic excitations and dispersions.

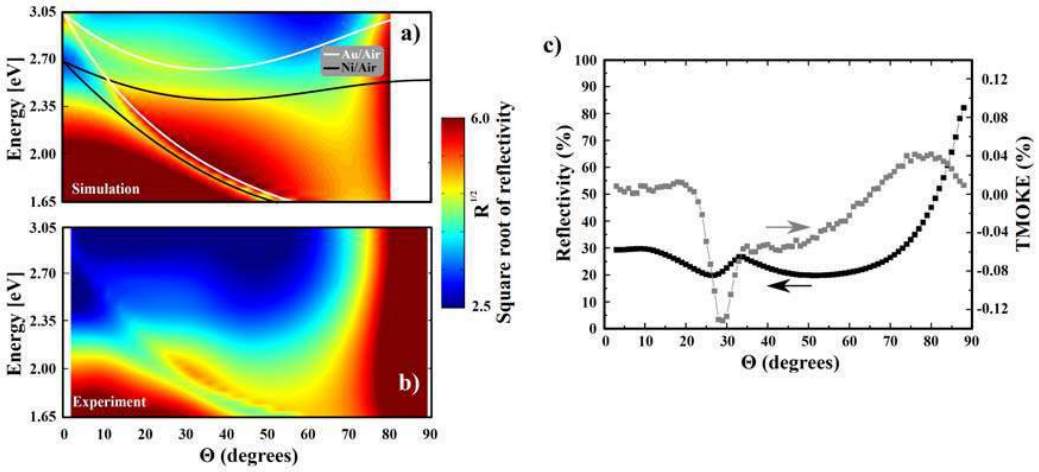

Figure 1: Examples of two-dimensional map representation of simulated (a) and experimental (b) reflectivity responses as a function of wavelength and incidence angle for a Ni/Au-capped hexagonal antidot magnetoplasmonic crystal (sample details in ref.[6]), with incident p-polarized light aligned with the next-nearest neighbor direction of the lattice. The positions found for the dispersion relations are in good agreement with the predicted dispersion relations. (c) Reflectivity and TMOKE asymmetry responses for the same sample for a wavelength of 636nm showing an enhanced magneto-optical activity mediated by the surface plasmon polariton modes.[7]. Figures taken from ref.[4, 5].

Abstract-The possibilities of fabrication of magnetic nanostructures using ion irradiation will be exampled with the recent achievements in FeAl and FeRh. Magnetization of both alloys at room temperature is highly sensitive to the structural state (ordered or disordered). This opens a way for lateral patterning of nanoscale ferromagnets embedded in paramagnetic (FeAl) or antiferromagnetic (FeRh) ordered matrix and to study the effect of planar geometry of magnetic interfaces.

Nanostructuring of magnetic materials is of vital importance for novel technological applications based on spin and magnon transport, manipulation of domain walls, and artificial spin textures and magnetic metamaterials. A variety of magnetic effects arising on the interfaces in multilayers composed of ferro-, antiferro- and non-magnetic materials boosted the breakthrough in spin-dependent phenomena. Further exploit of nanoscale effects in ferromagnets requires the planar structuring of thin films and lateral patterning. Several binary transition metal based alloys offer a unique opportunity for fabrication of laterally patterned ferromagnetic nanostructures using the structural disordering. The magnetization of $Fe_{60}Al_{40}$ was shown to be highly sensitive to the transition of structure from B2 (ordered) to A2 (bcc, or disordered) [1]. The nearly paramagnetic at room temperature ordered alloy can be turned into a ferromagnet with a saturation magnetization of up to 800 kA/m when the structural disorder is introduced. Similarly, antiferromagnetic in B2 ordered state $Fe_{50}Rh_{50}$ alloy turns into a ferromagnet in disordered state [2].

In this talk, we demonstrate the possibility of a fabrication of embedded ferromagnetic nanostructures using irradiation with neon ions. The magnetic domain structure of the patterned objects can be controlled by the variation of the lateral sizes of the structures and their shape. The fabrication of array of single domain islands surrounded with paramagnetic (FeAl) or antiferromagnetic (FeRh) media might find a response in the emerging field of nanomagnet logic and other applications where nanoscale magnets are required, such as spin-wave propagation materials, artificial spin ice and the lattices of arranged ferromagnetic nanoislands with matrix-mediated coupling.

Abstract We employ femtosecond laser pulses to excite magnetization precession in thin films of magnetostrictive metal galfenol $Fe_{0.81}Ga_{0.19}$, grown on (311)- and (001)-GaAs substrates. We demonstrate unambiguously that dynamical strain, generated due to picosecond lattice temperature increase, can alter magnetic anisotropy of the galfenol film. This dynamical strain-induced change of anisotropy allows excitation of magnetization precession even in relatively high magnetic fields, when the conventional contribution to the magnetic anisotropy change from the temperature increase itself becomes inefficient.

Changing magnetic anisotropy of a medium at the (sub)picosecond time scale can pave the way to the ultrafast control of magnetization orientation [1-3] and excitation of spin waves [4-8]. Ultrafast change of magnetic anisotropy of various media can be achieved via rapid increase of lattice temperature in response to the femtosecond laser pulse [4,5]. Such impact of laser pulses is usually treated as a rapid decrease of temperature-dependent magnetocrystalline anisotropy constants and manifests itself in triggering precession of magnetization. Another approach to change the magnetic anisotropy at ultrafast time scale is based on an effect of inverse magnetostriction. It has been demonstrated that picosecond strain pulses propagating through a magnetic material can change anisotropy of the latter and thus launch magnetization precession [6-8]. These two ways to control magnetic anisotropy are typically considered as alternative to each other.

When the thin magnetic film is excited directly by a femtosecond laser pulses, rapid increase of the lattice temperature sets up a thermal stress, which results in emergence of dynamics strain with complex temporal and spatial profile [9]. Thus, one can expect that in the optically-excited magnetic metallic film dynamical strain can contribute to the magnetic anisotropy change and compete to the conventional thermal change. However, the role of this strain in triggering ultrafast magnetization dynamics upon direct excitation of magnetic media remains unexplored.

Here we report on experimental and theoretical study of the magnetic anisotropy change in the magnetostrictive metallic galfenol ($Fe_{0.81}Ga_{0.19}$) films grown on GaAs substrates subjected to the action of femtosecond laser pulses [10]. By performing optical pump-probe experiments we demonstrate excitation of magnetization precession in the galfenol film, which originate from ultrafast magnetic anisotropy change. Unexpectedly, the trajectories of magnetization precession in the films grown on the high-symmetry (001)- and low-symmetry (311)-GaAs substrates appeared to be very different, indicating that magnetic anisotropy change

in these two cases rely on distinct mechanisms.

The most important result is that in the case of the low-symmetry (311)-galfenol film the ultrafast change of magnetic anisotropy results from both, thermal change of anisotropy constants, and on abrupt emergence of dynamical strain, which modifies anisotropy via inverse magnetostriction. We show that, by tuning applied magnetic field strength, we can change contributions from these two mechanisms to excitation of magnetization precession. While the thermal change of anisotropy allows to launch precession in relatively low magnetic fields, the strain-induced mechanisms remains efficient at fields upto et least 0.5 T. In experiments, competition between these two mechanisms manifests itself in nontrivial changes in magnetization trajectory.

We also show that the impact of optically-induced strain appears to be efficient in the case of low-symmetry film only, while in the high-symmetry (001)-galfenol film the excited precession relies solely on the ultrafast change of magnetic anisotropy parameters occurring due to laser-induced heating. This highlights importance of dynamical shear strain for manipulating magnetization, which occurs in low-symmetry structures only, in contrast to high-symmetry ones, allowing only longitudinal dynamical strain generated under optical excitation.

Abstract-Using ultrafast small-angle x-ray scattering at an x-ray free-electron laser, the magnetization dynamics of FePt nanoparticles embedded in a carbon matrix after excitation by an optical femtosecond laser pulse is investigated. It is found that some individual FePt nanoparticles neither switch nor demagnetiz, the origin of which is identified as the near-field modification of the incident laser radiation around FePt nanoparticles, as demonstrated by Finite Difference Time Domain simulations.

Light-matter interaction at the nanoscale in magnetic materials is a topic of intense research in view of potential applications in next-generation high-density magnetic recording. Laser-assisted switching provides an eficient pathway for overcoming the material constraints of high-anisotropy and high-packing density media, though much about the dynamics of the switching process remains unexplored. Using ultrafast small-angle x-ray scattering at an x-ray free-electron laser, the magnetization switching dynamics of FePt nanoparticles embedded in a carbon matrix following excitation by an optical femtosecond laser pulse was investigated. We observe that the combination of laser excitation and applied static magnetic field, one order of magnitude smaller than the coercive field, is sufficient to overcome the magnetic anisotropy barrier separating the “up” and “down” magnetic states. However, this magnetic switching is found to be inhomogeneous throughout the material, with some individual FePt nanoparticles neither switching nor demagnetizing. The origin of this surprising behavior is show to be the result of the near-field modification of the incident laser radiation around FePt nanoparticles, as demonstrated by Finite Difference Time Domain simulations of the film’s optical response.

Magneto-optics at atomic limit with nanoantennas and magnetic control of chiroptical plasmonic surfaces

Alexandre Dmitriev
Department of Physics, University of Gothenburg, Gothenburg 412 96, Sweden
Geballe Laboratory for Advanced Materials, Stanford University, Stanford, California 94305-4045, USA

Abstract: We show how the combination of optical nanoantennas and ferromagnets produces the sensitivities of the magneto-optical detection down to sub-atomic monolayer amounts of material. This combination also gives the 100%+ dynamic tunability to plasmonic surfaces by introducing the magnetically-tunable optical elements to the 2D plasmonic nanoantennas.

A major challenge facing the plasmon-based nanophotonics is the poor dynamic tunability. A functional adaptive nanophotonic element would feature the real-time large tunability of transmission, reflection of light intensity and/or polarization over a broad range of wavelengths, and would be robust and easy to integrate. Several approaches have been explored so far including mechanical deformation [1-3], thermal [4] or refractive index [5, 6] effects, and all-optical switching [7, 8]. Building on our previous advances of the combination of the plasmonic and ferromagnetic materials (magnetoplasmonics) [9-13], here we devise an ultra-thin chiroptical surface, built on 2D nanoantennas, where the chiral light transmission is controlled by the externally applied magnetic field. The magnetic- field induced modulation of the far-field chiroptical response with this system exceeds 100% in the visible and near-infrared spectral ranges, opening the route for nanometer-thin magnetoplasmonic light-modulating surfaces tuned in real time and featuring a broad spectral response.

We further design the nanoplasmonic antennas to produce tightly confined spot of the optical near-field enhancement. Positioning the magneto-optical dielectric in this spot produces largely enhanced magneto-optical signal from this material, allowing the reliable detection of the sub-atomic monolayer quantities of the material on cm^2-large surfaces.

All-optical magnetic switching: making use of fundamental magnetic interactions

Andrei Kirilyuk
Radboud University, Institute for Molecules and Materials, 6525 AJ Nijmegen, The Netherlands
a.kirilyuk@science.ru.nl

Abstract - The reversal of magnetization solely with the help of femtosecond laser pulses is an expanding area of research with more and more materials that can be switched, and various mechanisms responsible for switching. Here we concentrate on switching in rare-earth - transition metal alloys, where the inter-sublattice exchange is responsible for switching, as well as magnetic garnets, where the precessional switching is driven by the local change of anisotropy.

While the basic possibilities for direct laser manipulation of magnetization have been indicated a long time ago, only recently was it possible to apply such control in magnetically ordered materials [1,2].

The question was immediately triggered whether one could use the same mechanism for practical switching of the magnetization in e.g. recording media. A seemingly straightforward answer came very soon afterwards, with a direct demonstration of all-optical light helicity-dependent magnetic recording in thin films of metallic GdFeCo alloys [3]. In spite of the fact that the switching was clearly reproducible and robust, the exact process and mechanism of it remained elusive for a long time. The most obvious explanation via the inverse Faraday effect could only very qualitatively account for the observed features. Taking into account several factors, all-optical switching of the magnetization in rare-earth - transition metal alloys was assigned to a completely different effect: a combination of ultrafast laser-induced demagnetization with the angular-momentum conservation in the exchanged-coupled sublattices of a ferrimagnet, on a sub-picosecond time scale [4].

In spite of the recent extensive work on all-optical switching of magnetization in a variety of samples [5,6], confusion persists as to its mechanism. Here we demonstrate, using various time-resolved imaging techniques, that this confusion may be largely due to the fact that this phenomenon involves behavior on multiple scales, both in space and time. At 100's fs, independent demagnetization of sublattices is observed accompanied by spin diffusive processes at <10 nm distances, as shown by time-resolved X-ray scattering [7]. This is followed by the exchange spring driven behavior [4] with reversal and formation of skyrmion-like domains [8] at a few ps times.

In order to tune the exchange interaction between the sublattices, the alloyed samples were replaced with multilayers. Intriguingly, very large scale coherent precession could be observed that accompany the growth of large domains [9]. The presence of the compensation point added an extra spatial feature to the reversal dynamics in the multilayer samples.

To be technologically meaningful, the all-optical switching must be able to compete with the bit densities of conventional storage devices, restricting optically-switched magnetic areas to sizes well below the diffraction limit. We have recently demonstrated reproducible all-optical switching of magnetic domains of few tens of nm size [10], in a ferrimagnetic TbFeCo alloy using gold plasmonic antenna structures. It has also been found that the focusing of light to a nm-sized area can be helped by the light interference effects occurring within the magnetic structures themselves [11].

To summarize, such ultrafast exchange-driven ultrafast magnetization dynamics is not only potentially useful, but also provides us with invaluable information about the behavior of magnets away from their thermodynamic equilibrium.

However, the switching mechanisms in these materials are directly related to laser-induced heating close to the Curie temperature. Although several possible routes for achieving all-optical switching in magnetic dielectrics have been discussed, no recording has hitherto been demonstrated. Very recently, an ultrafast all-optical photo-magnetic recording in transparent films of the dielectric cobalt-substituted garnet was demonstrated [12]. A single linearly polarized femtosecond laser pulse resonantly pumps specific d−d transitions in the cobalt ions, breaking the degeneracy between metastable magnetic states. By changing the polarization of the laser pulse, we deterministically steer the net magnetization in the garnet, thus writing '0' and '1' magnetic bits at will. This mechanism outperforms existing alternatives in terms of the speed of the write–read magnetic recording event (less than 20 picoseconds) and the unprecedentedly low heat load (less than 6 joules per cubic centimetre).

To summarize, this is an exciting area that combines speed potential of photonics with the robustness of magnetic materials.

Phononics in ferromagnets:
coherent phonons to manipulate magnetization at the nanoscale

A. V. Scherbakov
Ioffe Institute, 194021 St. Petersburg, Russia
scherbakov@mail.ioffe.ru

Abstract- We utilize resonant phonon modes of phononic ferromagnetic nanostructures to manipulate their magnetization. Coherent phonons of the resonant frequencies excited by a femtosecond laser pulse remain localized inside a ferromagnetic layer and drive the magnetization precession. By tuning the precession frequency by external magnetic field, we achieve conditions of magnon-phonon resonance, which results in the drastic increase of the precession amplitude and lifetime.

Applications based on magnetic materials have confidently reached the nanoscale. An information bit in conventional magnetic recording or spin torque oscillators in spintronic devices are of nanometer sizes. Phonons are typically considered as a detrimental factor for nanoscale magnetism as they may induce spontaneous reverse of magnetization or spin decoherence. However, phonons may be also an effective instrument. In this research, we utilize coherent phonons for driving magnetization of ferromagnetic nanostructures and demonstrate interplay of phononic and magnetic properties at the nanoscale.

We study experimentally the ferromagnetic structures, whose design leads to formation of high-Q phonic resonances in sub-THz frequency range. As a ferromagnetic material we use Galfenol, which is an alloy of iron and gallium with enhanced magneto-elastic interaction [1]. In our first attempt [2], we examine a ferromagnetic layer of 59-nm width deposited on GaAs/AlAs superlattice. The superlattice serves as phononic Bragg mirror for narrow frequency band. Together with open surface of a ferromagnetic layer they form phonic Fabry-Perot nanoresonator with a ferromagnetic cavity. Such a structure possesses several narrow phonon resonances with frequencies between 10 and 40 GHz. In the second attempt, we use lateral nanogratings produced by the focus ion beam lithography in 100-nm Galfenol film. The gratings possess narrow phonon resonances with frequencies between 15 and 20 GHz depending on their structural parameters and orientations.

At experiment, we use conventional magneto-optical pump-probe technique to monitor in time-domain the response of magnetization on femtosecond optical excitation. In the structures of both types we observe dominant contribution of the optically excited coherent phonons to the time evolution of magnetization. The phonons with resonant frequencies remain localized inside the studied structures and drive the magnetization precession within their lifetimes. The phonon driving achieves maximum efficiency (largest amplitude and longest lifetime of precession) at the resonant conditions when the frequencies of ferromagnetic and phonon resonances are equal.

The suggested approach has prospective uses for sub-THz spin pumping and generation of high-amplitude microwave magnetic fields at the nanoscale.

Microscopic Electron-Phonon Scattering Dynamics In a Model Ferromagnet

S. Vollmar, K. Leckron, and H. C. Schneider*
Physics Department and Research Center OPTIMAS, University of Kaiserslautern, Germany
*corresponding author: hcsch@physik.uni-kl.de

Abstract-We describe our recent work on electron-phonon scattering in spin-degenerate and ferromagnetic model systems. For the latter, we employ a ferromagnetic Rashba model, in which the exchange interaction and spin-orbit coupling both contribute to the spin splitting. We show that a novel torque matrix element controls the spin-flip that is achievable in a system without precession around effective internal spin-orbit fields. For a combined magnetic and spin-orbit splitting, such precessional dynamics play an important role.

In 3d-ferromagnets, excitation by an ultrashort linearly polarized pulse can reduce the magnetization, as observed by the magneto-optical Kerr effect or X-ray magnetic circular dichroism, by 50% and more, even reaching a complete "quenching" of the magnetization for higher fluences. The spin angular momentum, as determined experimentally, is thus dramatically reduced. Despite the magnitude of this effect, no consensus has been reached as to the microscopic mechanism responsible for it on ultrafast timescales. A similar question has arisen more recently in the context of deterministic optical switching, where there is a contribution from the polarized optical field.

One possible microscopic mechanism for electronic dynamics that leads to a change in magnetization is electronic spin-flip scattering. In the context of demagnetization dynamics, spin-flip scattering is often called Elliott-Yafet scattering after a similar mechanism, which has been identified for semiconductors in the 1960s: In it, electronic spin flips occur due to scattering events with a phonon that connect initial and final states, which have different spin mixtures due to the momentum-dependent spin-orbit coupling.

Studies by Oppeneer and coworkers [1] and by us [2] of electronic density dynamics in ab-initio band-structures of ferromagnetic metals have shown that spin-flip electron scattering with phonons is rather inefficient and cannot explain the experimentally observed ultrafast magnetization dynamics. If one uses a model that includes a time-dependent (mean-field) exchange splitting, the effect of spin-flip scattering of electrons with phonons and other electrons can be amplified to reach the magnitudes observed in experiments [3], but the physics of how the spin angular momentum is "lost" in scattering transitions is hidden in the interaction matrix elements, because in these matrix elements the effects of the interaction and the spin-orbit induced spin mixing cannot be separated.

In this contribution, we describe our recent work on how to correctly describe electronic spin dynamics with spin-orbit coupling and electron-phonon interaction at the level of reduced spin-density matrices. Using this approach, we have reexamined electronic spin dynamics for two cases: (1) the original Elliott-Yafet problem where electronic spin flips occur in a pair of spin-mixed *degenerate* bands [4,5], and (2) a ferromagnetic model system, which contains the contributions of a ferromagnetic exchange "interaction" (at the mean-field level) and spin-orbit coupling.

We show explicitly how spin dynamics due to electron phonon scattering occurs in these cases. For case (1), the spin-dependent part of the electron-phonon interaction plays the most important role, which can be quantified using a torque matrix element. This approach allows us to generalize the original Elliott-Yafet spin relaxation time, so that it also works for strong spin mixing. For case (2), the *spin diagonal* electron-phonon interaction matrix element is mainly responsible for the spin dynamics. This case bears some resemblance to the Dyakonov-Perel mechanism, and we show in microscopic detail how spin dephasing contributes to the magnetization dynamics in the ferromagnetic Rashba model.

Abstract- We report on the latest developments in our studies on ultrafast magnetism, which reveal very intriguing spin switching phenomena by employing a novel experimental approach combining the femtosecond laser excitation with an ultrafast, element-specific X-ray probing of spins. In particular, by investigating the laser-driven magnetization dynamics in *ferrimagnetic iron garnets*, we observe an ultrafast magnetization switching process occurring over an extremely long lived (>>100 ps) transient ferromagnetic-like state. These findings challenge the current understanding of laser-driven magnetization switching phenomena.

Using light to control the magnetic order parameter on ultimate time and length scales is a core research activity of modern magnetism [1]. Of particular interest for both fundamental and applied science is the use of femtosecond (fs) laser pulses to fully switch the magnetization orientation of a spin ensemble on ultrashort time scales [2, 3].

Recent time-resolved XMCD investigations of ferrimagnetic GdFeCo alloys revealed the existence of a transient ferromagnetic-like state mediating the ultrafast magnetization switching of antiferromagnetically coupled Fe and Gd spins [2]. In a subsequent study, this transient ferromagnetic state was shown to drive a novel magnetization reversal mechanism where spin switching is purely thermal, *i.e.* without using any magnetic field [3]. Although groundbreaking, these experiments leave open several intriguing questions on the microscopic driving mechanism of the ultrafast magnetization reversal in the ferrimagnetic compounds. For instance, how does the symmetry and strength of the exchange interaction affect the magnetization switching process? What is the influence of the magnetization damping factor on the duration of the highly non-equilibrium transient ferromagnetic state and implicitly on the ultrafast spin switching? What is the role of the electronic structure of the host material, *i.e.* going for instance from a metallic to an insulating host?

Here, we report on a combined experimental and theoretical study that addresses these questions by investigating *insulating ferrimagnetic iron garnets* $Ho_3Fe_5O_{12}$ and $Gd_3Fe_5O_{12}$ in the close proximity of their magnetization compensation temperatures, T_{comp}=127 K and 291 K, respectively. Using advanced experimental (femtosecond optical excitation combined with ultrafast X-ray measurements) and computational (atomistic spin simulations) approaches, we reveal that femtosecond laser-induced heating of an insulating iron garnet leads to:

1) an ultrafast magnetization switching process over an extremely long lived (hundreds of picoseconds) transient ferromagnetic-like state involving all the constituent magnetic elements of the sample

2) very distinct dynamics of the antiferromagnetically coupled Fe^{3+} (otherwise electronically identical) ions that generates a time lag of about 100 ps between their transient evolution

Moreover, in iron garnets the ferrimagnetic coupling between the iron species (*i.e.* Fe^{3+} ions with tetrahedral and octahedral coordination) and between Fe^{3+} ions, and the rare earth Ho^{3+} and Gd^{3+} sublattices is mediated by super-exchange interaction via the oxygen anions. Therefore, by monitoring the laser-driven spin and electron dynamics in an element- and site-specific manner we obtained, for the very first time, a *direct view on the dynamics of the exchange interaction* itself during the magnetization-switching event.

These highly unexpected and counterintuitive insights challenge the current understanding of ultrafast, laser-driven spin reversal and open new ways for manipulating spins in magnetic solids. Possible implications for the magnetic switching phenomena in ferrimagnetic alloys and heterostructures will be discussed.

Abstract-We reveal a linear crossing dispersion in a multilayered structure containing two kinds of single-negative metamaterials. Distinct from the elliptical dispersion or the hyperbolic dispersion, linear crossing dispersion can bring about a variety of new phenomena such as beam splitting and negative-refraction imaging.

Topological transition of dispersion from a closed elliptic curve to an open hyperbolic curve can bring about useful physical effects such as the enhancement of the spontaneous emission [1], negative refraction [2], and collimation [3-4]. In fact, the topological transition can also occur when a hyperbolic curve changes from a dielectric-type hyperbolic curve (Fig. 1(a)) to a metal-type hyperbolic curve (Fig. 1(c)). At the transition point, the hyperbolic dispersion becomes a linear crossing dispersion, as is shown in Fig. 1(b). This linear crossing dispersion is very interesting because it has only two (positive and negative) slopes. In this work, we realize the linear crossing dispersion in a multilayered structure composed of ε-negative (ENG) metamaterial ($\varepsilon < 0, \mu > 0$) and μ-negative (MNG) metamaterial ($\varepsilon > 0, \mu < 0$) (i.e. two kinds of single-negative metamaterials). The thickness of each layer is deep subwavelength, which ensures the validity of effect-medium description. Owning to the linear crossing contour, the structure can split the normal incident light along two fixed directions (Fig. 2(a)). Moreover, combining two multilayered structures in which the growth direction of layer is perpendicular to each other, one can realize the negative-refraction imaging, as is shown in Fig. 2(b).

Abstract Plasmon nanostructures with ultrasmall mode volume can enhance light-matter interactions in nanostructure based cavity quantum electrodynamics. In the strong coupling regime, taking the evanescent mode provided by single mode nanowire as electromagnetic vacuum, we theoretically demonstrate the enhanced reversible photon-exciton interaction and fluorescence collection. In the weak coupling regime, we theoretically investigate the efficient photon emission of single emitter with metallic nanorod-coupled nanofilm structures. Furthermore, utilizing the liquid crystals, high-contrast switching of spontaneous emission is obtained.

Electromagnetic vacuum engineering plays a fundamental role in controlling light-matter interaction in quantum optics, cavity quantum electrodynamics (CQED), and quantum information devices. In previous studies, evanescent optical modes are thought of as cavity modes rather than providing an electromagnetic vacuum environment that the cavity resides in [1]. Taking the evanescent vacuum provided by a metallic or dielectric single-mode nanowire as the electromagnetic environment, in which a resonant Ag nanorod (AgNR) is embeded, we theoretically demonstrated the enhanced photon-exciton coupling and the increased fluorescence collection efficiency through the careful optical mode design [2]. The AgNR is too small to effect the evanescent optical mode of the nanowire, thus the evanescent mode is taken as the electromagnetic background and the AgNR as plasmon nanocavity, forming the nano-CQED system in evanescent vacuum (Fig. 1(a)). Due to the exponential decay of the evanescent wave (Fig. 1(b)), more localized field at the nanogap is obtained with nanowire (Fig. 1(c,d)). Naturally, the coupling coefficient g0 at the nanogap with nanowire is 4.2 times larger than that without nanowire (Fig. 1(e)). Rabi splitting is signature of strong interaction (Fig.1 (f)). Moreover, 47% of the emitted photons can be collected via the evanescent wave of the nanowire. This CQED in subwavelength-confined quantum vacuum holds promise for exploring the fundamental physics as well as the applications related to on-chip quantum information and scalable quantum networks.

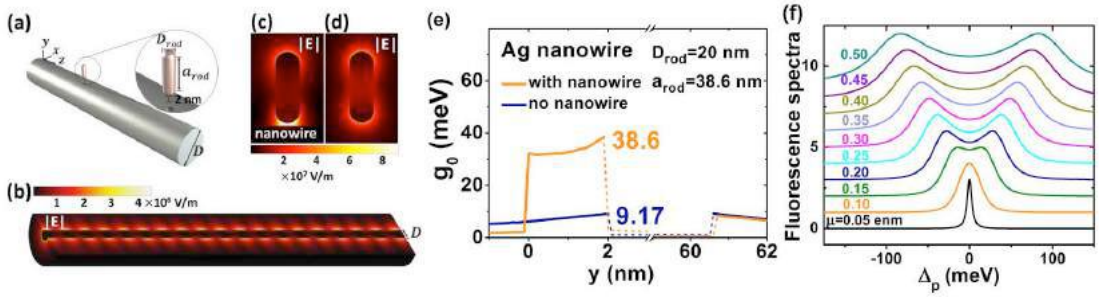

Fig. 1 (a) Schematic diagram of nano-CQED system in evanescent vacuum. (b) Simulation of evanescent electromagnetic mode for Ag nanowire. Electric field distributions of longitudinal modes (c) with nanowire and (d) without nanowire. (e) The coupling coefficient along the central axis of nanorod for μ=0.2 enm. (f) Normalized spontaneous emission spectra for different dipole moments.

The study of single photon emission is of fundamental interest for research in CQED, single photon sources, and cavity-basedlasing processes. Here, combining the advantages of ultrahigh photon emission rates achievable in the gap surface plasmon polaritons with high extraction decay rates into low-loss nanofibers, we theoretically investigated the efficient photon emission of a single emitter and one-dimensional nanoscale guiding of emitted photons in metallic nanorod-coupled nanofilm structures coupled to dielectric nanofibers [3]. Due to the ultra-strong hot spots of gap plasmons, the total decay rates and surface plasmon polariton channel decay rates are orders of magnitude larger than those characteristic of metallic nanofilms alone. Moreover, propagating single photons with decay rates of $290\gamma_0$–$770\gamma_0$ are guided into the phase-matched low-loss nanofibers. The proposed mechanism promises to have an important impact on metal-based optical cavities, on-chip bright single photon sources and plasmon-based nanolasers.

Furthermore, combining the gap surface plasmon with the liquid crystals and low index materials, we theoretically demonstrated both the ultrahigh spontaneous emission rate and a high-contrast switching of spontaneous emission rate [4]. With varying the optical axis of the liquid crystals, total spontaneous emission rate can be switched from $103\gamma_0$ to $8750\gamma_0$ with the contrast ratio of 85, among which the spontaneous emission rate of surface plasmon part is from $42\gamma_0$ to $3726\gamma_0$ with the ratio of 88. The proposed mechanism offers high-contrast, active switching of the spontaneous emission rate, which has potential application for on-chip quantum devices.

Abstract- The generation of optical vortex beams, which carry orbital angular momentum, has emerged as a vital approach to applications ranging from high-capacity optical communication to parallel laser fabrication. Here, we propose and experimentally demonstrate volumetric three-dimensional vortex array with space variant topological charges based on dielectric geometric metasurface. By employing the concepts of Dammann vortex gratings and spiral Dammann zone plates, 3D optical vortex arrays with micrometer spatial separation is achieved from visible to near-infrared wavelengths. Importantly, we show that the topological charge distribution can be spatially variant and fully controlled by the design.

Flat optics have attracted great interest for being a promising alternative to control light waves by implementing ultrathin planar elements, namely metasurfaces, with spatially varying phase response instead of relying on phase accumulation along optical paths [1-2]. Metasurfaces have shown the ability to overcome the limitations of conventional optics with a wide range of applications in wave front engineering, information processing, and spin controlled photonics. An important application for metasurfaces is the control and modification of optical beam profiles, and in particular the generation of orbital angular momentum (OAM) for light, which is pivotal in terms of both fundamental physics and practical applications [3-4]. The optical vortex beam has received increasing attention for its various applications, ranging from optical manipulation of microscopic particles and biological cells to free-space optical communication system.

Here, we propose and experimentally demonstrate the generation of a volumetric three-dimensional vortices with independently controllable topological charges that is based on a single ultrathin dielectric metasurfaces [5]. We employ the concepts of Dammann vortex grating (DVG) and spiral Dammann zone plate (SDZP) together with a lens factor to generate the metasurface phase profile with sub-wavelength pixel size. Figure 1 illustrates the generation and reconstruction procedure of such a 3D vortex array. The design technique allows for a well-defined, quantized, and fully controllable spatially variant topological charge distribution.

Such metasurface-based vortex generators can achieve truely 3D vortex arrays over a large volume with high uniformity. Furthermore, the geometric nature of the phase profile (based on a Pancharatnam-Berry-Phase)

enables the reconstruction of the vortices over a broad spectral bandwidth in the near infrared and visible wavelength range. Importantly, the metasurface can be designed to possess the remarkable capability of vortex beam detection. The flexibility of our approach enables on-chip parallel processing to 3D micro- and nano-fabrication, and offers the possibility of ultrahigh-capacity and miniaturized nanophotonic devices for harnessing angular momentum multiplexing and mode sorting.

Abstract- To generate Cherenkov radiation (CR) in natural medium, the electron energy threshold is higher than hundreds of keV. Even though various approaches were adopted, the high-energy electrons as high as tens of keV is still required in experiment. We demonstrate in hyperbolic metamaterial that the electron velocity threshold for CR is eliminated, and meanwhile, with this threshold-less CR, the first on-chip integrated free electron light source was realized.

To generate Cherenkov radiation (CR)[1] in natural medium, the electron energy threshold is higher than hundreds of keV[2]. Even though various approaches were adopted, the high-energy electrons as high as tens of keV[3] is still required in experiment. Here we proposed to eliminate the threshold of electron energy to generate CR with the help of hyperbolic metamaterial (HMM). The analytical and simulation results indicate that, even though electron energy is lower than 0.1keV, the CR could be obtained in HMM in a visible and near-infrared frequency region. Further, the on-chip integrated threshold-less CR source, consisted with a planar electron emitter, Au-SiO_2 multilayers HMM, and periodic metal nano-slits, has been realized. It is demonstrated that, with low-energy electrons (0.25-1.4keV), the CR is generated covering λ_0=500~900nm. The electron energy generating CR experimentally is two~three orders of magnitude lower than that in natural media and artificial structures. As we know, this is the first on-chip integrated free electron light source benefiting from the threshold-less CR. Although less than 1% of the light energy could be coupled to free space, the total output light power still reaches 200nW, which is two orders of magnitude higher than free electron light source by using other nanostructures. This work provides a way to realize threshold-less CR, opens up the possibility of exploring high performance on-chip integrated free electron light source and optoelectronic devices, and offers the platform to study the interaction of flying electrons with nanostructures on chip.

Strong couplings among triple Fano resonances in a 3D metamaterial

Jiafang Li,* Zhiguang Liu, and Zhi-Yuan Li
Laboratory of Optical Physics, Institute of Physics, Chinese Academy of Sciences, Beijing, China, 100190
*Email: jiafangli@aphy.iphy.ac.cn

Abstract- We report our recent experimental and theoretical works on strong couplings among triple Fano resonances in a 3D metamaterial, which is formed by integrating vertical asymmetric split-ring-resonators (aSRRs) along a planar metallic hole array with extraordinary optical transmission (EOT) built by means of homemade focused-ion-beam (FIB) manipulations.

In this talk, we report our recent studies on strongly coupled triple Fano resonances in a 3D metamaterial (MM). The 3D MMs are formed by integrating vertical asymmetric split-ring-resonators (aSRRs) along a planar metallic hole array with extraordinary optical transmission (EOT) built by means of homemade focused-ion-beam (FIB) folding technique. In such a configuration, the plasmonic system stably supports triple Fano resonance states. More importantly, the induced Fano resonances are widely tunable and strong coupling among triple Fano resonances occurs during the tuning process. These 3D MMs with significant and robust Fano resonances exhibit an extremely high sensitivity to refractive index of the environments in the near infrared wavelength region.

Abstract-The resonance behavior of optical antennas is commonly attributed to the excitation of a localized surface plasmon resonance (LSPR), which can be theoretically defined as the quasi normal mode (QNM). To clarify the physical origin of the LSPR, we build up an analytical model of the LSPR by considering a multiple scattering process of propagative surface plasmon polaritons (SPPs) on the antenna arms, which establishes explicit relations between the concepts of the LSPR and the propagative SPP.

Plasmonic optical nanogap antennas can efficiently accelerate the radiation of emitters such as molecules or quantum dots in the nanogap, or reciprocally, allow giant enhancement of near field in the nanogap under far-field illumination. They can be widely used in nonlinear optics, white light super-continuum generation, single-emitter fluorescence enhancement and surface enhanced Raman scattering [1]. The resonance enhancement is commonly attributed to an excitation of LSPR as the illumination frequency matches the eigen-frequency of the LSPR [2]. Theoretically, the LSPR can be defined as the QNM by treating the metallic nano-antenna as an open cavity [3].

To propose an insightful and effective theoretical treatment of nanogap antennas, here we build up an SPP Fabry-Perot model for the QNM of nanogap antennas by considering a multiple scattering process of SPPs on the antenna arms [4] [see Figs. 1(a)-(c)]. The existence of slightly-damped QNMs that cause the resonance nature of nanogap antennas is demonstrated with the model by seeking the solutions of two transcendental equations. The model sets a solid electromagnetic foundation for the intuitive picture that the LSPR (i.e. QNM) of the antenna actually arises from the Fabry-Perot resonance of SPPs at the complex eigen-frequency. With a few assumptions on the frequency-dependence of the field and with the use of complex pole expansion of meromorphic functions (Mittag-Leffler theorem), the field of the nanogap antenna excited by a nearby point emitter can be expanded upon the basis of QNMs, thus providing an analytical description of the frequency response of the field [Figs. 1(d)-(e)]. For calculating the Purcell factor, the model provides a new analytical expression of the mode volume of QNM in terms of the SPP scattering coefficients, which avoids the difficulty

in calculating the mode volume caused by the divergence of the QNM field at infinity that is overcome recently [3]. The present model establishes explicit relations between the concepts of the LSPR and the propagative SPP, and integrates the advantages of the Fabry-Perot and QNM formalisms in understanding the resonance of nanogap antennas, which may inspire new design strategies of antenna devices with different geometries.

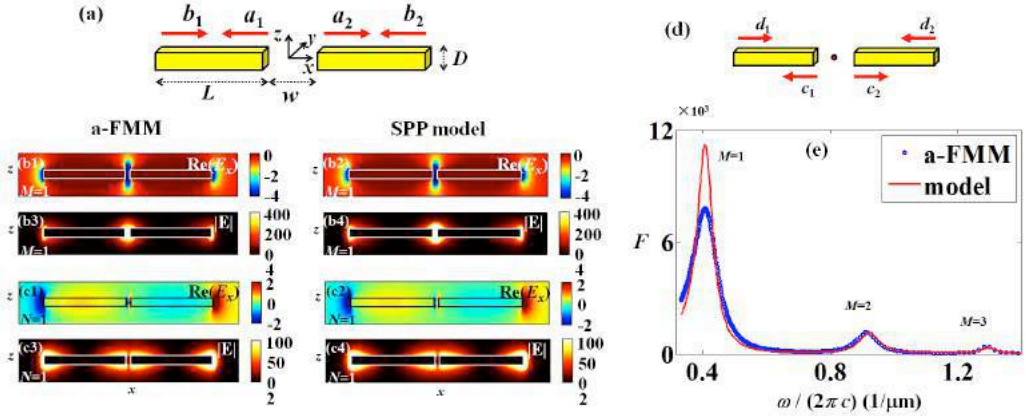

Figure 1 (a) Sketch of the SPP model for the QNM of the nanogap antenna, which is composed of two gold nano-wire arms of length L (with a square cross section of side length D=40nm) separated by a nano-gap (gap width w=30nm). a_1, a_2, b_1 and b_2 denote the complex amplitude coefficients of SPPs at the complex eigen-frequency of QNMs. (b)-(c) Field distributions of the first order symmetric and anti-symmetric QNMs. (d) Nanogap antenna excited by an x-polarized electric point source located at the center of the nanogap. (e) Spontaneous emission rate (normalized by the value in air) of the source versus illumination frequency ω. The results in (b), (c) and (e) are obtained with the full-wave aperiodic Fourier modal method (a-FMM) and the SPP model for L= 0.6μm.

Abstract-Plasmonic cavity resonators are designed by noble metal nanorod or nanotube metamaterials. A hybrid mode appears due to near-field coupling between plasmonic silver nanorod metamaterials and gold-film substrate. Additionally, T–L hybrid plasmonic modes resulted from the near-field coupling between transversal and longitudinal resonance modes with different order harmonics are found in gold nanotube metamaterials, performing electric fields partially localized into pores and at two ends based on extraordinary optical transmission coupling effect through inner-nanochannels of the gold nanotubes.

Plasmonic resonant cavities are capable of confining light at the nanometer scale due to both enhanced local electromagnetic fields and lower mode volumes, which exhibit promising applications in sources[1], sensing[2], enhanced nonlinear effects[3] etc. It has been noted that the conventional metal nanostrips as cavities with single metal-dielectric interfaces have large Ohmic losses. Whereas enhancement of plasmonic near-field coupling by designing two or multi metal-dielectric interfaces can decrease the Ohmic losses[4-6].

We have studied the near-field coupling of plasmonic nanorod metamaterials consisting of silver nanorod arrays embedded in anodic aluminum oxide (AAO) membranes[5]. Reflectance measurements reveal the

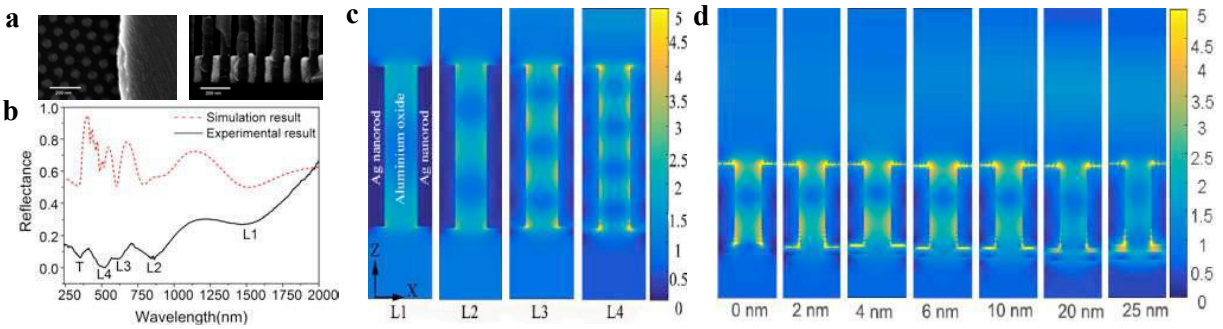

Figure 1. (a) SEM image of silver nanorod metamaterial, (b,c) Reflectance spectra and electric field distributions of the 420 nm long metamaterial, (c) Electric field distributions with the gaps between nanorods and substrate.

existence of multiple resonance modes of the nanorod metamaterials (Fig. 1b). Furthermore, FDTD numerical simulations display that the electromagnetic fields of the higher-order longitudinal resonance modes are focused at the interface between silver nanorods and aluminum oxide, and the electric fields at the interface form standing waves, which indicates that the silver nanorod metamaterials can work as plasmonic cavity resonators (Fig. 1c). An open plasmonic nanocavity exhibits sharp half-wave harmonics with the symmetric distribution of electromagnetic field in the interior of the cavities. A new hybrid mode resulting from the coupling of silver nanorod metamaterials with the gold substrate, and the resonance of the coupling mode gradually become weaker as the gap between the silver nanorod arrays and the gold film substrate increases (Fig. 1d).

On the other hand, plasmonic resonators based on a metamaterial consisting of periodic arrays of gold nanotubes embedded into AAO has been presented[6], and strong confinement of local fields with low losses is demonstrated. Higher-order resonance modes of surface plasmons localized in the gold nanotubes when the nanotube length exceeds some critical values are observed. The FDTD numerical simulations indicate that, the electric fields are associated with some higher-order longitudinal modes for the long nanotubes and some lower-order longitudinal modes for the short nanotubes or the nanotubes with thin walls, odd and even harmonics with standing-wave modes are tuned by the nanotube length. We find a new T-L hybrid plasmonic resonant cavity modes in the gold nanotube metamaterials resulting from the near-field coupling of both transversal and longitudinal modes (Fig. 2 b, c and d), furthermore, the T-L hybrid cavity modes dependent on the wall thickness and the length of the nanotubes, perform electric fields partially localized into pores and at two ends based on extraordinary optical transmission coupling effect through inner-nanochannels.

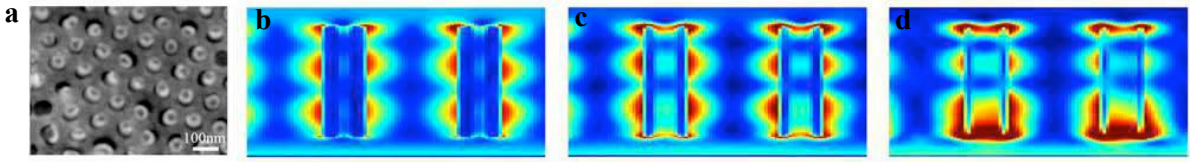

Figure 2. (a) SEM image of gold nanotube metamaterial, (b-d) Electric field distributions of the longitudinal resonance modes of the 5th order harmonics for the 17 nm, 10 nm and the T-L hybrid plasmonic mode for 5 nm thick nanotube walls, respectively.

Exact theory of Purcell effect and resonant-state expansion

E. A. Muljarov and **W. Langbein**

School of Physics and Astronomy, Cardiff University, Cardiff CF24 3AA, United Kingdom

The Purcell factor (PF) quantifies the change (relative to free space) of the radiative decay of a quantum dipole coupled to an open optical system. For example, the photon emission rate of an optical transition in a quantum dot can be strongly enhanced when the electron (or exciton) level is resonant to a photon cavity mode in an optical resonator, such as a planar microcavity or a dielectric microsphere. Consequently the light-matter interaction is also enhanced. That is why designing the PF is at the heart of photonics technology, striving to develop ever smaller or less lossy optical resonators. Although this well-known effect of enhancement of the spontaneous emission rate was discovered by E. M. Purcell [1] early in 1946, no general exact theory of the Purcell effect was available until recently.

We present here a general analytic theory of the Purcell effect [2], which is based on the expansion of the PF into all relevant resonances of the cavity and exact calculation of their effective mode volumes. We show that the expressions for the mode volumes so far known and used in literature (see e.g. Ref. [3]) are only approximately valid for modes of high quality factor, while in general they are incorrect. We rectify this issue, introducing the exact normalization of modes which we have used earlier to formulate the resonant-state expansion (RSE) [4]. To illustrate and verify our theory of the Purcell effect we use analytically solvable examples of homogeneous dielectric and metal spheres in vacuum.

We also present some illustrations of using the RSE in different geometries. The RSE is a rigorous perturbation theory of resonances in open optical systems, which we have recently invented [4] and subsequently applied to finite one-dimensional (1D), 2D and 3D systems, such as perturbed planar [5,7], cylindrical [6] and spherical resonators [8] with various perturbations, and recently generalized to include frequency dispersion [9], photonic-crystal structures [10] and light propagation in non-uniform waveguides [11]. We have demonstrated the ability of the RSE to accurately and efficiently calculate resonances of a perturbed open optical systems using the spectrum of a simpler, unperturbed one. Furthermore, we have compared the performance of the RSE with commercially available solvers, such as those using the finite difference in time domain (Lumerical) and finite element methods (ComSol), and showed on 2D and 3D examples that the RSE can be several orders of magnitude more computationally efficient [8,10]. The RSE is capable of calculating a numerically complete set of RSs for a given optical system – and this is required by the exact theory of the Purcell effect we present: Indeed, the full Purcell factor is a sum over all RSs of the optical system.

Ultratransparent medium and its applications

Jie Luo, Zhihong Hang, Yun Lai*
College of Physics, Optoelectronics and Energy & Collaborative Innovation Center of Suzhou Nano Science and Technology, Soochow University, Suzhou 215006, China
*corresponding author: laiyun@suda.edu.cn

Abstract- Photonic crystals are well known for exhibiting band gaps that block electromagnetic waves. Here, by designing the nonlocal effective parameters of photonic crystals to have special values, we demonstrate the ultratransparency effect [1] of photonic crystals, which can enhance the transparency of photonic crystals to an extreme level beyond any existing solid materials on earth. In an optimized example, near 100% transmission rate have been realized for almost any incident angle within (-90, 90) degrees. A proof-of-principle microwave experiment has been performed to demonstrate near 100% transmission within (-60, 60) degrees. The ultratransparency effect of photonic crystals opens a new route to approach the ultimate transparency. Its applications include generalized transformation optics, microwave transparent wall, etc.

Transparent media are the foundation of almost all optical systems. However, due to general reflection caused by impedance mismatch, transparency is not perfect in natural materials like dielectrics. In the past decades, artificial electromagnetic materials like photonic crystals (PhCs) and metamaterials have been proposed to realize unusual electromagnetic properties beyond natural materials. However, transparent solid material with the same level of transparency as air or free space is still an extremely difficult task to realize.

In this work, we propose to use pure dielectric PhCs to realize perfectly transparent media with the rare property of omnidirectional impedance matching, which allows 100% transmission of light at all incident angles. Unlike local media with equal frequency contours (EFCs) centered at the Brillouin Zone center, such PhCs are designed to exhibit elliptical EFCs "shifted" in the k-space, and thus contain strong spatial dispersion. Interestingly, the combination of perfect transparency, which eliminates all reflection, and elliptical EFCs, which eliminates aberration in virtual images, satisfies the two essential requirements of optical media for ideal TO devices. As a result, such perfectly transparent PhCs provide a low-loss and feasible platform for transformation optics devices at optical frequencies. Moreover, the "shift" of EFC enables new freedom of phase manipulation beyond the original framework. Since such PhCs are superior to normal transparent media like dielectrics in two major aspects: allowing maximal amount of light to pass through and creating aberration-free virtual images, they are hereby denoted as "ultra-transparent" media.

Abstract-In this presentation, we will report the mass fabrication of lithium niobate microdisk resonators on a chip. The quality factors for the fabricated resonators can be higher than one million. Nonlinear effects including second harmonic generation, electro-optic effect, and thermo-optic effect were observed in these resonators.

Lithium niobate whispering gallery mode (WGM) micro-resonators provide a platform for the study of nonlinear effects with low pump threshold and photonic devices allowing for active control. Although millimeter-sized lithium niobate WGM resonators with quality factor of the order of ten million can be successfully produced by using traditional optical fabrication techniques, it is difficult to fabricate on-chip lithium niobate micro-resonators with ultra-high quality factors. The fabrication of on-chip lithium niobate resonators recently made a great progress benefiting from the production of lithium niobate film on insulator [1].

In this presentation, we will report the mass fabrication of lithium niobate WGM resonator from lithium niobate film by photolithography, reactive ion etching, and wet etching following the recipe used by Loncar's group [2,3]. Besides, we also made lithium niobate silica hybrid resonators by depositing a layer of polycrystalline lithium niobate film on an inverted-wedge silica resonator [4], that is partially a bottom up method. In the hybrid resonators, thermo-optic effect induced by the absorption of a pump beam and electro-optic effect were realized. Meanwhile, second harmonic generation, electro-optic modulation [2], and two kinds of thermo-optic effects with opposite coefficients [5] were demonstrated in monocrystalline lithium niobate micro-disk resonators made from lithium niobate film. These lithium niobate micro-resonators are good candidates for active photonic devices having potential to be integrated.

Nonlinear optical imaging and spectroscopy of gap plasmons in single metal particle-on-film nanocavities

Dangyuan Lei[1,2]

[1]Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, China
[2]Shenzhen Research Institute, The Hong Kong Polytechnic University, Shenzhen, China
E-mail: dylei@polyu.edu.hk

Abstract – I will discuss our earlier and recent study on the light scattering response, photoluminescence and nonlinear optical properties of several plasmonic nanocavities comprised of metal film-coupled nanosphere monomers and dimers. Together with 3D full-wave electromagnetic simulations, the plasmon hybridization theory and multipole expansion model will be used to theoretically understood the observed experimental results such as single-particle scattering, polarization-resolved one-photon and two-photon photoluminescence and second-harmonic generation.

Main text – In this talk, I will first review our earlier investigation on the light scattering properties of two particle-on-film systems: a gold nanosphere on top of and partially embedded in a thin gold film [1]. Using polarization-resolved dark-field excitation, we revealed the coexistence of multiple gap plasmon modes in the two systems and the evolution of their scattering intensity and radiation pattern with incident polarization. Our results showed that the former system supports three plasmon resonances, originating from highly confined gap plasmons at the interface while the latter supports two dipolar modes having different orientation and damping rate. Secondly, I will show our recent results on using the polarization-resolved dark-field spectroscopy to study a nanosphere dimer-on-film system [2]. In addition to the two dipole-like plasmon modes sustained in the monomer-film system, the dimer-film system supports two new plasmon modes, one strong yet narrow resonant mode corresponding to a net bonding dipolar moment polarized along the dimer axis and one hybridized high-order resonance mode. Thirdly, I will show that that the spectral linewidth of the dipolar plasmon resonance of a gold nanosphere dimer on silica can be narrowed by a factor of ~4.6 by replacing the substrate with a gold mirror [3]. The measured linewidth is even smaller than its monomer counterpart (~30% reduction). Comprehensive theoretical analyses using multipole expansion model and full-wave electromagnetic simulations reveal that the observed linewidth shrinking originates from gold film-mediated intense plasmon hybridization between the bonding dipolar and quadrupolar gap modes. The intense dipolar-quadrupolar gap plasmon hybridization in the film-coupled system leads to a giant photoluminescence intensity enhancement (~200 times) and a dramatic emission linewidth narrowing in comparison with the dimer on silica. Finally, I will present our preliminary results on the TPL and SHG in a single gold nanosphere-on-film nanocavity, including polarization-dependent nonlinear emission spectroscopy and mapping [4]. We find that the emission pattern of the nanocavity appears as a double-lobe shape, with the axis of the two lobes aligned in the input polarization direction. The emission spectrum of the nanocavity is featured by a narrow SH emission peak and a broad TPL emission peak, and their emission patterns possess a similar double-lobe feature, indicating a same nonlinear emission enhancement mechanism.

Abstract - We present the experimental investigation of transverse spin angular momentum engineering in the evanescent fields of whispering-gallery modes in integrated micro-ring resonators. The spin-orbit interactions of light in the transversely confined fields and the cylindrical vector vortices in this structure are exploited for the manipulation of light within the degrees of freedom of optical angular momenta.

Transverse spin angular momentum (T-SAM) of light has been unveiled by recent advances in optics as a new member in the optical angular momentum (AM) family. In sharp contrast to the well-known longitudinal spin angular momentum (SAM), it exhibits spinning directions orthogonal to the propagation of light [1, 2]. T-SAM can typically be studied in highly inhomogeneous structured light fields, including surface plasmon polaritons [3], evanescent fields of guided and un-guided modes [4]. Light fields possessing T-SAM can enable various applications in bio-sensing, nano-photonics, etc. In particular, T-SAM in evanescent fields gives rise to robust spin-controlled directional coupling at optical interfaces [5] also known as the quantum spin Hall effect of light [6]. This effect has its origin in the spin-orbit interaction (SOI) of light, which universally occurs in transversely strongly-confined fields [7].

In this paper, we further introduce a more comprehensive platform for studying and manipulating SOI of light, by including the ability to engineer both the total angular momentum (TAM) and T-SAM in the near-field. The platform combines a whispering-gallery mode (WGM) resonator based optical vortex emitter [8] with precisely controllable global topological charge, and precisely engineered local T-SAM in the evanescent fields of the WGM modes. Enriched SOI effects in this platform can lead to the global conversion between the spin and orbital components of angular momentum in the emitted vortex [9]. The inherent local SOI in vortex emission/reception and global AM conversion allow for nano-photonic chiral interfacing in the full AM domain between travelling and bounded light.

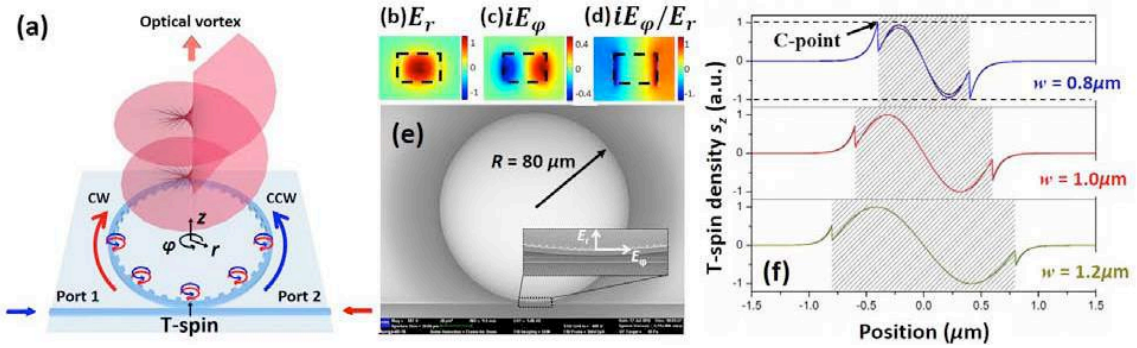

Fig. 1. (a) Device schematic, (b-d) field components of the WG mode, (e) SEM picture of device, and (f) calculated T-SAM density across the waveguide.

The schematic of the structure is shown in Fig. 1(a), where a micro-ring resonator consisting of a close-loop single-transverse mode waveguide is embedded with second-order gratings on the inner sidewall. The micro-ring is coupled with a two-port access waveguide (WG) [8]. In particular, for the quasi-TE mode supported in the high-index ring waveguide, a local tangential component (E_φ) along the sidewalls exists in quadrature phase with respect to the radial component (E_r), as shown in Fig. 1(b-c). Consequently, the local T-SAM of the evanescent field, with the spin axis in the z direction being orthogonal to the local propagation direction ($+\varphi$ or $-\varphi$) of the WGM, is determined by iE_φ/E_r (Fig. 1(d)), or in the form of $s_z \propto \mathrm{Im}[E^* \varphi E_r]$ [10]. The T-SAM at the inner sidewall can be flip-flopped by injecting light from the alternative ports 1 or 2.

The embedded sub-micron grating elements (Fig. 1(e)) scatter the evanescent fields near the inner sidewall, collectively producing a vortex beam travelling perpendicular to the resonator plane [8]. The locally coupled spin and orbital angular momentum (OAM) at each grating point [5] is directed to free-space and transformed into the globally interacting angular momenta in the emitted vortex. We have previously shown that the total angular momentum (TAM) is defined by the near-field topological charge l_{TC} which is only decided by the resonant wavelength and the number of grating elements [8, 9]. The polarization of the emitted field, on the other hand, is defined by the local T-SAM at each grating element, which can be engineered simply by changing the WG geometry. The AM states of the vortex $<l, s>$, where $l+s=l_{TC}$ [9], can therefore

be manipulated to traverse the full higher-order Poincare sphere [11]. By reciprocity, this structure can also be used to selectively receive AM-carrying beams [12] providing a chiral interface between bound and travelling vector vortices.

The simulations and experiments in this paper were both performed with the silicon nitride (SiN_x) resonator/WG fabricated on the silicon wafer. SiN_x is used for its moderate refractive index (n~1.9) so that a larger range of T-SAM density can be accessed over Silicon WGs. An SEM image of a fabricated device of R = 80μm is shown in Fig. 1(e).

The effects of WG geometry on the T-SAM density in the evanescent fields is shown in Fig. 1(f), where the hashed area indicates the WG cross-section as three different widths of WG (w = 0.8μm/1.2μm/1.6μm) are considered. The calculated electric contribution of quasi-TE mode T-SAM density across the WG is plotted along the radial direction also with various WG heights (h = 0.4μm/0.6μm/0.8μm). The T-SAM density generally decays away from the WG sidewalls in accordance with the evanescent fields. However, the peak density in the vicinity of WG sidewall surfaces is strongly dependent on the WG dimensions. Notably, positions of local circular polarizations (CPs) or $s_z = \pm 1$ (also referred to as C-points in singular optics [13]) can be found at the sidewalls with specific WG designs (e.g., as shown in the cases of w = 0.8μm in Fig. 1(f)). Therefore, various T-SAM density values can be achieved with routine WG design.

The measurement of engineered T-SAM and SOI in the emitted vortices was performed with the setup shown in Fig. 2(a). The quasi-TE WGM is excited by launching horizontally (TE) polarized light into one of the ports 1 or 2, and the vertically emitted beam is collimated with a 20X objective lens. Here we employ two separate techniques to measure the SAM state of the global beam. First, a radial polarization converter (RPC) [14] is used to measure the E_φ and E_r contribution in the beam, as the RPC can convert these two spatially variant components into uniformly x- and y-polarized fields, respectively. By detecting the power of the converted fields after a linear polarizer, the polarization ellipticity for various l_{TC} values is obtained and plotted in Fig. 2(b-c), with two different WG heights (0.4μm/0.6μm) and four widths (0.8μm/1.0μm/1.2μm/1.4μm). A wide range of polarization ellipticity (0.3~1.0) is achieved by tailoring the WG width. In particular, light of ellipticity $\sigma \approx 1$ can be observed (e.g., w = 0.8μm in Fig. 2(c)). We also verify these results by comparing the power of left- and right-hand circular-polarized (LHCP/RHCP) components in the light using quarter-wave plate (QWP) and linear polarizer. A ratio ranging from 1 to 16dB can be obtained as shown in Fig. 2(d-e), and the ratio can be inverted by injecting light into the opposite access WG port. These results show that the SAM in the global beam agree well with the local near-field T-SAM density in Fig. 1(f).

The OAM component in the vortices is demonstrated by the interferograms shown in Fig. 2(f). As TAM is only defined by l_{TC}, OAM is subject to the near-field T-SAM manipulation as it decides the far-field SAM. When the local near-field is linearly polarized, the emitted beam is an equal split of states $<l_{TC}\text{-}1, +1>$ and $<l_{TC}\text{+}1, -1>$ [8, 9]. Whereas with particular T-SAM values, for example the C-point of s=+1 as shown in Fig. 2(g), the OAM component of l_{TC}-1 becomes dominant. Vector vortices of arbitrary state $<l, s>$, where l+s is an integer, can be generated/received with this structure.

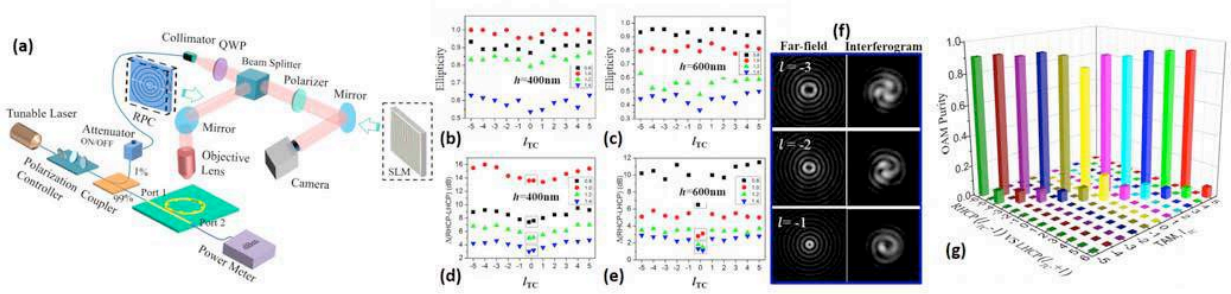

Fig. 2. (a) Experimental setup, (b-c) measured ellipticity, (d-e) measured circular polarization ratio, (f) inteferograms, and (g) polarization purity.

Overall, the two-fold spin-orbit interaction of light is demonstrated which is utilized to manipulate the spin and orbital angular momenta carried by complex vortex light fields. Potential applications include chiral waveguide couplers for vector vortices in quantum and classical information systems, as well as particle manipulation.

Abstract- Balanced gain and losses in geometries beyond those of mere trivial compensation have prompted a series of optical counterparts evoking the fascinating physics of parity-time symmetry. We will expose two more complex variants. Firstly, those that arise when tackling such a simple issue as apodizing a complex periodic index sequence. And secondly a very disordered version whereby statistics of the outcome becomes nontrivial, in relation with non-ergodicity and so called Geometric Brownian Motion (GBM), i.e., random walk in multiplicative space.

A bird's view of the dominant paradigms in optoelectronics should undoubtedly emphasize optical coherence. Consequently to that state of matter, it can be said that the *phase* is commonly seen as the crux of most modern optics. Correspondingly, altering the phase through electro-optics, and thus tuning of the real part of the index of refraction, has been the main paradigm for the tuning of the current generation of functional devices. In this picture, a somewhat implicit trend emerged that *gain and losses* should be felt as related to the "incoherent" part of the process, and for instance the laser phenomenon of phase/amplitude coupling as a side complexity.

It is one of the merits of the flourishing of the Parity-Time symmetry concept in optics to trigger a deep revision of this state of matter. The basic enticing characteristics of PT-symmetric operators is to behave, up to a point, as conservative ones even though they have non-Hermitian (gain and loss) character. From this new paradigm, even with fixed material losses − as arise in most instances of envisioned miniature plasmonic devices,− it is possible to build up couplers and other sophisticated "coherent" optoelectronic functions based on tunable gain rather than tunable index [1]. While the case for this approach is now clearer, leading to revisit coupled laser physics for instance, opportunities to *explore the role of complex gain and loss spatial distributions* can be also revisited.

We explore in this paper two roads that, according to our belief, could go beyond mimicking existing functions.

We first discuss more complex form of gain/loss organization: firstly in the case of PT-symmetric Bragg grating [2], known for their unidirectional reflection we show that various flavors of local PT symmetric Bragg gratings that stem from apodization concepts bring rich optogeometric variants. Namely, by considering

separately the apodization of real and imaginary parts of the PT-symmetric Bragg grating, a set of interesting filtering properties can arise, spanning various configuration from flat-top filters to “unilateral” functions with enhanced sidelobe suppressions. Furthermore, we discuss what changes of local “binary” guide properties such as width or gain/loss is most appropriate to implement these effects. This leads us to consider the merits of various “supersymmetric” variants of the real+imaginary index distribution.

Next, we give a hint of unexpected synthetic properties in the case of disordered systems. We do not look at PT-symmetric systems but rather at a simple chain of alternate gain and loss regions. In case the spatial phase evolution can be forgotten (as would be the case for extreme miniature plasmonic resonators), we are essentially left with a multiplicative random walk, also called a Geometric Brownian Motion (GBM) : in such distributions, the logarithm of the intensity evolves like a random walk, and could take the classical Gaussian shape in its more basic form. Thus the intensity distribution is the exponential of a Gaussian, also known as the log-normal distribution. Within some assumptions that can be drawn from recent considerations on such GBM in other fields [3,4], there are non-ergodic effects, with the mean along a given walk not taking the same limit as the mean of an ensemble of walks at a given finite distance from their start. Carrying this concept to gain and loss and plasmonics, we envision a set of plasmonic guides, so that each of them embodies a single random walk. As a consequence of non-ergodicity, the opportunity arises of an information-rich optical output that can carry interesting features from the (plasmonic) disorder, which might be a tunable disorder eventually.

Along this line, we will explore how the core GBM paradigm is modified when minimally realistic ingredients are taken into account rather than the elementary GBM: the phase and the possible coupling between individual walks, i.e. between gain/loss individual channels in our analogy.

We hope to give a different light on disordered systems in plasmonics from such an interdisciplinary perspective.

Abstract - We demonstrate visible frequency, room-temperature, ultra-narrow-linewidth lasing of surface plasmon polaritons (SPPs) propagating along the floor of a metallic open-cavity Fabry-Perot resonator formed by template stripping and coated with a subwavelength-thick layer of dye gain medium. The lasing threshold is lowered by pumping the gain medium with an SPP standing wave, generated using a low-profile grating located on the cavity floor. Darkfield transmission sampling of the lasing SPP mode via a recessed nanoslit enables high-contrast, high-figure-of-merit refractive-index sensing of analytes interacting with the open cavity.

Ongoing miniaturization of the footprint of optical systems and circuits requires development of wavelength scale optical elements able to efficiently generate, manipulate and detect light. Achieving coherent optical sources with narrow linewidth and nanoscale mode-confinement in one or more dimensions has been central to this quest. More recently, metal based resonators sustaining surface plasmons have emerged as a promising route to achieve stimulated emission or lasing at nanometer-scale dimensions. For example, optically-pumped lasing plasmon modes formed by localized surface plasmons on dye-coated resonant nanoparticles and nanoparticle arrays (*1–3*), or by gap plasmons confined to a dielectric layer of nanoscale thickness between a metal surface and a semiconductor gain medium (*4–8*), have been recently demonstrated.

Here, we show, for the first time, lasing of propagating surface plasmon polaritons (SPPs) confined to an open Fabry-Perot cavity. Ultra-narrow linewidth, visible frequency lasing is achieved at room-temperature. The cavity consists of a template-stripped (*9*) ultra-smooth flat Ag surface orthogonally bound by a pair of Ag sidewalls (10, 11), forming a trough-shaped, micron-scale width resonator for SPPs exhibiting a record-high quality factor, and a figure-of-merit for refractive-index sensing that is an order of magnitude higher than that of a state-of-the-art surface-plasmon resonance (SPR) sensor (*12*, *13*). By incorporating a subwavelength thickness of DCM-doped (3mM) polymer film on the trough floor, and optically pumping the dye from the open side of the cavity, we demonstrate room-temperature SPP lasing in the red (*14*). We show (Fig. 1) how the lasing threshold and linewidth can be lowered by incorporating a low-profile tapered grating in the cavity floor to couple the excitation beam into a pump SPP, providing strong modal overlap with the gain medium. The record narrow lasing linewidth (≈ 0.24 nm) achieved here is substantially smaller than that of localized–plasmon lasers (*1–3*) and comparable to that of the best semiconductor-based gap–plasmon lasers (*5*, *7*) demonstrated to date. Transmission-configuration sampling of the lasing intensity with minimum perturbation to the both pump and emission SPPs is achieved via an evanescently coupled nanoslit recessed below the cavity floor, opening the way to active, multiplexed platforms for high figure-of-merit refractive index sensing and surface-analyte detection, in which arrays of open-cavity SPP lasers are directly integrated onto electronic imaging chips.

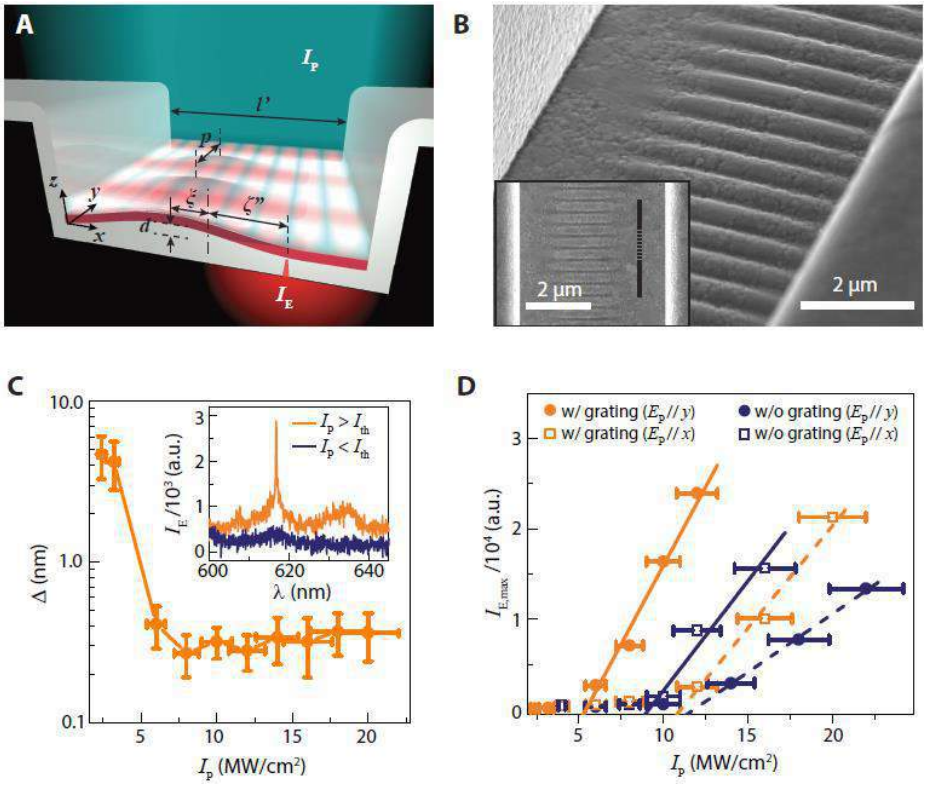

Figure 1: Experimental characterization of grating-decorated SPP-pumped SPP laser. (A) Schematic diagram of a template-stripped, open-cavity SPP laser with cavity metal (Ag) thickness 300 nm, cavity width l' = 4.4 μm and height 2 μm, decorated with a low-profile grating of periodicity p = 350 nm, amplitude d = 40 nm, and offset ξ = 320 nm from the cavity center, coated with a 260-nm thick layer of PMMA:DCM gain medium, illuminated an normal incidence with a nanosecond pulsed pump-beam of wavelength λ_P = 480 nm, intensity I_P, and linear polarization perpendicular to the grating. The schematic blue-green and red standing waves illustrate the grating-coupled pump SPPs and cavity-trapped lasing SPPs, respectively. A 50-nm-wide slit, recessed 50 nm below the cavity floor, offset ζ''= 1.5 μm from cavity center, evanescently samples the lasing SPP mode and transmits a wave of proportional intensity, I_E, into the far-field on the other side of the device (glass substrate). **(B)** Tilted-view SEM image of the template-stripped cavity resonator illustrating the grating-decorated cavity floor. **Inset:** top-view SEM image of the device, where the nominal location of the buried recessed sampling slit is indicated by the dotted black line. **(C)** Evolution of the SPP emission linewidth Δ with increasing pump intensity I_P. **Inset:** representative emission spectra of I_E for I_P below (I_P = 4.0 MW/cm^2) and above (I_P = 6.0 MW/cm^2) the lasing threshold (I_{th} = 5.6 MW/cm^2). **(D)** SPP lasing turn-on characteristics I_E vs. I_P on a linear scale for grating-decorated and grating-free devices as a function of in-plane pump polarization.

Metamaterial Structures for Healthcare Applications

Thin Metamaterial Antireflection Coating In-vivo Measurements to Test the Transmission Enhancement through Human Tissue

H. Cano-García[1, 2*], S. Saha[1], I. Sotiriou[1], P. Kosmas[2], and E. Kallos[1, 3]

Abstract-This paper presents for the first time experimental results of a metamaterial antireflection coating designed to work in contact with human tissue. The metamaterial performance is tested using two patch antennas operating between 59 GHz and 62 GHz that send and receive signals through a human hand. The measurements show an average of 4.4 dB enhancement in transmission when the metamaterial is added in front of the hand.

The high value of relative permittivity of the skin compared to air creates an impedance mismatch. This impedance mismatch is present in most of the non-invasive biomedical applications that use electromagnetic radiation (EM). Solving this impedance mismatch problem would help to develop more accurate and less power consuming devices. For example, the sensitivity and specificity of microwave imaging systems would be improved and their limitations, high false negative rate and high false positive rate, would be significantly reduced. The accuracy of microwave hyperthermia treatment would be enhanced, permitting to focus heat on the exact location of the tumor target, without burning healthy tissue. The power levels used in electrosurgery would also be reduced providing a more efficient way of coagulating small blood vessels. And, finally, the precision and reliability of non-invasive blood glucose monitoring would be improved, allowing sensing the blood properties in a more accurate way.

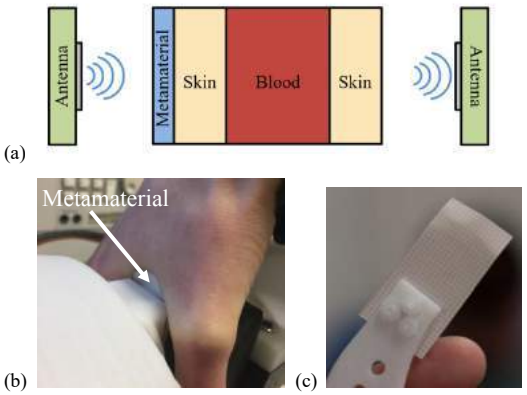

Figure 1: (a) Cross section (not to scale) of the schematic design consisting of an AR metamaterial unit cell placed in contact with a skin-blood-skin slab and excited using patch antennas. (b) Photo showing the experimental setup. (c) Photo showing the metamaterial film

To solve this impedance mismatch, the authors propose to use an antireflection (AR) coating with a similar design than the one presented in [1]. Previously, in [2,3] the authors presented an AR coating design optimized to work in contact of tissue, comprised by 0.5 mm of skin, 1 mm of blood and 0.5 mm of skin. In [2] the authors presented simulations results of this AR metamaterial that achieved 1.4 dB enhancement in the transmitted power. This metamaterial design was fabricated and tested in an in-vivo experimental study using pig subjects, [3], and it achieved 1.9 dB improvement in the transmitted signal.

Here we present in-vivo measurements of this AR metamaterial film when used in presence of human skin. For these measurements, the metamaterial film was placed in front of the skin and two patch antennas,

operating between 59 GHz and 62 GHz, were used as an excitation source (Figure 1a). The antennas were transmitting and receiving signal through the boneless part of the hand located between the index finger and the thumb (Figure 1b). To help the flattening of the skin surface, the antennas were enclosed inside two custom made plastic holders, capable of adjusting the antenna-sample distance.

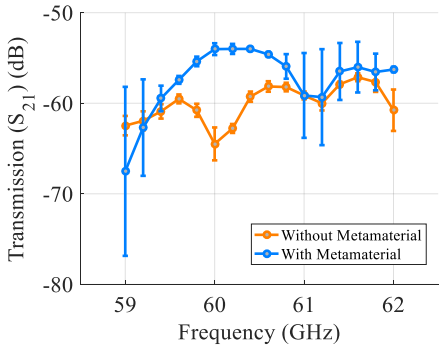

Figure 2. Comparison of the S_{21} recorded signal with and without the presence of the AR metamaterial.

The experimental study was performed at University of Roehampton, London, UK. The transmitted and received signal was measured using a Vector Network Analyzer (Keysight Technologies' E8361A PNA).

To quantify the performance of the metamaterials, two different types of measurements were recorded: (i) antennas transmitting through the tissue without metamaterial; (ii) same as (i) but adding the metamaterial film between the antenna and the hand (Figure 1). Between measurements the holders were slightly moved using micropositioners to facilitate the placement or the removal of the metamaterial between the antenna and the hand.

Figure 2 shows the transmission coefficient (S_{21}) for the two different types of measurements on a single human subject. The error bars represent the standard deviation of two sets of five measurements. Between these two sets the metamaterial was removed and placed again. Between 59.3 GHz and 61 GHz the average increase in transmission achieved when the metamaterial is added is 4.4 dB.

The main reason for the differences between measurements is the possible movement of the hand when the holder was removed to insert or remove the metamaterial. Note that the error bars are more significant on the measurements with the metamaterial. This could be because the position of the metamaterial changed between the two sets of measurements affecting differently to the bending produced on the metamaterial when conforming to the hand shape; and therefore, creating accidental air gaps between the metamaterial and the tissue.

The authors thank Richard Mackenzie and his team from University of Roehampton and Nadine Geddes for their contribution in the human trials. The authors would also want to thank George Palikaras for his support and scientific guidance. Moreover, the authors acknowledge the financial support of InnovateUK and EPSRC for this study.

Tunable Hybrid Metasurfaces for Magnetic Resonance Imaging

Alexey Slobozhanyuk[1,2]
[1]Nonlinear Physics Center, Australian National University, Australia
[2]Department of Nanophotonics and Metamaterials, ITMO University, Russia
[*]corresponding author: aleksei.slobozhaniuk@anu.edu.au

Abstract- Metasurfaces have become a new paradigm in the studies of artificial subwavelength structures due to their potential to overcome many challenges typically associated with metamaterials. However, a majority of demonstrated metasurface structures possess fixed properties, e.g. fixed operational bandwidth or functionality. An active control of metasurface functionalities and bandwidth is highly desirable for engineering an advanced electromagnetic and photonic devices. Here, we suggest and demonstrate experimentally a novel type of tunable metasurface capable of dramatic enhancing the image quality.

Metasurfaces [1] are artificial ultrathin structures representing a planar realisation of metamaterial concept [2]. One important application of metasurfaces is the enhancement of image quality which is crucially important in different fields of biology, medicine and nanotechnologies. In particular it was demonstrated experimentally that the metasurface lens, designed for optical frequencies, can be used to provide diffraction limited focal spots [3] and to resolve features with subwavelength spacing, while parity-time symmetric nonlocal metasurfaces allow ideal aberration-free optical images [4]. Another field where metasurfaces can potentially help is related to Magnetic Resonance Imaging (MRI), known to be one of the most important clinical modalities for detection of various diseases in human bodies. More precise, MR image quality is limited by signal to noise ratio (SNR) that is relatively low for the majority of current machines and therefore MR image acquisition is usually a very time consuming process. Recently a new conceptual idea has been suggested to substantially increase SNR of commercial MRI with the aid of metasurfaces made by resonant metallic inclusions [5]. Later, this effect was confirmed during in-vivo imaging and spectroscopy of the human brain [6].

In this talk, we will review our recent activities with metasurfaces application for MRI and also present a novel hybrid tunable metasurface capable to enhance substantially the MR-image quality, allowing to resolve smaller features of images, e.g. tumours, much faster and more efficiently.

Abstract-

In this talk, we will present results on van der Waals materials for active infrared photonics, with a focus on graphene and few-layer black phosphorus. We take advantage of the electrostatically tunable optical properties of graphene to design active devices for controlling absorption, emission, and phase. We additionally consider ultrathin black phosphorus as a novel platform for IR optoelectronics, demonstrating gate-tunable transmittance due to an ambipolar Burstein-Moss and Quantum Confined Franz-Keldysh effect.

van der Waals materials provide an excellent platform for tunable photonics in the infrared (IR). By electrostatically gating these ultrathin materials, tunable absorption, emission, polarization, and phase can be achieved. In this talk, we will present several experiments that take advantage of this dynamic response, establishing new physical mechanisms for achieving tunability, and demonstrating progress towards reconfigurable mid-IR metasurfaces.

Graphene, a monolayer Dirac semi-metal, is an ideal platform for tunable plasmonics in the mid-IR. With a charge carrier density of $\sim 10^{12}$ cm^{-2} which can be controlled with an electrostatic gate, graphene supports IR plasmons which can be spectrally tuned. In this talk, we will present results demonstrating highly confined, tunable plasmons in graphene with confinement factors up to $\lambda_0/\lambda_p \sim 100$ and electromagnetic simulations implying a local density of optical states more than 10^6 larger than free space.[1] This tight confinement results in very strong interactions of the plasmons with their environment, leading to coupling with phonon polaritons in neighboring materials, including other monolayers such as hexagonal boron nitride, which we observed experimentally[2]. By combining these graphene resonators with a quarter-wavelength thick dielectric spacer layer of SiN_x and a gold back reflector, also known as a Salisbury Screen, absorption in the graphene resonators is enhanced up to 24.5%, an order of magnitude higher than without this design.[3] We will also comment on the use of this structure for actively modulation thermal radiation, with kHz switching speeds.[4]

Metasurfaces offer significant potential to control far-field light propagation through the engineering of amplitude, polarization, and phase at an interface. We will present an extension of tunable graphene-based nanophotonics platforms for applications to reconfigurable metasurfaces. Using a gate-tunable graphene-gold resonator geometry, we demonstrate highly tunable reflected phase at multiple wavelengths and show up to 237° phase modulation range at an operating wavelength of 8.50 μm. We observe a smooth monotonic modulation of phase with applied voltage from 0° to 206° at a wavelength of

8.70 μm. Based on these experimental data, we demonstrate with antenna array calculations an average beam steering efficiency of 50% for reflected light for angles up to 30°, relative to a ideal metasurface, confirming the suitability of this geometry for reconfigurable mid-infrared beam steering devices.[5]

Finally, we will present results on field effect optoelectronic modulation of quantum-confined carriers in black phosphorus. We report measurements of the gate-tunable infrared optical response of thin black phosphorus. We interpret the observed spectral changes as a combination of an ambipolar Burstein-Moss (BM) shift of the absorption edge due to band-filling under gate control, and a quantum confined Franz-Keldysh (QCFK) effect, phenomena which have been proposed theoretically to occur for black phosphorus under an applied electric field. Distinct optical responses are observed depending on the flake thickness and starting carrier concentration. Transmission extinction modulation amplitudes of more than two percent are observed, suggesting the potential for use of black phosphorus as an active material in mid-infrared optoelectronic modulator applications.[6]

Terahertz-Light Emission in Graphene-Based Active Plasmonic Metamaterial Heterostructures

T. Otsuji[1*], T. Watanabe[1], A. Satou[1], D. Yadav[1], S. Boubanga-Tombet[1], T. Suemitsu[1], and V. Ryzhii[1]
[1]RIEC, Tohoku University, Japan
[*]otsuji@riec.tohoku.ac.jp

Abstract-This paper reviews recent advancement on the research toward graphene-based active plasmonic metamaterials for terahertz (THz) light emission. The dual-gate graphene channel transistor structure serves carrier population inversion, promoting spontaneous broadband THz emission. Active plasmonic meta-surfaces implemented into the gate structure can transcend the incoherent light-emitting action to the amplified stimulated emission of THz radiation.

Carrier-injection pumping of graphene can enable negative-dynamic conductivity in the THz spectral range, which may lead to new types of current-injection THz lasers [1]. The dual-gate graphene channel transistor structure serves carrier population inversion in the lateral p-i-n junctions under complementary dual-gate biased and forward drain-source biased conditions, promoting spontaneous broadband incoherent THz light emission. A distributed feedback (DFB) laser cavity structure implemented into the gate electrodes can transcend the incoherent broadband light-emitting-diode (LED) to the single-mode lasing action. We fabricated the test devices and confirmed aforementioned LED and single-mode laser operations at 100K [2, 3].

To increase the operating temperature and output radiation intensity, further enhancement of the THz gain is mandatory. Asymmetric dual-grating-gate meta-surface structures may promote plasmonic superradiance [4] and/or plasmonic instabilities [5, 6], giving rise to giant THz gain enhancement at plasmonic resonant frequencies. Dyakonov-Shur type instability owing to the Doppler-shift effect at the plasmonic cavity boundaries, Ryzhii-Satou-Shur type instability owing to the carrier transit-time effect in the periodically modulation-doped channel, and plasmonic-boom instability are the possible mechanisms.

Widely Tunable Semiconductor Antennas for Reconfigurable Metasurfaces

J. A. Schuller
Electrical and Computer Engineering Department, UC Santa Barbara, CA, USA
*corresponding author: jonschuller@ucsb.edu

Abstract-The ability to engineer the optical phase at subwavelength dimensions has led to metasurfaces that provide unprecedented control of electromagnetic waves. To reach their ultimate potential, metasurfaces must incorporate reconfigurable functions. The central challenge is achieving large tunability in subwavelength elements. Here, we describe two different approaches for achieving order-unity refractive index shifts: free-carrier refraction and thermo-optic tuning

We experimentally demonstrate wide tuning of single-particle infrared Mie resonances through doping[1], and demonstrate simulations of electrically reconfigurable III-V heterojunction metasurfaces based on these effects[2,3]. We conclude with recent experimental demonstrations of dyamic, ultrawide tuning of Mie resonators based on two distinct thermo-optic effects: 1) modifying the electron mass and carrier density in InSb and 2) exploiting the anomalous temperature-dependent bandgap of PbTe.

Abstract- Rectifying stripe-teeth metasurfaces, consisting of microantenna arrays with infrared resonances, coupled to vertical Metal-Insulator-Metal (MIM) diodes having an insulating barrier layer, were designed, fabricated, and characterized with FTIR microscopy and current-voltage (I-V) measurements. Resonances agreed well with FDTD models and the electrical measurements showed that the NbO_x-based diodes have modest large barrier heights and nonlinear I-V curves, allowing for prediction of their rectification response. These, and Al_2O_3-based microrectenna arrays, were illuminated by infrared and visible laser beams, and their direct current was characterized as a function of bias voltage and compared to quantum rectification models.

Absorption in a semiconductor is limited by the band gap. An array of "microrectennas" could theoretically efficiently rectify from near- to far-infrared frequencies, converting the incident THz voltage to direct current via a nonlinear receiver. Vertical metal-insulator-metal (MIM) diodes have produced power from optical-frequency fields, produced by a metamaterial planar stripe-teeth Al or Au antenna array lying above the vertical diode. We have recently published a model of MIM diodes and their predicted current-voltage (I-V) characteristics and rectification[1].

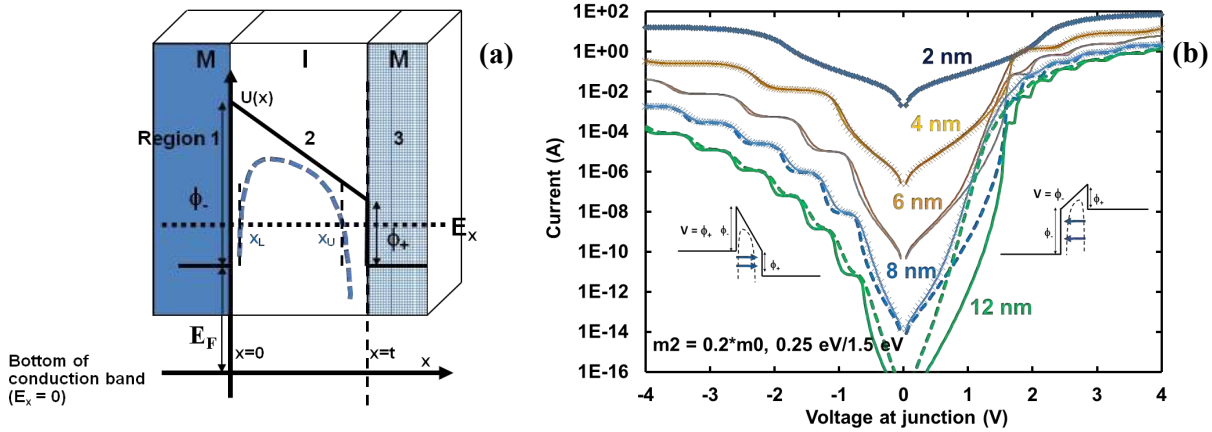

Figure 1: (a) Model of the MIM diode. Region 1 is the metal with larger barrier height, region 2 is the barrier layer (thickness t) with the trapezoidal potential function U(x), and region 3 is the metal with lower barrier height. (b) Predicted I-V curves as a function of barrier thickness and temperature, for both forward bias (V < 0) and reverse bias (V > 0), predicting Fabry-Perot resonance effects.

These stripe-teeth arrays are similar to stripe arrays that have demonstrated, (Wu (2011)) near-perfect absorption in the infrared, except that "teeth" break the left-right symmetry at normal incidence and produce a net a.c. voltage into the substrate, similar to "optical rectification" except that direct current also flows. We designed, fabricated, and analyzed these stripe-teeth microrectenna arrays in the near- and short-wave infrared and planned for LWIR. Stripes extracted the direct current; teeth lay along the x-axis and, when excited by the incident electric field,

produced the resonant a.c. field, determined by the spacing of the teeth along the y-axis. The antenna-amplified z-component of the electric field, was rectified by Atomic-Layer-Deposited (ALD) Au/NbO_x/Nb, Al/Al_2O_3/Au, or Al/Al_2O_3/Al diodes.

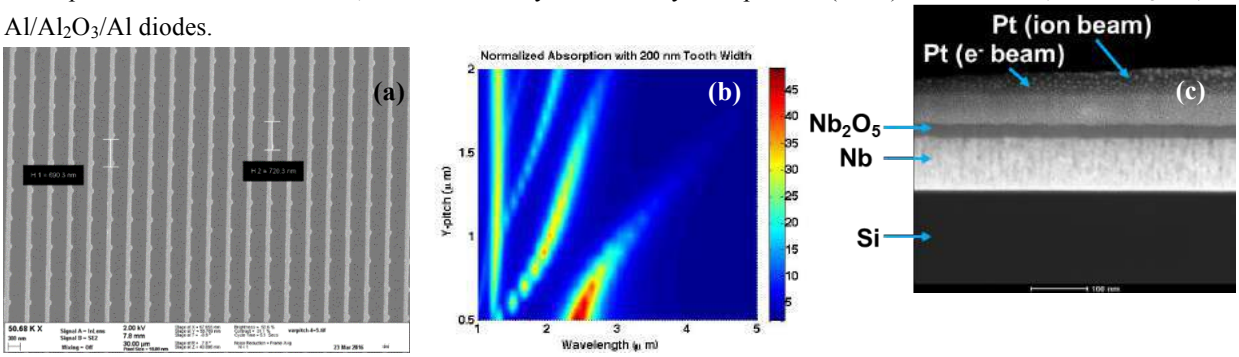

Figure 1: (a) Electron microscopy (EM) image of chirped microrectenna arrays designed at NSRDEC and MITLL (b) Stripe-teeth resonances (normalized absorption) for E-field || x, as a function of wavelength and y-pitch (the vertical line is the fixed cross-stripe resonance); infrared microscopy measurements confirmed this. (c) Transmission EM image of novel NbO_x-Nb based MIM diode.

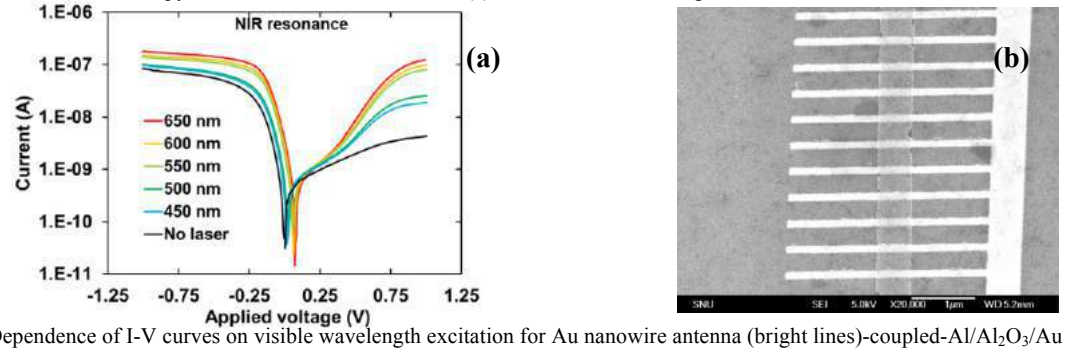

Figure 3: Dependence of I-V curves on visible wavelength excitation for Au nanowire antenna (bright lines)-coupled-Al/Al_2O_3/Au diodes. (b) Plan view EM image of these nanorectennas. Vertical diodes form where the transmissive Al stripe and the Au antennas cross.

I-V measurements from Al/Al_2O_3(22 nm)/Al test diodes gave current densities in the range of μA/cm^2 with an application of +/- 6V, while Au/NbO_x(20 nm)/Nb test diodes produced similar current densities with smaller voltages, due to their smaller (< 1 V) barrier heights. Al/Al_2O_3/Au diodes were much more conductive than their Al/Al_2O_3/Al counterparts, suggesting a reduced barrier height due to a different ALD barrier layer.

These microrectenna arrays are currently being illuminated with visible and infrared cw lasers. For the Au/NbO_x/Nb, and Al/Al_2O_3/Au diodes, if the laser's photon energy is comparable or greater than the voltage scale of the I-V nonlinearity, the Tucker formula for quantum rectification responsivity (R in A/W) is appropriate (Eq. 1, where $\hbar\omega/e$ is the photon energy divided by electronic charge and $I_{dc}(V_0)$ is the direct current under a bias of V_0).[2]

$$R = \frac{e}{\hbar\omega}\left[\frac{I_{dc}\left(V_0+\hbar\omega/e\right) - 2I_{dc}(V_0) + I_{dc}\left(V_0-\hbar\omega/e\right)}{I_{dc}\left(V_0+\hbar\omega/e\right) - I_{dc}\left(V_0-\hbar\omega/e\right)}\right] \quad (1)$$

For the Al/Al_2O_3/Al diodes, it is possible that the formula for classical responsivity may be used instead.[2] Illumination of Pt/NbO_x/Nb and Al/Al_2O_3/Au microrectenna arrays with 514 nm and 450 – 650 nm photons, respectively, produces a significant change in the output current and a shift in the I-V curve and a ~ 5 nA short-circuit current, respectively.[1] Comparison of the experimental measurements with the responsivity prediction is ongoing, and for the Al/Al_2O_3/Au microrectenna arrays may require a new explanation for the observed reduction in diode barrier height.

Abstract-We present a comprehensive study of radiative heat transfer in ångström and nanometer-sized gaps from both an experimental and theoretical point of view. Our results establish the fundamental validity of fluctuational electrodynamics in modelling near-field radiative heat transfer (NFRHT) down to single-nanometer gaps. Furthermore, our work suggests that unexpectedly large thermal conductances found in previous works are due to the presence of surface contamination.

Radiative heat transfer between objects at different temperatures is of fundamental importance in applications such as energy conversion, thermal management, lithography, data storage, and thermal microscopy [1]. It was predicted long ago that when the separation between objects is smaller than the thermal wavelength, which is of the order of 10 μm at room temperature, the radiative heat transfer can be greatly enhanced due to the contribution of evanescent waves (or photon tunneling). In recent years, different experimental studies have confirmed this long-standing theoretical prediction. However, in spite of this progress, there are still many basic open questions in the context of near-field radiative heat transfer (NFRHT). Thus, for instance, recent experiments exploring the radiative thermal transport in nanometric gaps have seriously questioned the validity of fluctuational electrodynamics [2,3], which is presently the standard theory for the description of NFRHT. In this work, we address the issue of radiative heat transfer in the extreme near-field regime when objects are separated by nanometer-size distances. In particular, we have accomplished a very detailed comparison of novel NFRHT experiments performed with scanning thermal probes with state-of-the-art simulations based on the fluctuating-surface-current formulation of the heat transfer problem. The ensemble of our results clearly show that fluctuational electrodynamics provides an adequate description of the NFRHT between both metals and dielectrics all the way down to nanometer-size gaps [4]. Besides, our analysis of NFRHT in sub-nanometer gaps suggest that past reports of large deviations from the predictions of fluctuational electrodynamics are probably due to surface contamination effects. We also demonstrate, from measurements of apparent tunneling barrier heights, that such deviations can be systematically attenuated by carefully cleaning the surfaces as indicated by an increase in the apparent barrier height [5].

Highly Integrated Dual-Channel Metamaterial Thermal Detector for Mid-IR Optical Gas Sensing

A. Lochbaum[1*], Y. Fedoryshyn[1], C. Hafner[1], and J. Leuthold[1]
[1]Institute of Electromagnetic Fields (IEF), ETH Zurich, 8092 Zurich, Switzerland
[*]corresponding author: alexander.lochbaum@ief.ee.ethz.ch

Abstract- We demonstrate a dual-channel, CMOS-compatible metamaterial thermopile detector, exhibiting near-ideal peak absorptivity values (A=0.99), and narrowband absorption characteristics (Q = 15.1 at 4.29 µm). The ultra-thin metamaterial perfect absorber (MPA) makes additional blackening layers and filter elements obsolete, allowing for highly integrated, low-cost optical gas sensing systems. Employed in a non-dispersive gas sensing setup, the MPA detector leads, in comparison to a non-structured thermopile, to a 3.9-fold increase in analyte resolution, with a simultaneous 6.5-fold decrease in humidity cross sensitivity.

The ubiquitous trend towards low-cost integrated sensing solutions, e.g. for medical or automotive applications, drives the demand for efficient and selective mid-infrared (mid-IR) detectors [1]. Thermopiles (TP) are well known as low-cost detectors for the mid-IR wavelength range and are widely used in non-dispersive infrared (NDIR) gas sensors. However, they suffer from a low spectral selectivity due to their thermal detection principle, and from the low absorptivity values of typical TP membranes. This makes additional filter elements and blackening layers necessary, which limit the size, cost and speed of these detectors. Recently, metamaterials have been investigated as a promising candidate to overcome those limitations by resonantly enhancing their absorptivity in the mid-IR to values close to unity, over a potentially narrow bandwidth [2]. However, the limited resonance quality factors of actually demonstrated metamaterial absorbers restrict their use for selective gas analysis, and the integration of a sufficiently narrowband metamaterial absorber on a thermal detector has not been shown for far. In this paper, we monolithically integrate for the first time narrowband metamaterial perfect absorbers (MPA) on thermopile detectors and demonstrate their performance for sensitive and selective gas analysis in the mid-IR.

The structure of the MPA detector and the MPA unit cell are shown in Figure 1(a). The metamaterial absorber area (270×300 µm^2) is centered on the dielectric TP membrane and comprises a periodic arrangement of subwavelength unit cells. Each unit cell consists of a cross-shaped metal resonator (Cu), separated from the metal backplane (Cu) by means of a

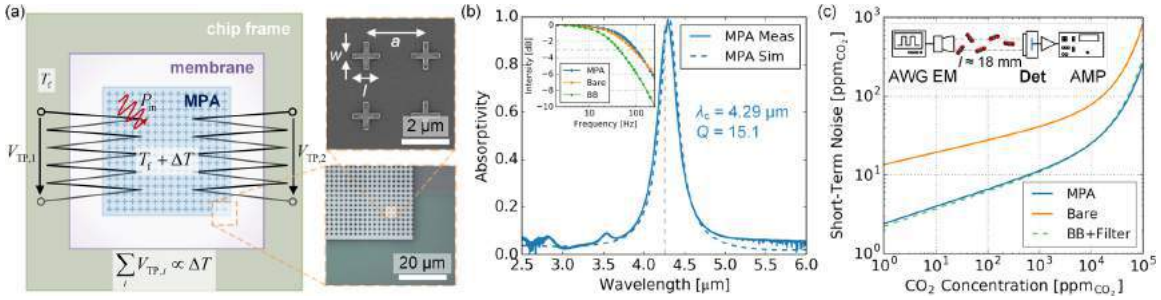

Figure 1. (a) Schematic of the metamaterial detector and details of MPA unit cells. (b) Simulated and measured absorptivity of the MPA structure. Inset: frequency response of the MPA detector in comparison to thermopiles with carbon-black ("BB") and without ("Bare") absorber structure. (c) CO_2 resolution of sensing systems employing MPA, non-structured ("Bare") and dielectrically-filtered ("BB + Filter") thermopiles. Inset: Schematic of non-dispersive gas sensing setup.

dielectric spacer layer (Al_2O_3). Geometrical parameters of the unit cell have been optimized by full-wave simulations for resonant absorption at $\lambda_c = 4.26$ µm, yielding in $a = 2$ µm, $l = 1.03$ µm, $w = 192$ nm, $t_{metal} = 100$ nm, and $t_{dielectric} = 90$ nm. The MPA structure has been fabricated in a series of post-processing steps on top of commercial thermopile substrates. Details on the employed optimization and fabrication processes can be found in [3]. The measured absorptivity of the MPA structure is shown in Figure 1(b). The structure yields a peak absorptivity $A = 0.99$ at the center wavelength $\lambda_c = 4.29$ µm, in very good agreement with the simulation results. In the inset of Figure 1(b), the frequency response of the MPA detector is compared against the frequency response of a carbon-black coated TP and a TP without absorber layer. Due to its low thermal mass, the MPA does not impair the dynamic properties of the underlying detector ($f_{-3db} = 95$ Hz), in contrast to a conventional carbon-black absorber, which increases the detector time constant by a factor of two. Besides its efficient blackening and low thermal mass, the high quality factor $Q = 15.1$ of the MPA enables sensitive and selective gas analysis without the need for additional filter elements, which has been demonstrated in a series of non-dispersive gas sensing experiments using CO_2 (absorption resonance: $\lambda_{CO2} = 4.26$ µm) as an analyte. The experimental setup is displayed in the inset of Figure 1(c). A hotplate emitter (EM) is positioned opposite to the detector under test (DET), separated by a metal-coated absorption channel ($l = 18$ mm). The emitter is driven by a signal generator (AWG), and the TP signal is lock-in amplified (AMP). The performance of the MPA detector in such a setup has been compared against a TP without absorber coating, as well as a TP with carbon-black absorber coating and a commercial dielectric filter ($\lambda_f = 4.26$ µm, FWHM = 180 nm). The measured absolute CO_2 resolution of each system configuration, as derived from the relative analyte sensitivity of the detector signal at various CO_2 concentrations, is shown in Figure 1(c). For the MPA detector system, a resolution of 8.99 ppm_{CO2} at $c_{CO2} = 400$ ppm has been measured, outperforming the non-structured TP by a factor of 3.9 and reaching the resolution of the reference, dielectrically-filtered absorber system. Furthermore, the MPA detector system exhibits a 6.5-fold reduced humidity cross sensitivity (6.4 ppm_{CO2}/%rH) in comparison to the non-structured TP (41.8 ppm_{CO2}/%rH), which can be directly attributed to the narrowband absorption characteristics of the MPA structure. To demonstrate the high integration density of the MPA concept, we realized a dual-channel MPA detector by incorporating two spatially separated MPA areas on the same TP membrane, as shown in the inset of Figure 1(b). The center wavelengths correspond to a sensing ($\lambda_1 = 4.26$ µm) and a reference ($\lambda_2 = 3.91$ µm) channel, with their measured absorptivity spectra shown in Figure 2(a) relative to the atmospheric absorption. The resulting difference signal between both TP areas exhibits excellent stability with virtually no drift, even over extended measurement periods, Figure 2(b), which showcases the MPA technology's potential for advanced detection schemes.

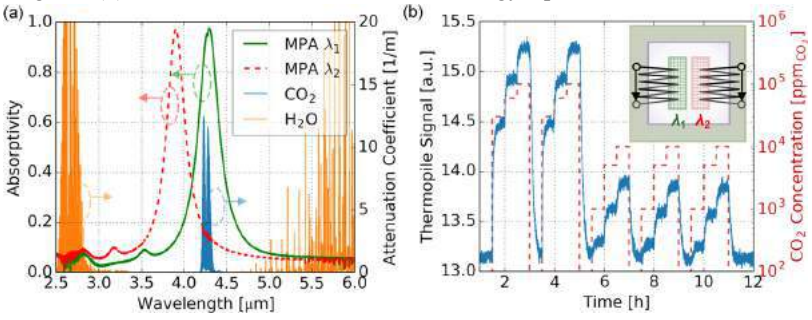

Figure 2. (a) Absorptivity of sensing (λ_1) and reference (λ_2) channel as measured on the dual-channel MPA detector together with the atmospheric attenuation (40 %rH, 400 ppm_{CO2}, at 25°C). (b) Dual-channel detector signal together with the applied gas concentration. Inset: schematic of dual-channel MPA detector.

Graphene Plasmon-Assisted Mid-Infrared Light Emission

L. Kim[1], V. W. Brar[2], S. Kim[1], and H. A. Atwater[1*]
[1]California Institute of Technology, USA
[2]University of Wisconsin - Madison, USA
[*]corresponding author: haa@caltech.edu

Abstract – Plasmon emission is predicted to be a highly efficient decay mechanism of photoexcited hot carriers in graphene, competing with optical phonon emission. To facilitate coupling of emitted plasmons with photons, we created graphene nanoribbons whose resonances live above, below and near the optical phonon energy. We observe carrier density-dependent graphene plasmon-assisted light emissions in the mid-infrared under femtosecond laser excitation. We explore how plasmonic modes alter decay pathways for photoexcited hot carriers and affect the resulting infrared radiation.

The decay dynamics of excited carriers in graphene have attracted wide scientific attention, owing to the much lower relaxation rate of excited 'hot' carriers than is seen in many three-dimensional materials. However, plasmons can significantly reduce the photoexcited charge carrier lifetime in graphene, and this plasmon effect on excited state decay gets larger with increasing carrier density, as indicated by recent theoretical calculations and angle-resolved photoemission experiments.[1,2,3,4] We report experimental results suggesting that graphene plasmons excited by ultrafast pumping affect the radiative emission rate. This work has important implications for achieving ultrafast optical control of mid-infrared light emission. While traditionally achieving control of infrared radiation has required heating and cooling of an object – a relatively slow process – plasmon-assisted light emission resulting from sub-100fs decay of hot carriers could provide a method for ultrafast generation and modulation of infrared radiation.

The reported lifetimes of excited carriers in the presence of graphene plasmon emission range from a few femtoseconds to 100s femtoseconds.[3,4] Such timescales suggest that plasmon emission is a decay channel with whose strength is comparable to optical phonon emission, which is widely considered to be the dominant decay mechanism at carrier energies above the "phonon bottleneck" (i.e., the optical phonon energy). In planar continuous graphene sheets, plasmon emission is difficult to observe because emitted plasmons decay non-radiatively, owing to the large momentum mismatch between graphene plasmons and free space light. Radiative emission of graphene plasmons can be dramatically increased by defining nanoribbons in graphene to allow detection of plasmon-coupled light emission. The confined plasmonic resonances of graphene nanoribbons are tunable by changing sizes and carrier densities of graphene nanoribbons, enabling us to spectroscopically tune the detected plasmon energy across the mid-infrared wavelength regime.[5] By creating plasmon resonances above, below and near the optical phonon energy, we can observe how graphene plasmon modes affect the decay mechanisms of photoexcited carriers via measurement of mid-infrared light emission. Photoexcited hot carriers are created in graphene nanoribbons with a 100-fs pulsed laser excitation at $\lambda = 850$ nm, and the resulting infrared emission is collected and analyzed with a Michelson interferometer for varying graphene carrier densities.

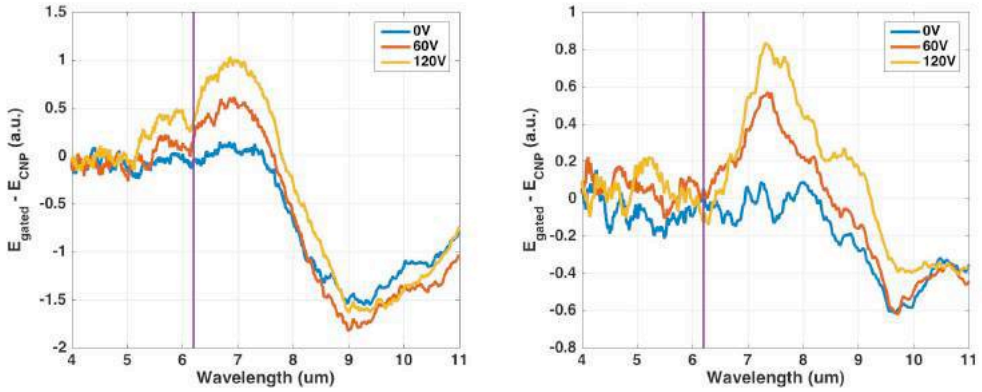

Figure 1. Carrier-dependent emission from bare graphene (left) and 50nm nanoribbons (right) under 100-fs pulsed laser excitation at $\lambda = 850$ nm. The higher gate voltage means higher carrier density. The vertical purple lines indicate the optical phonon energy (200 meV).

Figure 1 shows carrier density-dependent emission spectra from bare graphene (left) and patterned graphene (right). In both cases, the emission intensity is larger for higher graphene carrier density, which is controlled via the changes in applied gate voltage. The emission spectra of bare graphene are broad and show features across a wide energy range – both above and below the optical phonon energy. By contrast, the emission spectra from 50nm ribbons show relatively narrow peaks exclusively at the resonance frequency ($\lambda \sim 7.5$um), and the peaks blue shift with increasing carrier density. By comparing the emission spectra of bare and patterned graphene, we study the effects of propagating plasmons and confined plasmons on hot carrier decay mechanisms and the resulting light emission.

Topological plasmons in graphene

T. Christensen,[1] **D. Jin**,[2] **L. Lu**,[3] **& M. Soljačić**[1]

[1]Department of Physics, Massachusetts Institute of Technology, Cambridge, MA 02139, USA

Abstract— We discuss recent work on topological plasmonic states in two-dimensional electron gases under an applied magnetic field. By periodic nanostructuring, new high-frequency topological edge states can be synthesized beyond the conventional low-frequency edge magnetoplasmon. In moderately doped graphene, these high-frequency unidirectional edge plasmons can exist at frequencies up to tens of terahertz, reaching the far-infrared regime.

Spurred by the contemporary topological understanding of the quantum Hall effect in fermionic systems, a broad class of nontrivial topological bosonic phases have emerged in recent years. Among these, time-reversal-symmetry ($\mathcal{T}$) broken topological bosonic systems—proposed in a variety of quasiparticles, spanning photons, phonons, excitons, polaritons, and magnons—which host unidirectional and backscattering-immune edge states along structural terminations, hold great promise for the development of nonreciprocal and defect-tolerant devices. So far, however, the achievable operating frequencies of these $\mathcal{T}$-breaking platforms are low, typically in the GHz regime. This restriction, which represents a severe obstruction to applications, is ultimately due to the scarcity of workable high-frequency $\mathcal{T}$-breaking mechanisms.

Recently, efforts to expand the zoo of topological bosons have encompassed plasmonics as well. Notably, it was recently shown [1] that the conventional low-frequency edge magnetoplasmons, which exist along the terminations of two-dimensional electron gases, arise as a consequence of a nontrivial topology of the underlying bulk bands. We will discuss our recent proposal [2] for a new class of high-frequency $\mathcal{T}$-broken topological edge plasmons enabled by periodic nanostructuring of the underlying two-dimensional system. Specifically, in a triangular antidot lattice etched into graphene, we find that a new high-frequency topological edge plasmon emerges under a magnetically induced gapping of a bulk Dirac-degeneracy. This edge plasmon is unidirectional, immune to backscattering by structural defects, and exists at frequencies up to tens of THz, even in moderately doped graphene. Graphene is a particularly attractive candidate material for topological plasmonics by virtue of its low intrinsic loss, tunable carrier density, and chiefly, by its large magneto-optical response. This finding identifies a practical path to topological $\mathcal{T}$-broken operation in the far-infrared regime, and simultaneously enriches the field of topological photonics with the characteristics hallmarks of plasmonics—strong optical confinement and enhanced light–matter interaction.

Abstract- Terahertz (THz) responses of topological insulator Bi_2Se_3 exhibit a strong interaction between Dirac surface plasmon and optical phonon near 2 THz. Employing time-resolved THz spectroscopy, we investigated the spectral manifestation of plasmon-phonon interaction after photoexcition. Ultrafast THz measurements in Bi_2Se_3 micro-ribbon reveal the ultra-high modulation depth of 2,400% assisted by Fano-like plasmon-phonon-destructive interference. When plasmon frequency is controlled by changing the dimension of Bi_2Se_3 micro-slits, we observe the different relaxation dynamics of hot optical phonon after photoexcitation.

Engineering surface plasmon provides an efficient tool to modulate THz wave. A high modulation depth is expected to be emerged in topological insulator (TI) Bi_2Se_3 due to the strong optical modulation capability of Dirac plasmons [1]. In this work, we explore the ultrafast optical modulation of Dirac plasmons in a micro-ribbon array of Bi_2Se_3 by using time-resolved optical-pump THz-probe spectroscopy. Under optical pulse injection, the surface plasmon frequency is shifted beyond the phonon frequency in the THz range, which significantly changes the extinction spectra. As a result, an unprecedented, giant modulation depth up to 2,400% is obtained with very low fluence of optical control pulse (45 $\mu J/cm^2$). Our theoretical calculations show that the plasmon frequency shift arises from the photo-doping of the non-topological two-dimensional electron gas (2DEG) formed due to downward bending of the bulk bands near the surface [2, 3]. Unlike conventional semiconductor-based plasmonics, various species of quantum states, such as Dirac electrons, massive 2DEG and semiconductor-like bulk, which together with plasmon–phonon interference lead to dynamic spectral modulation in TIs, provide a novel platform for controlling plasmons.

The atomic composition of Bi_2Se_3 poses a limit to the control of the phonon resonances. Although prior studies have found that the electron-phonon coupling is a way to manipulate the phonon resonances [4], these methods require a complicate experimental system. Here, using the strong interaction of Dirac surface plasmon and optical phonon [1, 5], we demonstrate a simple methodology of altering the phonon resonances by lithographically-engineered surface plasmons in Bi_2Se_3. Our ultrafast terahertz investigation reveals that the phonon cooling is suppressed when the Dirac plasmon energy exceeds the phonon resonance, resulting in anomalous phonon stiffening. On the other hand, we observe that the phonon cooling is greatly accelerated (within 1 ps) when the plasmon energy is smaller than the bulk phonon, leading to phonon broadening. This observation suggests that engineering the plasmon-phonon coupling provides an alternative to dynamically control the phonon energy without atomic modification. These results thus provide a promising laboratory for novel topological insulator applications, ranging from topological thermoelectric effects to tunable terahertz plasmonic devices.

Abstract- We theoretically, numerically and experimentally demonstrate hollow core fibres with hyperbolic metamaterial cladding having more than double the single-mode bandwidth of metallic waveguides. In the THz such fibres offer a unique combination of being mechanically flexible, with low optical loss and large single-mode bandwidth.

An essential component in developing compact terahertz devices are waveguides [1]. Among several waveguide solutions proposed for guiding THz radiation, hollow-core waveguides are one of the best options due to low losses of THz waves in air [1]. However, these waveguides usually have diameters of the order of several wavelengths and consequently are rigid, multimode pipes for guiding THz radiation rather than flexible fibres. The emergence of metamaterial opens a new avenue to overcome some of the limitations of hollow-core THz waveguides, by providing new guidance mechanisms and extreme birefringence that guide a single polarization [2,3]. We have demonstrated that fiber-drawing techniques can be used to produce large quantities of metamaterials with electric and magnetic responses [5,6]. Fibers containing arrays of thin metal wires have been produced, which have an electric response depending on the size and spacing of the wires. In this presentation, first we will discuss the characteristic equations for guided modes and the relevant mode existence conditions of a hollow-core waveguides with uniaxial metamaterial claddings [7,8]. Then we will show that a hollow-core waveguide with wire metals in the cladding can only confines transverse magnetic (TM) modes due to extreme anisotropy of wire metamaterials [9]. Finally, we will show experimental results demonstrating how utilizing metal wires in the cladding of a THz hollow-core waveguide can lead to flexible fibres with large single mode operating bandwidth (0.22-0.34 THz), 2.5 times larger than that which can be achieved using metallic hollow core waveguides [9].

Abstract— A monolayer graphene is able to produce a Faraday rotation of several degrees in modest magnetic field at terahertz frequencies. Using a metallic metasurface of sub-wavelength optical resonators placed in strong proximity to graphene, an increase of the non-reciprocal effect can be achieved over a broad range of frequencies. We demonstrated via simulations that increasing the geometric symmetry of the single resonator the performances of the device improved. The combination of both a huge polarization rotations (more than 20 degrees) accompanied by a large transmission amplitude, candidates this device as a prototype for sub-wavelength non-reciprocal element, like Faraday rotator and optical isolator.

Among the unique properties of graphene, its giant Faraday rotation ($\sim 6^\circ$) at terahertz (THz) frequencies [1] has attracted a lot of attention in order to approach a new prototype of non-reciprocal element with sub-wavelength dimensions. Focusing on the THz radiation, several works have succeeded to further enhance the non-reciprocal behavior of graphene [2], but most of them achieving this result at the price of losing the intrinsic two-dimensional character provided by graphene itself.
Triggered by the observation that (magneto-)optical response of graphene is strongly influenced by the presence of a planar square array of split-ring resonators (SRRs) at a distance of a few tenths of nanometers from it [3], we have been motivated to investigate by full wave simulations how the non-reciprocal polarization rotation can be greatly enhanced adopting this structure (Figure 1**a**).

We observed that the planar geometry of the specific resonator which constitutes the metasurface has a strong influence on both Faraday rotation angle (θ_F) and transmittance (T) of the system. Even just for common square electric-SRR shape, the hybrid metasurface provides an increase of the Faraday rotation in correspondence of the metasurface resonance. This result, however, comes at the expense of T which results to be very small even after an optimization of the geometric parameters. Nevertheless, devices that aim to work as a Faraday isolator or rotator need to have both high θ_F and T. Their performance can be indeed defined by a dimensionless parameter γ_F which is a function of the transmittance T and of θ_F [4]: $\gamma_\mathrm{F}(\mathrm{T}, \theta_\mathrm{F}) = \frac{|2\mathrm{T}\sin\theta_\mathrm{F}|^2}{(1-\mathrm{T}^2)^2}$. In order to have γ_F as large as possible, several other shapes have been studied. During this process of optimization, we found that shapes characterized by a higher degree of symmetry imply an improvement of the performances. If we take into account also the FWHM of γ_F as function of frequency and we define as figure of merit the product $\frac{\mathrm{FWHM}(\gamma_F)}{\nu(\gamma_\mathrm{F}^{\max})} \times \gamma_\mathrm{F}$, where $\nu(\gamma_\mathrm{F}^{\max})$ is the frequency of maximum γ_F, the improvement of the performances of the system for three symmetry group (C_2,C_4 and C_8) can be seen in Figure 1**b**. Following this trend, the geometry of the resonators which is observed to have the largest value of γ_F is that reported in Figure 1**a**, belonging to C_8 group. The electric and magnetic field spatial distributions of the resonator is shown in Figure 1**c**. The impact of the real part of the refractive index (n) of the substrate on the device performance has also been investigated. We found that lower values of n provide a larger value of the figure of merit, as it clearly appears from the comparison between the red and blue curves in Figure 1**b**, calculated for n equal to 1.5 and 2.5, respectively. In the fabricated device, the used substrate is Cyclic Olefyn Copolymer (COC), which has n$\sim$1.5 and optical losses under 3 cm^{-1} at THz frequencies. The measured transmission spectrum (in the absence of external magnetic field) is shown in Figure 1**d**

in comparison to the corresponding simulation.
Obviously, also the graphene Drude parameters highly influence the non-reciprocal properties. In panel **e** and **f**, the curves for θ_F and γ_F as function of frequency are shown for four values of the Fermi energy, respectively.

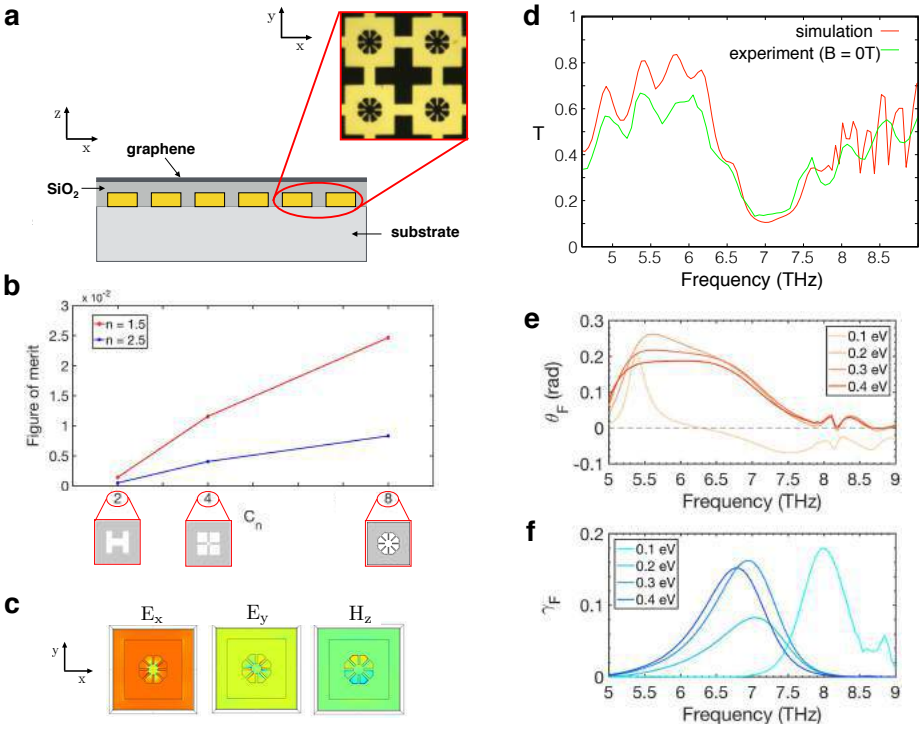

Figure 1: **a)** Device sketch showing the layers of the structure. Graphene, placed on the top, is separated by a 200 nm thick layer of oxide (SiO_2) from the 100 nm thick and 3×3 mm^2 wide metasurface of periodically arranged and interconnected (25 μm long) square resonators. An optical image of the resonators of a fabricated sample is shown. At the bottom a 100 μm thick layer of Cyclic Olefyn Copolymer (COC) is placed as substrate. **b)** Simulated figure of merit of the system for three different planar geometry of the resonators belonging to the symmetry group C_2, C_4 and C_8, respectively. The three geometric shapes are also shown at the bottom of the figure. **d)** Spatial distribution inside the unit cell of the x and y components of the electric field $\vec{E}$ and of the z component of the magnetic field $\vec{H}$ for the excited optical mode of a single resonator belonging to C_8. **d)** Comparison between measured transmission spectrum of fabricated sample in absence of external magnetic field and the corresponding full-wave simulation. In panels **e** and **f**, the simulated Faraday angle θ_F (rad) and dimensionless γ_F factor as function of frequency for the metasurface belonging to the C_8 symmetry group are inserted, respectively. The same quantities are studied for different values of graphene Fermi energy (0.1, 0.2, 0.3 and 0.4 eV). In all simulations the bias magnetic field is set to 7T and the graphene mobility is fixed at 4.000 cm^2/Vs.

In conclusion, we have studied a system consisting of a resonant metasurface put in close proximity to a graphene monolayer at THz frequencies. We demonstrated by simulations that this sub-wavelength structure strongly enhances the graphene Faraday rotation and that the performances can be strongly improved by increasing the symmetry of the unit resonator geometry. Its scalability allows to tune this operating region over the whole THz range, or, provided it is arranged in a connected fashion, it can be used as a back gate to change the Fermi energy of graphene, adding another powerful functionality for the tunability of the system.

Abstract-We present an analytical, classical electromagnetic description of the nonlinear optical response associated with tunable plasmons in graphene nanostructures. Our model uses two-dimensional graphene conductivities as input to obtain the nonlinear response of the desired nanostructures. The results are shown to be in excellent agreement with realistic quantum-mechanical simulations based on a tight-binding description of electrons in graphene combined with the random-phase approximation for the response functions.

Graphene exhibits a remarkably high intrinsic nonlinearity that can be pushed even further when the optical frequency is tuned to the plasmon resonances of the material [1-4]. Atomistic simulations provide an accurate description of these phenomena, although their computational cost is prohibitive for large graphene nanostructures [3,4]. An alternative formalism consists in relying on classical electromagnetism, using the local nonlinear conductivities extracted from models of extended graphene. We show that both of these approaches are in excellent agreement for sufficiently large structures (10s of nm in lateral size) when describing second- and third-harmonic generation, as well as the Kerr effect. Additionally, we exploit an eigenmode decomposition of the optical field in the classical formalism to obtain analytical expressions for the plasmon-driven resonant response of the graphene ribbons and finite islands, in excellent agreement with full numerical calculations. This analytical description constitutes a valuable asset to explore nonlinear optical phenomena in the context of graphene plasmonics, and can also be applied to model nonlinearities in other planar plasmonic materials, such as thin metal layers.

Abstract-Any planar structure can be superimposed with its mirror image. Despite lacking conventional chirality, planar metamaterials exhibit stronger and more diverse chiral optical effects than conventional materials. Planar chirality associated with the twist of flat spirals and mirror asymmetry introduced by the direction of illumination give rise to directional transmission asymmetries, giant linear and nonlinear optical activity, circular polarization reflectors and perfect absorbers as well as wavevector selective spectral filters.

It is a common misconception that chiral optical effects require chiral materials, i.e. materials that cannot be superimposed with their mirror image. In fact, chiral optical effects occur in chiral experiments.

A flat spiral does not have conventional chirality as it can be superimposed with its mirror image by flipping it over. Nevertheless, circularly polarized waves of opposite handedness will interact differently with a planar twisted object. As the planar twist reverses for opposite directions of observation, the handedness of the optical effect reverses for opposite directions of illumination, resulting in directionally asymmetric transmission [1]. An effective planar twist can result from oblique incidence onto any planar pattern and thus directionally asymmetric optical properties should be expected for any lossy planar metamaterial [2]. The effect can be engineered to yield perfect absorption for one circular polarization, while the other is reflected without polarization change, providing an opportunity to develop circularly polarized cavities for sensing and lasers [3].

A chiral experiment with an effective three-dimensional twist can result from oblique incidence onto any planar structure lacking two-fold rotational symmetry. For planar metamaterials, this can lead to exceptionally large optical activity for both transmitted [4] and reflected light [5] and exploiting nonlinearity enhancement in plasmonic metamaterials 10-million-fold larger nonlinear optical activity than in natural materials has been observed [6]. The effects are inherently tuneable due to their dependence on the angle of incidence and they allow the realization of switchable circular polarization perfect absorbers [7] as well as resonant spectral passband filters that are directional notch filters [8].

An overview over concepts developed over the last decade and associated experimental breakthroughs will be given.

Nonsymmorphic topological photonic crystals

Ling Lu

Instituite of Physics, Chinese Academy of Sciences, Beijing, China
linglu@iphy.ac.cn

Abstract— After discussing the consequences of band dispersions of glide, screw and time-reversal symmetries, I will show examples of 2D photonic crystal waveguides and 3D photonic crystal waveguides with glide and time-reversal symmetries. Then I will go over the discovery of Weyl points in a nonsymmorphic photonic crystal. At last, I will present a 3D magnetic topological photonic crystal hosting a single surface Dirac cone, protected by glide reflections. Such a gapless surface state is fully robust against random disorder of any type.

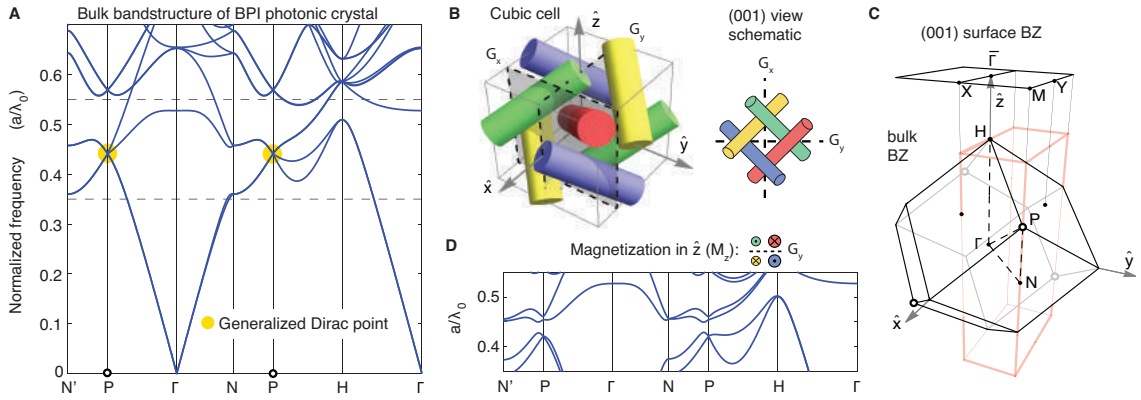

Figure 1: Bulk band structures of the BPI photonic crystal in bcc lattice. A) The GDP is between the first four bands. B) The cubic unit cell of length a consisting of four identical dielectric rods oriented along the bcc lattice vectors of (111) (red), $(11\bar{1})$ (yellow), $(1\bar{1}1)$ (blue) and $(\bar{1}11)$ (green). The rods go through $(0,0,0)a$, $(0,0.5,0)a$. $(0.5,0,0)a$ and $(0,0,0.5)a$ respectively. There are two glide reflection planes (G_x and G_y) in the structure, invariant on the (001) surface. The top-view schematic illustrates the relations between the rods under operations of G_x and G_y. C) The bcc BZ and its projection onto the (001) surface BZ. The transparent red box outlines the volume in the bulk BZ that projects to half of the surface BZ. D) Bulk band structure showing that the GDP opens when magnetization is applied on the rods without breaking G_y.

ACKNOWLEDGMENT

I thank all my collaborators on nonsymmorphic photonic crystals.

Rectangular holey glide-symmetric metasurfaces for ultra-wideband anisotropy

Abstract- Metasurfaces have recently gained popularity for designing lens antennas. Particularly, fully metallic metasurface lens antennas present low losses and are ideal for space applications. In this work, we present a novel asymmetric unit cell that can be employed for the design of anisotropic lenses. The unit cell consists of two glide-symmetric layers. A rectangular hole is edged at the bottom layer, which is periodically mirrored and translated in the top layer. This unit cell provides low dispersion over a wide band and produces anisotropic high refractive index as required for typical lenses in antennas.

Metasurfaces are two-dimensional versions of metamaterials [1, 2]. By using metasurfaces as in [1-3], flat lenses can be designed, proving high directive beam scanning antennas. These antennas find application for wireless communications, especially at the very high frequencies, where array have a high cost, due to their need of phase shifters [4].

In [3], glide symmetric metasurfaces were proposed to obtain stable refractive indexes over an ultra-broadband frequency range. Those proposed structures were fully metallic, which is an asset for space applications, and inherently have low loss capabilities. Additionally, using this glide-symmetric based approach, it has been demonstrated that glide-symmetric can be employed to produce bandgaps which can be employed for gap waveguide technologies [5].

Glide-symmetric metasurfaces consist of two layers, which are translated half period and mirrored [6-10], and they were extensively studied in the ‘60s and ‘70s in the one dimensional configuration. Although the first studies of two-dimensional glide-symmetric unit cells have provided promising properties [3,5], only isotropic configurations have been proposed.

Here, we propose rectangular holey structures that can be employed to produce an anisotropic response. Our asymmetric unit cell consists of two layers as shown in Fig. 1 with rectangular holes, which are glide-symmetric. Fig. 2 shows the simulated dispersion diagram of the proposed asymmetric unit cell in both x and y directions, with the variation of the depth of the rectangular hole. It is noticed that for the propagating wave along the x direction, the fundamental mode varies with the depth of the hole, but for the waves propagating in y direction, no significant variation is observed. In both cases, the mode is non-dispersive, opening possibilities for the design of ultra wideband anisotropic flat lenses.

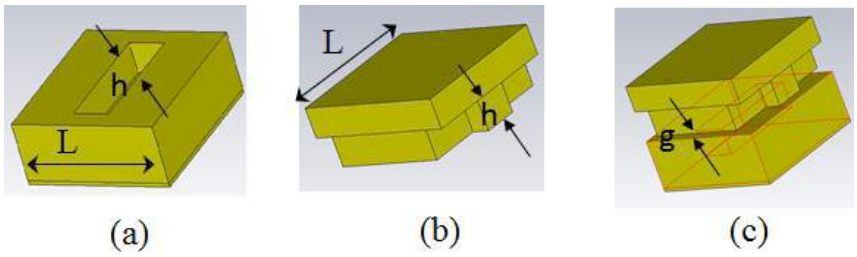

Fig. 1: (a) Bottom layer (b) top layer (c) overall unit cell [L= 4mm, g= 0.15 mm].

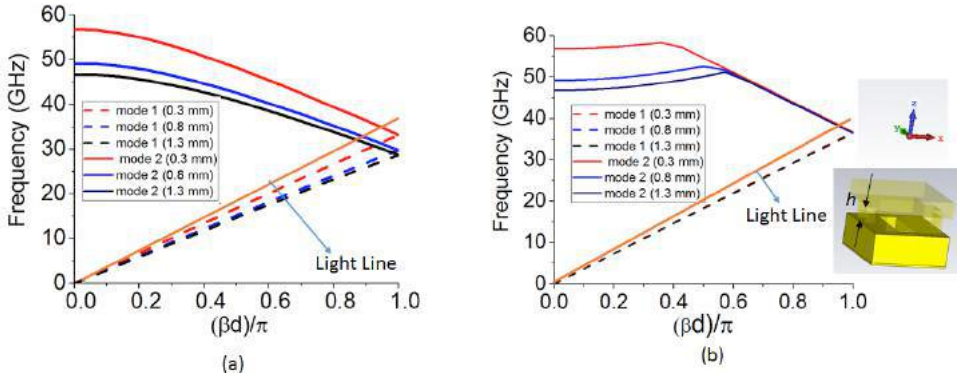

Fig. 2: Dispersion diagram for different h values: (a) x direction (b) y direction.

Study of propagation characteristics in a waveguide with twist-symmetric holes

F. Ghasemifard and **O. Quevedo-Teruel**

KTH Royal Institute of Technology, Sweden
fatemehg@kth.se

Abstract— The effect of twist symmetry, a special kind of higher symmetries, in a one dimensional periodic structure has been studied. It has been shown that by adding twist symmetry, achieving less dispersive and denser materials is possible. Moreover, it has been shown that the location of bandgap is changed by adding twist symmetry or changing the degree of twist symmetry.

Glide and twist (screw) symmetries are a certain class of higher symmetries. A glide-symmetric structure is a structure which coincides with itself under a half-period translation followed by mirroring with respect to a glide plane [1]. A p-fold twist-symmetric structure is a structure which coincides with itself under a translation of d/p and a rotation of $2\pi/p$ around the twist axis, where d is the period of the unit cell [1]. Here, we name p as the degree of the twist symmetry. By generalizing the Floquet theorem, periodic structures possessing these higher symmetries were studied in the 1960's and 70's [1, 2, 3, 4].

Recently, glide-symmetric metasurfaces have been proposed. These metasurfaces present low frequency dispersion [5, 6] and can be used to implement wideband flat lens antenna [5]. In these works, it has been shown that a metasurface with glide symmetry acts as a medium with a constant equivalent refractive index over a broad range of frequencies. Moreover, compared to the conventional metasurfaces, higher equivalent refractive indices are achievable by glide-symmetric metasurfaces [5]. Glide-symmetric structures can also be employed in gap waveguide technology [7].

Here, we study the effect of adding twist symmetry to a coaxial waveguide with periodic holes. For this purpose, three different periodic configurations with the same periodicity are investigated. The first one is a coaxial waveguide, composed of an inner and outer conductor, separated by air, with holes located periodically on the inner conductor. Since this structure can be considered as a translation of the holes, it does not possess higher symmetries. However, the second and third configurations are the same coaxial waveguide with 2-fold and 4-fold twist symmetric holes on the inner conductor. The inner conductors of all the cases and their dispersion diagrams have been illustrated in Figure 1. In all cases the inner and outer radii of the coaxial waveguide are, respectively, 1.49 mm ($D/2$ in Figure 1) and 1.59 mm; the periodicity is 12 mm and the sides of the holes $L = 2.4$ mm and $A = 4.69$ mm (A is the length of the arc part of the hole).

The results demonstrate that the dispersive nature of the lowest propagation modes in the coaxial waveguide with periodic holes (Single hole configuration in Figure 1) is reduced or even removed by adding twist symmetry. Moreover, the results reveal that by increasing the degree of the twist symmetry, higher effective refractive indices are achievable. Furthermore, it is clear that the location of bandgaps can be changed by adding twist symmetry or by changing the degree of the twist symmetry. For instance, in the single hole case, there is a bandgap from 10.05 GHz to 13.45 GHz and in 2-fold case, there is a bandgap from 18.26 GHz to 25.91 GHz, whereas, for the frequencies below 30 GHz there is no bandgap in 4-fold case.

In conclusion, by adding glide or twist symmetry to periodic structures, we will have more control on the propagation characteristics of periodic structures. This effect could be used in designing travelling wave antennas such as leaky-wave antennas. Moreover, periodic structures with higher symmetries can be used to realize wideband flat antennas.

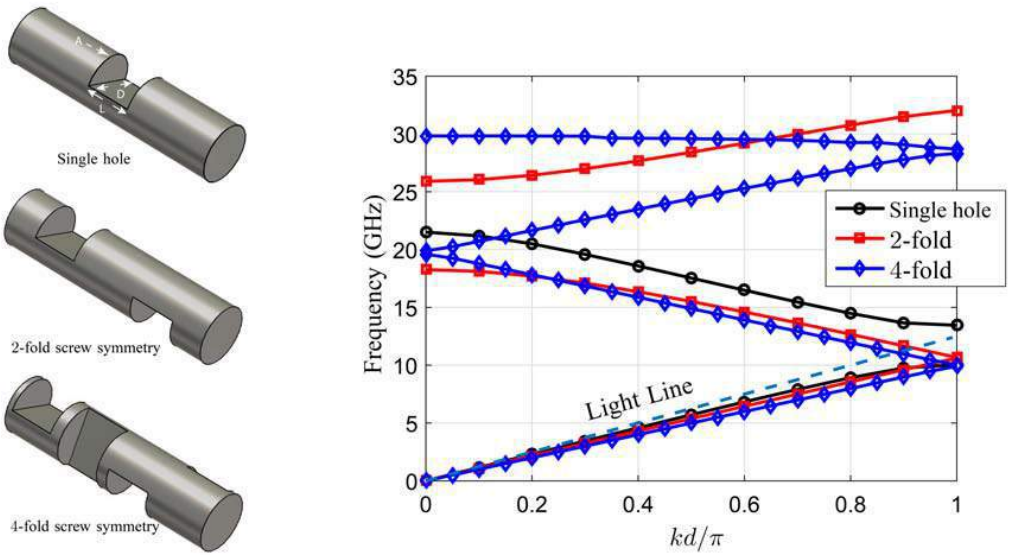

Figure 1: (Left) Inner conductor of a coaxial waveguide with periodic holes (Single hole) and the same coaxial waveguide with 2-fold and 4-fold twist-symmetric holes. In all structures the inner and outer radii of the coaxial waveguide are, respectively, 1.49 mm (which is $D/2$) and 1.59 mm; the periodicity is 12 mm, and the sides of the holes $L = 2.4$ mm and $A = 4.69$ mm (A is the length of the arc part of the hole). (Right) Dispersion diagrams of a coaxial waveguide with periodic holes (Single hole) and the same coaxial waveguide with 2-fold and 4-fold twist-symmetric holes.

Cost-effective Integrated Waveguide Circuits at High Frequencies Using Glide-Symmetric EBG Structures

M. Ebrahimpouri[1], **O. Quevedo-Teruel**[1*]

[1] Electromagnetic Engineering department (ETK) in School of Electrical Engineering, KTH Royal Institute of Technology, Stockholm, Sweden

[*]oscarqt@kth.se

Abstract- Here, we present a cost-effective and easy method to manufacture integrated waveguide circuits at high frequencies. Glide-symmetric holey EBG structure enables us to realize gap-waveguide technology economically since it only requires drilling holes on metallic plates and larger periodicity of it with respect to the pin-type EBG at the same frequency results in higher accuracy of manufacturing at high frequencies. Introducing this method provides a way for mass production of gap waveguide technology at high frequencies.

Hollow metallic waveguides are one of the earliest types of transmission lines. They have been popular because of their properties like high power handling capacity, low-loss and cross-talk free characteristics. However, these waveguides are expensive and difficult to manufacture at high frequencies. To overcome this problem, substrate integrated waveguide (SIW) [1] and gap waveguide technology [2] were proposed during last years. Although SIW structures are compact and can be manufactured using PCB technology, they are not efficient at high frequencies due to the losses originated by dielectrics. Additionally, SIW requires of metallic vias with diminutive periodicity to minimize leakage, increasing their total cost at high frequencies. Gap waveguide technology is new alternative to hollow metallic waveguides at high frequencies. In gap waveguide, there is no need to have contact between upper and lower plate, due to the use of pin-type EBG at the sides of the wave-guiding region, which is an advantage for manufacturing. Furthermore, waves are guided in the air, which results in less lossy transmission lines. However, at high frequencies thin and tall metal pins are required to prevent leakage in this technology, which increases the costs of manufacturing. To solve this problem, half-height pin-type EBG was proposed [3].

Here, we propose an alternative solution, glide-symmetric holey EBG structures. Manufacturing our proposed EBG structure is easier than pin-type EBG since it only requires drilling holes on metal. Periodicity of this EBG structure is about 3 times larger with respect to pin-type EBG, which results in higher accuracy of manufacturing at high frequencies. A glide-symmetric unit cells is created after a periodic mirror and translation [4-8]. Glide-symmetric structures has demonstrated to produce non-dispersive responses [9] and extraordinary bandgaps [10].

Fig. 1 (a) and (b) present the structure of square lattice of this unit-cell and dispersion diagram over its Brillouin zone, respectively. According to this figure, this EBG structure has a stop-band from 40 GHz to77 GHz. Therefore, this EBG structure can be used with standard rectangular waveguide (WR-19) in U-band (40 GHz- 60 GHz). Fig. 2(a) presents the proposed waveguiding structure. The glide-symmetric holey EBG at the location of gap prevents leakage and provides almost perfect transmission similar to shielded rectangular waveguide (RW). Fig. 2(b) compares transmission in a perfect RW with our proposed waveguiding structure and a

waveguide, which is made in two parts and EBG structure is not placed at the location of gap . Considering Fig. 2(b), a small gap at side walls creates significant leakage, while by placing EBG structure at the location of gap, we can have almost perfect transmission.

Symmetry properties of planar particle arrays and their role for non-reciprocal and one-way guiding.

Y. Mazor and Ben Z. Steinberg
School of Electrical Engineering, Tel-Aviv University, Israel
steinber@eng.tau.ac.il

Abstract-Resonant particle arrays have been considered as waveguides for various applications. We present a general theory for analyzing the breach of geometrical symmetries required to allow for non-reciprocal guiding and optical isolation. Both, the unit cell symmetry and the properties of the particles themselves play a role in this study. The structure symmetry can be combined with specific particles properties to yield various wave phenomena. Their role in achieving non reciprocity, non-even dispersion, and one-way guiding, will be discussed.

In the context of polarizability theory and discrete dipole approximation, particle arrays response is governed by the difference equation [1]

$$p_n = \alpha_n \sum_{m \neq n} G(r_n - r_m) p_m + \alpha_n E^{inc}(r_n)$$

where p_n and α_n are the equivalent dipole response and polarizability tensor of the n-th particle, located at r_n. Here $G(r)$ is the free space dyadic Green's function. The formulation above holds for any set of particles as long as the particles are electrically small, and the inter-particle distance is large compare to the typical particle size. Specifically, we are interested in cases where at least part of the particles possess non-symmetric polarizability tensor that supports Faraday rotation. This property can be achieved, e.g. by using ferrite particles. In the optical regime, particles made of plasmonic Drude-like material under magnetic bias would possess such properties.

Examples of the particle arrays studied under the present framework are shown in Fig. 1. Any periodic planar strip-like array belongs to at least one group of the seven Frieze symmetry groups schematized in Fig. 1(a). It has been shown, however, that if the particles are merely spherical, then bias magnetization (and the ensuing Faraday rotation) are not sufficient to achieve non-even dispersion and one-way behavior; the associated particle array must possess at least two parallel chains in order to achieve these appealing properties. This observation stems from the obvious geometrical fact that a periodic particle array that consists of a single chain of spherically symmetric particles is "too symmetrical"; it belongs to most of the seven Frieze groups. Non-even dispersion and one-way guiding can reside only in the p1 and p1m1 groups [2].

A single chain particle array can be forced to reside in the aforementioned groups only, if one assign to each particle a property that is not preserved under any type of reflection. A geometrical rotation may provide the solution, in which case the particles must not be spheres, in order to render the rotation meaningful. Indeed, it has been shown that magnetized particle chains of the types shown in Figs. 1(b) and 1(c) possessing conventional and longitudinal chiralities, provide the desires breach of EM symmetries [3,4]. Of particular interest is the structure of Fig. 1(c) as it can be made completely flat, thus it is more convenient for fabrication.

It is interesting to examine the structure's dependence on the rotation step angle $\Delta\theta$. When observed in the "laboratory" frame, these structures seem periodic only for rational $\Delta\theta/\pi$. However, it can be shown that by observing the system in a *rotating* coordinate system $r_n \mapsto T_n r_n$ where T_n is a matrix of rotation by $n\Delta\theta$ about the z axis, the chain in Fig. 1(b) can be made periodic with period d for any $\Delta\theta/\pi$, rational or not. To contrast, there is no coordinate transformation under which the longitudinal chirality chain in Fig. 1(c) can be made periodic if $\Delta\theta/\pi$ is not a rational number. This structure, thus, is much richer in terms of spectral and geometrical features, and optional realizations. Furthermore, it suggests a testbed to study a plethora of fundamental physical phenomena. For example, the passage from a completely symmetric structure, to a one that provides only the basic breach of symmetries permitting one-way behavior, and then on to the case of non-reciprocal quasi-periodic structure (irrational $\Delta\theta/\pi$), are all encapsulated within the same structure. The passage is provided by a slight change of parameter. Figure 1(d) shows the spectral properties of the chain in Fig. 1(c), in the $\Delta\theta/\pi, \omega$ plane, under magnetization. A reminiscent of the Hofstadter's butterfly is seen, where the one-way property is color coded into the plane.

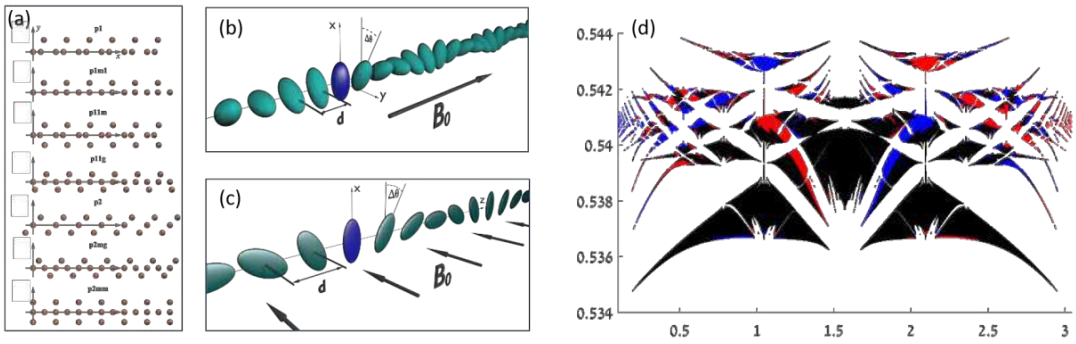

Figure 1. Particle arrays and one-way guiding. (a) The seven Frieze group for strip-like particle arrays. (b), (c) Single chains that provide the required breach of symmetries for one-way guiding (d) Spectral properties of the chain in (c), color coded according to the allowed propagation direction. Black points represent two-way guiding. Red or blue points represent only left or right-way guiding.

In this work the symmetry properties of these interesting structures will be discussed and illuminated via examples.

Generalized glide symmetry and topological edge states in layered media

S. A. R. Horsley[1]

[1]Department of Physics and Astronomy, University of Exeter, Stocker Road, Exeter, UK, EX4 4QL
s.horsley@exeter.ac.uk

Abstract— In this talk I shall discuss the theory of glide symmetry and its generalization to include mixtures of translation and polarization transformation, or translation and time reversal. I shall discuss an example where a wave propagates through a sequence of anistropic slabs, showing how generalized glide symmetry can be used to control the frequency gaps at the Brillouin zone boundary. Following from this I shall discuss the existence of edge states at the interface between two such stacks of slabs, finding the relationship between the Zak phase and the surface impedance of each stack.

Our understanding of wave propagation through periodic media is founded on Bloch's theorem [1]: translation through one spatial period leads to a phase difference, $\varphi(x+a) = \mathrm{e}^{\mathrm{i}Ka}\varphi(x)$. Typically the frequency increases until K reaches the edge of the first Brillouin zone, where there is a frequency gap before the next band of propagation.

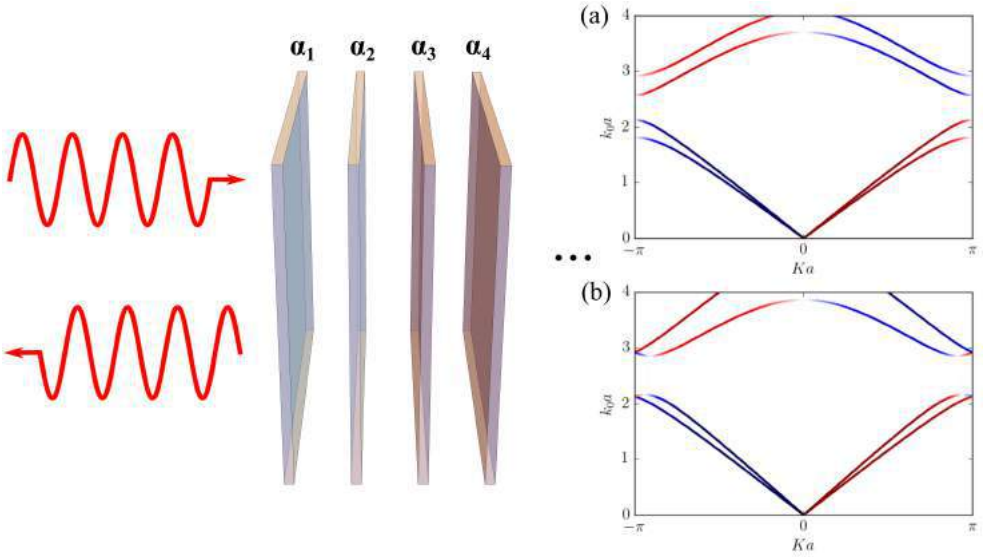

Figure 1: An an example of generalized glide symmetry we consider a series of thin anisotropic slabs characterised by tensors $\boldsymbol{\alpha}_i$. In general such a sequence of slabs exhibit a band gap at $K = \pm\pi/a$ as shown in panel (a) (color indicates direction of power propagation, red positive and blue negative). Panel (b) shows a case where we have imposed a translation–polarization glide symmetry, closing the band gaps at the Brillouin zone boundary.

But this isn't the full story. As usually defined, the first Brillouin zone is only the correct choice if symmetry under translation by a is the most basic symmetry operation. An obvious case where this doesn't hold is a badly chosen unit cell, which might e.g. contain two periods of the structure. In this case the unit–cell transfer matrix $\boldsymbol{T}$ can be written as the square of another transfer matrix $\boldsymbol{t}_{1/2}$

$$\boldsymbol{T} = \boldsymbol{t}_{1/2}^2$$

and the eigenvalue of $\boldsymbol{T}$, $\mathrm{e}^{\mathrm{i}Ka}$ is the square of the eigenvalue of $\boldsymbol{t}_{1/2}$, $\mathrm{e}^{\mathrm{i}Ka/2}$, the band gaps closing at the false Brillouin zone boundary $K = \pm\pi/a$. There are other less trivial cases where there

is a more basic symmetry of the structure, equal to a translation by a/N in addition to another symmetry operation $\boldsymbol{U}$

$$\boldsymbol{T} = \left(\boldsymbol{U} \cdot \boldsymbol{t}_{1/N}\right)^N = \ldots \boldsymbol{U}^{!\ 2} \cdot \boldsymbol{t} \cdot \boldsymbol{U}^2 \cdot \boldsymbol{U}^{!\ 1} \cdot \boldsymbol{t}_{1/N} \cdot \boldsymbol{U} \cdot \boldsymbol{t}_{1/N} \tag{1}$$

One kind of symmetry operation $\boldsymbol{U}$ is a rotation of the structure by an angle $2\pi/N$. When $N = 2$ such structures are said to exhibit *glide* symmetry. This symmetry has attracted some recent interest [2, 3], both in the context of the design of broadband metasurface lenses, and as a useful symmetry in topological photonics. However, it is clear that $\boldsymbol{U}$ is not restricted to spatial rotations. In this talk I shall explore such generalized glide symmetry operations where $\boldsymbol{U}$ can represent a time reversal operation or a transformation of the polarization. In the former case I shall connect generalized glide symmetry with PT–symmetry, and shall illustrate how band gaps can be closed by suitable design of a unit cell, even though the unit cell exhibits no purely spatial sub–division.

As a simple system where we can explore applications of generalized glide symmetry we consider a wave propagating through a sequence of anisotropic plates (see figure 1),

$$\frac{d^2}{dx^2}\begin{pmatrix} E_y \\ E_z \end{pmatrix} + k_0^2 \begin{pmatrix} \epsilon_{yy}(x) & \epsilon_{yz}(x) \\ \epsilon_{zy}(x) & \epsilon_{zz}(x) \end{pmatrix} \begin{pmatrix} E_y \\ E_z \end{pmatrix} = 0$$

where the permittivity tensor is represented as a sequence of delta functions $\boldsymbol{\epsilon}x) = \mathbf{1} + \sum_n \boldsymbol{\alpha}_n \delta(x - x_n)$. I shall discuss how to implement generalized glide symmetry in this system.

Following on from the discussion of glide symmetry I shall cover the criteria for the existence of edge states at an interface between two different sequences of such anisotropic slabs. In this part of the talk I shall discuss a generalization of the result of Xiao et al. where it was found that the closure of a band gap leads to a change in a topological quantity known as the Zak phase, which can be used to characterize layered media that support edge states at their interface.

Symmetry protected topological states of acoustic Kagome lattices

khanikaev@gmail.com

Abstract-We demonstrate that an acoustic Kagome lattice formed by an array of interconnected resonant cavities exhibits a new class of topological states protected by C3 symmetry. This acoustic topological metamaterial exhibits a topological transition when a detuning is introduced between the inter-cell and intra-cell hopping amplitudes. The edge states emerge on either truncated ends of the lattice terminated by a cladding layer or at the domain walls between topologically nontrivial and trivial domains.

Recently there has been a significant surge of interest in topological states supported by classical systems, which was inspired by their unique properties such as robustness against various forms of perturbations, as well as the ability to emulate exotic quantum states of matter. A variety of topological systems have been emulated with great success in mechanical, acoustic and electromagnetic structures, encouraging the use of their exotic characteristics in practical applications.

In this work, we study the emergence of a topological state in an acoustic Kagome lattice [33] induced by altering inter-cell and intra-cell hopping amplitudes; the system represents the two-dimensional analogue of the well-established 1D SSH model [1]. We develop a rigorous analytical approach, which allows characterizing the topological state of the system by calculating its topological invariant. The presence of topological edge states on the truncated end interfaced with the cladding layer and at the domain wall, respectively, validates the prediction of existence of the described topological transition. Numerical simulations on the existence of topological edge states and the robustness of edge states to the structure defects with and without C3 symmetry at the boundary are performed and also agree with our analytical prediction.

As in the case of one-dimensional SSH arrays, we expect that in two-dimensional Kagome system the topological transition will be accompanied by the emergence of edge states when a finite system is considered. To verify their existence from first principles, we performed FEM simulations of a supercell with different boundary conditions. A periodic boundary condition was imposed on connectors in the horizontal direction to form an acoustic ribbon that is infinite in the $(\frac{\sqrt{3}}{2}, \frac{1}{2}, 0)$ direction and has a finite width in the vertical $(0,1,0)$ direction. We examined both situations of topologically trivial and topologically nontrivial lattices, and found that only in the topologically nontrivial case (characterized by topological invariant $w = 1$) the bulk band gap hosts additional acoustic modes localized at the opposite truncated ends of the ribbon. Figures 1(a) and (b) show the dispersion of the acoustic ribbon for both respective cases. As shown in figure 1(a), edge states are absent inside the bandgap, while figure 1(b) reveals the presence of the pair of the edge states (shown by red and blue lines, localized at zigzag and armchair cut, respectively) inside the complete acoustic band gap of the bulk acoustic bands (shown by black lines). The field profiles corresponding to the two modes localized at the interfaces of the ribbon are shown in Fig. 1(c). Note that while there are also other non-topological edge modes that appear at the interface of the ribbon in both situations, and which are shown by pink colour bands in Figs. 1(a) and (b), these modes are always present, and coexist with the bulk modes regardless of topological phase

transition, which are similar to Tamm surface states in condensed matter. They therefore represent topologically trivial edge modes not of interest in this paper.

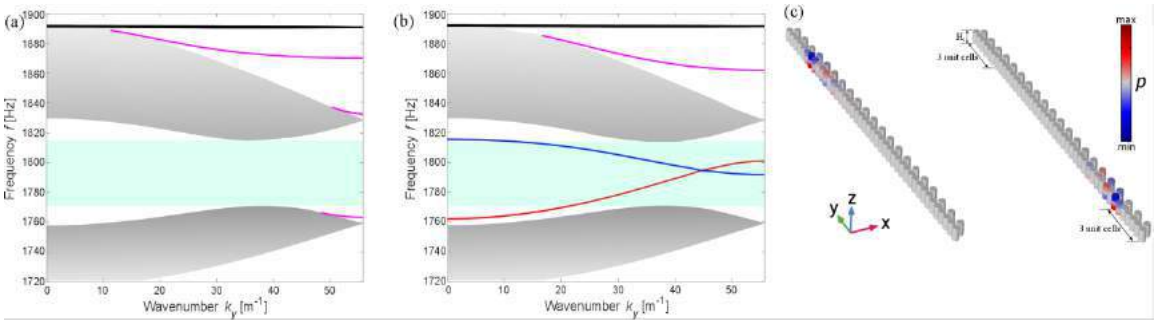

Fig. 1: Two situations of topologically trivial and topologically nontrivial lattices. (a) Trivial band diagram – no edge states go through the complete band gap (green); (b) nontrivial – edge states present inside the complete band gap; and (c) two field profiles corresponding to the blue and red bands in (b), respectively. Pink colour bands show topologically trivial edge modes.

In summary, we have demonstrated the emergence of a topologically nontrivial acoustic phase in distorted Kagome lattices of acoustic resonators. The topological classification based on a tight-binding description and the consequent definition of a meaningful topological invariant were applied to predict the topological transition of this acoustic metamaterial and the existence of topologically protected edge states. To support our analytical results, we performed numerical simulations confirming the presence of topological edge states on both interfaces of the lattice terminated by cladding layer and at domain walls separating topological and trivial crystals. The proposed structure is amenable to physical implementation and the topological edge modes of the Kagome lattice discovered here are worth further investigation based on the real experimental system.

Mesoscopic Crystals with Glide Symmetry Planes for Electric Displacement Manipulation

J. Shin*, T. Chang, and Y. H. Lee
Korea Advanced Institute of Science and Technology, Republic of Korea
*corresponding author: qubit@kaist.ac.kr

Abstract-Mesoscopic crystals or three-dimensional metamaterials with deep-subwavelength unit cells can be designed to manipulate the effective electric permittivity tensor over a broad frequency bandwidth. Especially, crystals with glide planes can have a giant macroscopic electric displacement while the mesoscopic electric displacement field averaged over the dielectric region in a unit cell is very small. The relative magnitudes of the individual elements of the resulting effective permittivity tensors are affected by the symmetry of the crystal. This effect can be used to control linear and nonlinear susceptibilities in unconventional ways.

For the last decade, numerous artificial electromagnetic materials with diverse range of sub-wavelength unit cell designs have been proposed and their unusual properties have been investigated. Though the shapes and sizes of the motifs vary greatly, many of them share the common fact that they are designed for electromagnetic waves with temporal frequencies near specific resonances (often interpreted as the *inductor-capacitor* resonances in analogy with electric circuits) controlled by the constituent materials and their geometries. Direct utilization of the resonances makes it easy to obtain extreme values of effective material properties such as very negative, near zero, or very positive values, but it also imposes constraints on their frequency responses: typically more extreme designs are also more dispersive in frequency, making it challenging to achieve broadband operations.

On the other hand, metamaterial designs with inherently broadband properties have also been explored [1-4]. This class of metamaterials relies on the quasi-static boundary conditions of electric and magnetic fields to control the effective medium properties of an array of deep-subwavelength-scale unit cells. As the phase retardation over a unit cell scale is almost negligible, the effective properties are potentially very broadband. One possible source of frequency dispersion is the absorption and dispersion of the constituent materials themselves: for example, the electric permittivity of metals is a strong function of frequency and it might influence the effective parameters. However, in many cases, the large absolute value of the permittivity of metals minimizes the fields inside the metal and the resulting effective parameters are not very sensitive to the exact values of metal permittivity, showing near-constant values over broad frequency range unless the dielectric is lossy or the metallic region constitutes too much part of the unit cell.

When a 2D crystal has a mirror line like Fig. 1(a) and the macroscopic electric field is parallel to the line, the conductors A and B (C and D) have the same electric potential and the dielectric region between them has negligible electric fields. By contrast, a crystal with a glide reflection like Fig. 1(b) has different mesoscopic field profiles under the same macroscopic electric field condition: the conductors A, B, C, and D have progressively different electric potentials and there can be strong electric fields in all regions of the dielectric. Moreover, if the metallic regions have flat geometries parallel to the mirror line, the mesoscopic electric fields in

the region between two flat metals are almost perpendicular to the mirror line and the direction of the fields is alternating up and down within a unit cell. Hence, if the electric displacement is averaged over the dielectric region in a unit cell, it is nearly cancelled. However, the macroscopic electric displacement can be very large in this situation. This difference in the macroscopic behavior of the two structures in Fig. 1 can be utilized in three dimensional crystals as well. The increased dimension allows many different mirror and glide symmetry configuration possibilities in 3D and it can result in highly anisotropic effective electric susceptibility tensors.

Abstract— In this paper we investigate the effect of twist symmetries on guiding structures. A reduced dispersive nature of the structure can be seen when the structure possesses twist symmetry. The analysis yields that higher twist-symmetric structures can be used for low dispersive wave guiding. A promising application of this kind of structure is leaky-wave antennas, which can utilize the low dispersion of the structure.

The limitations of metamaterials, e.g the narrow operational bandwidth, reduces the usefulness of such materials in microwave components. Some of these limitations can be addressed by various methods, one of which is to introduce additional symmetries into the structure. If these symmetries are arranged such that the unit cell coincides with itself after more than one linear or angular translation or reflection, the structure can be said to possess higher symmetries [1, 2, 3]. The effective period of a structure possessing higher symmetries is smaller than the actual period of the unit cell [1]. There are mainly two types of higher symmetries discussed in the literature so far, glide and twist symmetries. A structure possesses glide symmetry if the initial unit cell is mirrored in a plane and then translated half its period. Similarly, a structure possesses twist symmetry if instead of a mirroring, a rotation around its axis of symmetry is made together with a translation [1]. The number of rotation operations, p, executed to compose the full unit cell determines the order of twist symmetry, the structure is p-fold twist-symmetric. Several studies on glide symmetry has been presented [4, 5, 6, 7]. Here, we focus on studying the propagation characteristics in a coaxial twist-symmetric structure.

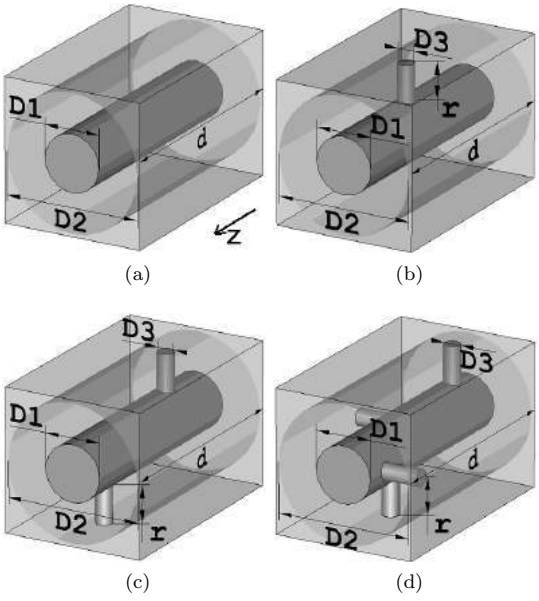

Figure 1: Configurations: (a) Without pins, (b) One pin, (c) 2-fold twist-symmetric structure, (d) 4-fold twist-symmetric structure.

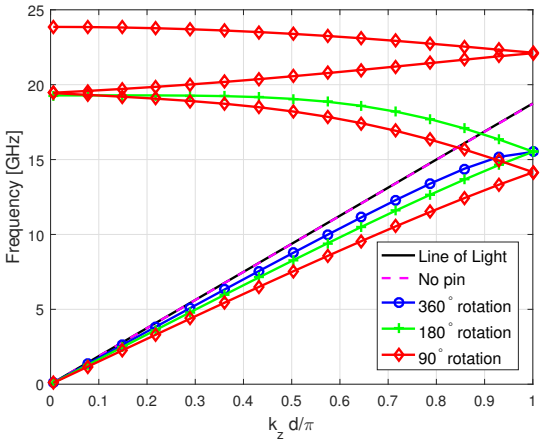

Figure 2: Dispersion diagram for the proposed structures. The dimensions are: $D1 = 2$ mm, $D2 = 4.62$ mm, $D3 = 0.6$ mm, $r = 1.3$ mm and $d = 8$ mm.

The structures considered are variations of a coaxial cable. The symmetries are introduced by placing pins on the inner conductor, terminating close to the outer conductor. There is a small air gap between the pins and the outer conductor. Four twist-symmetric structures are used for the study and they can be seen in Fig. 1. One of the structures, Fig. 1a, is an ordinary coaxial cable. For the rest of the configurations, 1b-d, the rotation between two adjacent pins in the unit cell is 360°, 180° and 90°, respectively.

The chosen dimensions are $D1 = 2$ mm, $D2 = 4.62$ mm, $D3 = 0.6$ mm, $r = 1.3$ mm and $d = 8$ mm. Using these dimensions, the air gap between the pins and the outer conductor becomes 0.1 mm. Simulation with these structures are carried out in *CST Microwave Studio*. The resulting dispersion diagram from these structures is presented in Fig. 2.

If no pins are used, i.e the structure is a coaxial cable, the dispersion diagram is coincident with the light line. When the rotation is either 90° or 180° between two adjacent pins, the guiding structure experiences low dispersion, resulting in a wide operational bandwidth. Since the apparent period is smaller in a twist-symmetric structure, modes from neighboring Brillouin zones are present without band gaps at the Brillouin zone boundaries. These results show similarities with results from studies made on 1D- and 2D-glide symmetry [8, 9, 10]. If only one pin is placed in each unit cell, the structure is periodic by only a translation of the pin and does not possess higher symmetries, the actual period of the structure is the same as the period of the unit cell. The mode is then dispersive and we have band gaps at the Brillouin zone boundary. By placing more pins in each unit cell, the medium is made denser with a higher effective refractive index, thus the structure can be tailored to exhibit the desired propagation characteristics. Promising applications of structures utilizing twist symmetries are leaky-wave antennas, which can utilize the low dispersion as well as the increased control of the effective refractive index.

Advances in Nanolasers

Semiconductor Microlasers with Curve-Side Polygon Resonators

Yong-Zhen Huang, Hai-Zhong Weng, Zhi-Xiong Xiao, Yue-De Yang,
Jin-Long Xiao, and Yun Du

Unidirectional emission microcavity lasers have been realized by directly connecting an output waveguide to circular and polygon microcavities. However, mode *Q* factors reduce greatly for circular microcavities connecting an output waveguide. In this talk, we propose and demonstrate semiconductor microlasers with curve-side polygon resonators, which can still have ultra-high *Q* factors even as it connected an output waveguide.

For a curve-side square resonator (CSR) in Fig. 1(a), which is a hybrid of circular and square, mode *Q* factors can be greatly enhanced as the transverse mode field patterns are well confined as shown in the inset of Fig. 1(b) with near zero vertices radiation loss. The circular sides can work as concave mirrors for focusing the mode light beam in the CSR. With the enhancement of mode *Q* factors, lasing spectra transfer from single mode at δ = 0.9 μm to dual-mode lasing at δ = 1.1, 1.3, and 1.5 μm as shown in Fig. 1(b). Stable dual-mode lasing was realized with frequency interval of sub-THz suitable for photonic generation of THz wave [1].

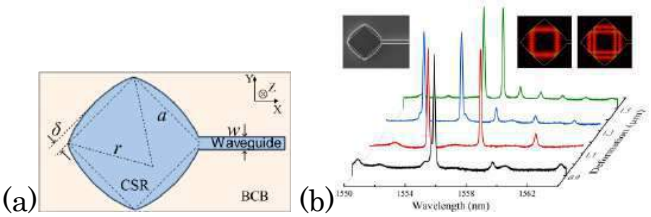

Fig. 1. (a) Schematic diagram of the CSR with a vertex output waveguide, and (b) lasing spectra of CSR lasers at 31 mA with a = 16μm and w = 1.5μm and δ = 0.9, 1.1, 1.3, and 1.5 μm.

For a curve-side hexagonal resonator (CHR) connected an output waveguide, we can have much higher *Q* factor than a microdisk resonator connected with an output waveguide at the same size. For a CHR microlaser with a side-length of 7.5 μm, deformation δ = 0.51 μm, and an output waveguide width of 2 μm, single mode operation is realized with a side-mode suppression ratio of 43 dB [2]. The results indicate that single transverse mode operation is easy to realize for CHR microlasers. Furthermore, flat small signal modulation responses are obtained with a 3-dB bandwidth of 13 GHz.

In conclusion, we have proposed and demonstrated that curve-side polygon microcavites for enhancing mode *Q* factor and controlling lasing spectra.

Abstract-We study the field enhancement in lasers with spatial modulations showing PT-symmetry and axial symmetry including a central defect. The merge of these two symmetries created by the modulation of the complex index, strongly directs light to the central point obtaining important localization effects. The concentration capabilities of these potentials is implemented in the Complex Ginzburg-Landau equation as a simple VCSELs model to generate very narrow and bright beams when a central defect is included to avoid field saturation given by the nonlinearities.

The spatial modulation of the complex refractive index, i.e. refractive index and gain-loss modulations, has demonstrated strong capabilities to tailor light dispersion, including diffraction and diffusion, showing different spatial effects in linear light propagation along this kind of potentials[1-3]. Further, the same modulations in nonlinear systems introduce the management of spatial instabilities that intrinsically appear in laser systems and amplifiers[4-6]. One of the most interesting symmetries of complex spatial modulated materials is the PT-symmetry, where the real part of the modulation shows even symmetry while the imaginary part shows odd symmetry[7].

In this work we propose PT-axisymmetric potentials including a central defect for field localization and enhancement in laser systems. The localization of light in a central beam with small width and high intensity opens the possibility to obtain laser light sources with very narrow and bright beams. An important characteristic of PT-potentials is that the coupling between left-propagating modes and right-propagating modes can be strongly unidirectional when the real and gain-loss modulations are balanced leading to new features on light waves such as asymmetric unidirectional reflectors or invisible materials[8]. The merge of the PT-symmetry and axial-symmetry can derive in complex potentials leading to a unidirectional coupling to the left on the right half-space and to the right on the left half-space in the one-dimensional case and equivalently radial inwards couplings in two-dimensional system (see Fig.1a and Fig.1b). The coupling between harmonics always directed to the axis at x=0, allows the field concentration.

The linear light propagation through PT-axisymmetric potentials creates an extreme localization at $x=0$, exhibiting an exponential temporal growth due to the system linearity[9]. On the contrary, the application of such potentials to laser models, and in particular to the Complex Ginzburg-Landau equation as a simplified VCSEL model, shows typical turbulent states with no field concentration. The system nonlinearities introduce field saturation and limit the maximum intensity of the output beam. The inclusion of a central linear defect in the structure avoids saturation and allows the field concentration.

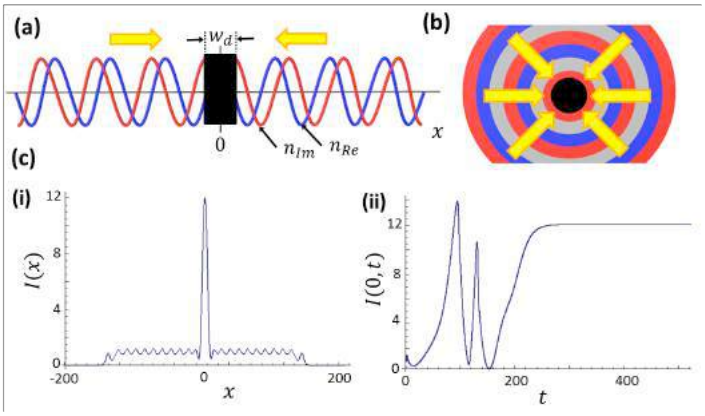

Figure 1. *(a)One-dimensional PT-axisymmetric potential with an axial defect of width w_d at x=0. Index modulations (blue) and shifted gain-loss modulations (red) creates the PT-potential and introduce the directional coupling to the axis.(b)Two dimensional PT-potential with a linear central defect (black).(c) Stationary field for the VCSEL model with pump above threshold and (d) temporal evolution of the field at the central point.*

We explore such potentials in 1D and 2D, scanning the main parameters as laser pump, linewidth enhancement factor of the semiconductor, amplitude of the PT-modulated potential, i.e. refractive index amplitude and gain-loss amplitude, as well as the width of the defect. Results show field concentrations 10 times larger than the saturated laser intensity with stationary behaviors and pulsed regimes. Finally, we include losses in the central part of the VCSEL model to consider the field coupling to an output fiber.

Fundamental Scaling Laws of Nanophotonics: Case Laser

Abstract-Here we report on an analysis show scaling laws for optoelectronic devices, and how various types of optical cavities directly influence the performance of three classes of photonic devices, namely laser sources, electro-optic-modulators, and photodetectors. The device-underlying optical cavities show Purcell factor maxima as a function of cavity length exceeding 1000, 20, and 200 for a micro ring resonator, Fabry Perot, or plasmonic nanocavity, respectively highlighting the physical tradeoff between optical loss management and field confinement.

Scaling laws based on fundamental physics predict a high potential to improve optoelectronic devices relative to the state-of-the-art applying the FOM = {Datarate/bit} / {Power/bit x Area x Cost}. Ignoring engineering-limited device design constrains, basic physics dictates a lower-bound power consumption for optoelectronic devices of about 0.1aJ/bit. The general switching speed depends on the chosen switching effect, and both the optical and electrical dynamics penalty. The uncertainty principle gives an upper bound for the device speed and can be femtosecond fast in tunnel-based systems. We discuss scaling laws and benchmarks [1] of three prominent opto-electronic devices, namely, laser [2-4], electro-optic modulator [5], and photodetector. The work is based on underlying light-matter-interaction enhancement via optical resonators to include the microring, Fabry-Perot, and plasmonic nanocavity. We raise questions towards establishing a roadmap for optical information processing (i.e. logic and communication) including noise considerations at the detector, quantum entanglement, and realistic integration aspects such as technology hybridization [6] at the link level for high bit-flow-density metrics.

With previous investigations being ad-hoc in their approach to exploit nanoscale device functionality, an understanding leading to fundamental scaling behavior for this new class of devices is outstanding. Here we investigate the fundamental scaling laws for Nanophotonics as a function of nominal device length. Performance criteria of three critical interconnect devices are analyzed with respect to their scaling behavior. Underling to all devices are three types of optical cavities that support enhancing the fundamentally weak interaction between light and matter, namely, microring resonators, Fabry Perot cavities, and plasmonic metal particle-based cavities. An interesting, but actually expected find is, that all cavity types do not perform well for vanishing cavity lengths due to dominance of loss channels. However this critical length is strongly dependent on the cavity properties and varies by more than two orders of magnitude. With the high Purcell factors that can be realized despite high losses in nanoscale cavities, we investigate fundamental achievable optoelectronic device performance.

In our device performance scaling laws results we find that the thought 'smaller-is-better' is not true for nanophotonics and non-monotonic scaling laws are found. With a goal for down-scalability in mind, key results show the possibility the ability to design; 1) laser sources with threshold currents at 1 uA and 100 GHz fast modulation, 2) electro-optic modulators with 10's aJ/bit energy efficiencies and THz fast modulation speeds, and 3) photodetectors with responsivities approaching 1 A/W and ~ps-fast response times. Understanding the potential and limits for Nanophotonics will be a guiding insight not only for device designers, but increasingly also at the circuit level, since a true comparison between both the electronic and photonic technology options is now possible [7-9].

Abstract-This paper discusses nanoscale engineered metal-dielectric-semiconductor resonant gain geometries confined in all three dimensions used to create a new type of nanolasers and light emitters. When these emitters are driven in a pulsed regime, dynamic hysteresis is observed and characterized.

Achieving the most compact footprint for photonic components is an important factor in the design of integrated optical devices. As the size of a conventional dielectric semiconductor laser is decreased towards λ_0, three effects adversely influence the lasing process. Firstly, the roundtrip path of the optical wave in the gain medium is shortened, secondly radiative losses are increased and finally the field confinement inside the resonator is reduced, resulting in less overlap of the optical mode with the gain medium. All of these effects serve to increase the lasing threshold, so that lasing cannot be achieved below a certain size limit. One approach for alleviating these issues is to incorporate metals into the structure of dielectric cavities, because metals can suppress leaky optical modes and effectively isolate them from their neighbouring environment. The ultimate challenge is to reduce the size of the laser resonator in all three dimensions. A wide spectrum of resonator architectures has been explored, including circular [1, 2] metallo-dielectric cavities, metal-semiconductor coaxial cavities [3], nanopillar/nanowire cavities [4, 5] and plasmonic cavities (SPASERs) [6-9]. To date, the majority of studies on nanocavity lasers have focused on the proof of concept demonstration of lasing behavior. In particular, the measurement of a "kink" in the light-out versus light-in curve (LL-curve) is prevalently used as affirming evidence for lasing and is often the only method adopted to identify the lasing threshold [1-8]. However, it is well known that the "kink" in the LL-curve diminishes as β increases. Therefore, for high-β nanocavity lasers, LL-curve measurement alone can neither fully characterize lasing nor unambiguously identify the lasing threshold. On the other hand, measuring the second order intensity correlation function $g^2(\tau) = \langle I(t) \rangle \langle I(t+\tau) \rangle / \langle I(t) \rangle^2$, where $\langle I(t) \rangle$ represents the expectation value of the nanolaser output intensity at time t, is a more definitive method to confirm lasing [9]. Recently, we demonstrate [10] that by employing nanosecond pump pulses, different emission regimes of a nanolaser can be characterized via the full width at half maximum (FWHM) of a $g^2(\tau)$ peak. We demonstrate the applicability of this technique with a high-β metallo-dielectric nanolaser and further report the first coherence measurement on this type of nanolaser operating at room temperature. We show that while $g^2(\tau)$ peaks narrow in the spontaneous emission (SE) and amplified spontaneous emission (ASE) regimes as stimulated emission increases in proportion, their FWHMs increase in the lasing regime due to dynamical hysteresis (DH), a phenomenon triggered when a laser is driven across

its threshold. The usage of nanosecond pulses is the key to the observation of DH and, therefore, essential to this characterization technique.

Abstract: Surface plasmon polariton (SPP) nanolasers have recently emerged as a promising candidate to generate coherent light source in nanophotonics integration circuit. The properties of SPP nanolaser such as group velocity, mode area, modulation speed and threshold performance are able to manipulated by the dispersion relation. In this paper we have investigated the characteristics of SPP nanolaser and managed to approach the limit of surface plasmon amplification by stimulated emission radiation (SPASER).

Recently, the development of nanolaser involving surface-plasmon-polariton (SPP) operation has attracted the attention to construct ultra-compact integrated photonic devices and systems [1]-[3]. The characteristics of SPPs can be determined by the dispersion relation of the device structure, which is influenced by the material's permittivity and structural parameters. One straight forward way to manipulate the dispersion relation of the SPP nanolaser relies on the thickness control of the insulator layer in between the semiconductor and the metal thin film for the semiconductor/insulator/metal (SIM) nanolaser structure, which becomes one of the most popular plasmonic structure to confine the optical field and potentially break the optical diffraction limit. However, the tailoring range of the dispersion relation was mainly limited by the materials. To investigate the characteristics of SPP nanolasers with significant dispersion difference, we chose the SPP nanolasers with different metals to compare the properties difference between SPP lasers operating nearby the SP frequency and the SPP laser operating far away from the SP frequency. For more reliable SPP laser operation, ZnO nanowire provides exciton binding energies larger than thermal energy at room temperature (25.6 meV) and strong oscillation strength to interact with SPP. Thus, the ZnO nanowire was chosen in our study for stable SPP laser operation under different circumstances. Since the active emitter was chosen to be ZnO, operated in the near UV range (370-390 nm), aluminum and silver are used to properly generate SPPs. Typically, aluminum has a relatively high surface plasmon frequency. The ZnO nanolaser on Al is operated away from the SP frequency, rendering itself operating as a typical SPP nanolaser with low threshold condition. On the other hand, since Ag has an interband transition at around 350 nm, the dispersion relation of surface plasmon near 370 nm will be significantly bent, leading to ZnO nanolasers operating approaching the limit of surface plasmon amplification by stimulated emission radiation (SPASER). By investigating characteristics of Al- and Ag-based ZnO nanolasers, intriguing phenomena such as the quantum plasmonic effect, ultrafast modulation, strong interaction between the exciton and surface plasmon [4], and high characteristic temperature operation [5] will be discussed.

Controlled Multi-modal Nanolasing from Plasmonic Superlattices

T. W. Odom[1*]
[1]Northwestern University, Evanston, IL USA
[*]corresponding author: todom@northwestern.edu

Abstract. This talk will describe how to engineer different combinations of nanolasing modes by controlling the structural parameters of the multi-scale plasmlnic nanoparticle arrays.

Band structure engineering is critical for controlling the emission wavelengths and efficiency in electronic and photonic materials. Single band-edge states that show trapped slow light have been used as high-quality optical feedback for lasing from photonic bandgap crystals and metal-dielectric waveguides. Recently, we demonstrated that single band-edge lattice plasmons in periodic metal nanoparticle arrays could contribute to single-mode lasing at room-temperature with directional emission. However, the manipulation of more than a single band-edge mode for nanolasing has not been possible because of limited cavity designs. This talk will describe a new architecture based on plasmonic superlattices—finite-arrays of nanoparticles grouped into microscale arrays—to achieve multi-modal lasing. The underlying mechanism was found to depend on trapped slow light at both zero and non-zero wavevectors. We will discuss how the spectral separation and spatial emission angles of the lasing modes can be tuned by changing patch periodicity. Such characteristics may enable multi-frequency multiplexing and fast-processing of nanoscale coherent light for on-chip photonic integration.

Nanowire (NW)-based light sources, owing to their strong light localization [1, 2], ultra-small footprint [3], high mechanical flexibility [4], large aspect ratio [5, 6], high photoluminesence efficiency and large fractional evanescent field [7], have shown huge potential in areas including communication, diagnosis, and environmental monitoring [8-10]. Optimization of the parameters of NW light sources, such as the emission spectrum and efficiency, is significant for their practical applications. Recently, we have systematically investigated controlling of parameters of nanowire light emitting devices. Using the absorption-emission-absorption effect, we have achieved broad wavelength controlling and tailoring of single NW laser (40 nm for pure CdSe NW and 119 nm for CdSSe bandgap graded NW) (Fig. 1a) [11, 12]. We have also greatly enhanced the external quantum efficiency (up to 0.9%) for a Schottky junction-based NW ultraviolet light emitting diode (LED) by hybridizing single Ag NW with p-GaN substrate (Fig. 1b) [13]. Moreover, we have deeply investigated the modulation of the polarization and emission mode for NW/nanobelt laser sources [14]. Finally, we have successfully applied NW based light sources to break the bottleneck in nanoscopy and achieved the first nanoscale light source-based wide-field and far-field label-free sub-diffraction imaging by hybridizing ring-shaped fluorescent NWs with subwavelength film waveguides (Fig. 1c-d show an experimental result for a 150 nm slot, 100 nm spacing sub-wavelength structure). The reliability and versatility of our approach have been demonstrated by imaging integrated chips, Blu-ray DVDs, biological cells, and various subwavelength 2D patterns, with a viewing area of up to 1000 μm^2, one order of magnitude larger than previous far-field and full-field nanoscopy reports [15]. Our investigation will greatly expand the flexibility of NW based light sources for practical applications in biology, physics, materials science, and so on.

Abstract-Nanoscale light sources operating efficiently at low powers are required for future optical interconnects. Here, we present, both theoretically and experimentally, the carrier dynamics in metal-dielectric cavity nanopillar light-emitting diodes. The nanoLEDs operate at telecommunications wavelengths, featuring tens of nanoWatt waveguide-coupled powers and GHz-range modulation bandwidths. Furthermore, an extremely low surface recombination velocity of 260 cm/s in passivated InGaAs nanopillars is reported, a result of crucial importance for the development of efficient nanoscale optoelectronic devices for nanophotonic integrated circuits.

Electronic data connections are increasingly becoming a bottleneck in the exponential growth of data traffic worldwide. Future optical interconnects are the obvious successors but will require ultrasmall light sources with sub-micrometer sizes to achieve low energy consumption (<10 fJ/bit), and ultrafast speeds [1]. Nanoscale light sources have been developed recently using either metal, metallo-dielectric or photonic crystal nanocavities [2]. Despite much progress, nanolasers and nano-light-emitting diodes (nanoLEDs) operating efficiently at low powers and suitable for photonic integration are lacking. Among numerous challenges, in both light-emitting diodes and lasers, radiative and nonradiative recombination rates play a key role in the efficiency. Radiative recombination (both spontaneous and stimulated) is affected by the small mode volume in nanoLEDs and nanolasers, potentially leading to strong Purcell enhancements and higher speed [3,4]. On the other hand, nonradiative recombination rates, specifically surface recombination rates, are also very high due to the high surface-to-volume ratios [5], typically leading to low radiative efficiencies.

Here, the authors present recent work on waveguide-coupled metal-dielectric cavity nanopillar LEDs on silicon working at telecommunications wavelengths [5], and featuring more than 20 nW waveguide-coupled powers and GHz-range modulation bandwidths at room-temperature (RT). The efficiency of the reported nanoLEDs currently lies between 0.01 and 1 percent, at RT and at 10 K, respectively, mostly limited by nonradiative recombination effects. We show that a passivation method using sulfur treatment, followed by silicon oxide capping deposited by plasma-enhanced chemical vapor deposition, strongly suppresses the surface recombination at the InGaAs surfaces of nanopillars from a few hundred picoseconds to more than 20 nanoseconds [6]. The estimated surface recombination velocity, decreases from about 2×10^4 cm/s in the untreated nanopillars down to around 260 cm/s. To our knowledge, this is a record low value in undoped InGaAs semiconductors. Most importantly, our passivation studies reveal that the SiO_x capping layer not only protects the pillars' sidewalls against oxidation, as reported in [7], but actively takes part in the passivation process. This will ensure substantial improvements in the efficiency of future nanoLEDs and reduce the threshold current in nanolasers, which are of crucial importance for their application in optical interconnects.

Finally, the performance of the experimental nanoLEDs is analyzed using a rate equations model which properly takes into account the nanocavity effects in the spontaneous emission rate and the spatial and spectral overlap between carriers and photons. The ultimate limits of scaling down these nanoscale light sources leading to Purcell enhancement of the emission and higher speeds are also theoretically analyzed.

Abstract- We directly image surface plasmon emission, an intrinsic but unrevealed feature of spasers in spatial, momentum and frequency spaces simultaneously. We demonstrate a nanowire spaser with a coupling efficiency to plasmonic modes of 74%. This coupling efficiency can approach 100% in theory when the diameter of the nanowire becomes smaller than 50 nm. Our results provide clear evidence of the surface plasmon amplifier nature of spasers and will pave the way for their various applications.

The recent rapidly advancing nanoscience and technology calls for a nanoscale laser spot for various technologies, such as nanolithography, high-density data storage and uper resolution imaging. However, conventional lasers amplify photons where diffraction limit puts a forbidden barrier to scaling down its physical size and mode volume. In 2003, David J. Bergman and Mark I. Stockman proposed a new class of amplifier, named spaser, an acronym of surface plasmon amplification by stimulated emission of radiation [1]. In stark contrast to classical laser, spaser amplifies surface plasmons instead of photons providing an optical amplifier with size beyond diffraction limit, which is of major interest for numerous applications, ranging from all-optical computing to biomedical sensing. Because of that, numerous works have been reported on the experimental implementation of spasers [2-14]. However, up to now, spasers have only been characterized by the photons scattered to the optical far field. According to its original definition, a spaser is a surface plasmon amplifier that does not necessarily generate radiative photon output. Its intrinsic surface plasmon emission is yet unrevealed "dark" emission due to its evanescent nature. Consequently, there is a lack of direct evidence of spasing, and the intentional manipulation and utilization of spaser emission becomes difficult to achieve. Here, for the first time, we directly image surface plasmon emission, an intrinsic but unrevealed feature of spasers in spatial, momentum and frequency spaces simultaneously [15]. We demonstrate that spaser can serve as a pure surface plasmon generator with the ratio of surface plasmon emission over total radiation approaching to 100% and experimentally demonstrated 74%. Our results supply an unambiguous evidence of spasing behavior, an intrinsic but unrevealed feature of this intensively studied new class of optical amplifier. Furthermore, in contrast to the scattered photons, the surface plasmon emission of spasers is the crucial element for various nanophotonic applications.

Abstract- we report a plasmonic nanolaser with excellent stability in biocompatible aqueous solution by surface passivation. The overall yield of stable operation is over 68%. We demonstrate these passivated plasmonic nanolasers as refractive index sensors. The figure of merit (FOM) of intensity sensing is 8000.

Plasmonic nanolaser with strong field confinement beyond diffraction limit is of major interest for numerous applications, ranging from all-optical computing to biomedical sensing. However, to achieve lasing state, the gain materials in plasmonic nanolasers have to be pumped hard enough for population inversion. In the strong plasmonic lasing field, the optical excited gain materials are easy to experience nonreversible photochemical reactions [1-5], which is a major hurdle for its practical application. And despite the rapidly advanced research in plasmonic nanolasers [6-9], there is no study on their stability and yield yet. Here, for the first time, we demonstrate that the yield of plasmonic nanolasers with excellent stability can be over 68% in water by surface passivation. As a comparison, the as-fabricated plasmonic nanolasers based on CdSe gain material only have a stably lasing yield of about 4%. We further demonstrate that these passivated plasmonic nanolasers can be excellent refractive index sensors in aqueous solution. The figure of merit of intensity sensing is about 8000 which is about 40 times higher than the state-of-the-art surface plasmon resonance sensor. Our results indicate that plasmonic nanolaser can operate stably in biocompatible aqueous solutions with high yield which will pave the way for its real world applications, especially in biomedical research and applications.

Abstract- we report a room temperature plasmonic nanolaser with threshold on the order of 10 KW cm^{-2} corresponding to a pump density in the range of modern laser diodes. We find unusual scaling laws that allow plasmonic lasers to be more compact, faster, lower threshold and power consumption than photonic nanolasers when the cavity size approaches or surpasses the diffraction limit.

Plasmonic nanolasers are a new class of quantum amplifiers that generate coherent light well below the diffraction barrier bringing fundamentally new capabilities to biochemical sensing, super-resolution imaging and on-chip optical communication. However, a debate about whether metals can enhance the performance of lasers has persisted due to the unavoidable fact that metallic absorption intrinsically scales with field confinement [1-10]. Particularly at room temperature, plasmonic nanolasers still have high thresholds in excess of MW cm^{-2}, preventing their practical usage. Here, we report plasmonic nanolasers with record low thresholds on the order of 10 KW cm^{-2} at room temperature, which are comparable to those found in modern laser diodes. We show that plasmonic nanolaser threshold scales linearly with device volume, which is opposite to the trend seen in conventional lasers. This unusual scaling law means plasmonic lasers have superior performance over photonic lasers in terms of lower thresholds and power consumption when the cavity size is smaller than the diffraction limit. This clarifies the long-standing debate over the viability of metal confinement and feedback strategies in laser technology and identifies situations where plasmonic lasers can have clear practical advantage.

Abstract- Surface plasmon lasers offer strong light-matter interaction possibilities and many advanced applications in nanophotonics, biology and information technology. However, due to large intrinsic metal Ohmic losses, plasmonic laser suffers from either high threshold or low operation temperature, which limits the practical applications. Here firstly a room-temperature ultra-violet surface plasmon laser using GaN nanowires will be introduced. The lasing threshold is ~3.5 MW/cm^2. Furthermore, we demonstrate a method based on intrinsic self-absorption of semiconductor to tune plasmonic nanowire lasing wavelength.

Abstract This talk will begin with a summary overview of recent efforts in achieving lasing operation using a monolayer of transition metal dichalcogenides. We will then present our recent results in demonstrating the first room temperature laser operation using a monolayer molybdenum ditelluride integrated with a silicon photonic-crystal nanobeam structure. We will show that room temperature lasing can be achieved at very low threshold under a continuous wave laser pumping.

Transition metal dichalcogenides (TMDs) have attracted a great deal of attention due to their distinctive properties and potential applications in electronics and optoelectronic devices [1, 2]. Unlike their bulk counterparts, two-dimensional monolayers of the most of the TMDs are direct bandgaps semiconductors [3], with strong optical emission. Therefore, monolayer TMDs could be an efficient active material, with the thinnest gain medium possible. Laser operation based on monolayers of TMDs were firstly reported at cryogenic temperatures, employing a monolayer WSe_2 coupled onto a GaP photonic-crystal cavity [4], or a monolayer WS_2 with a Si_3N_4 microdisk [5]. These laser demonstrations still have high threshold that prevents their lasing at room temperature, which are necessary for any practical application.

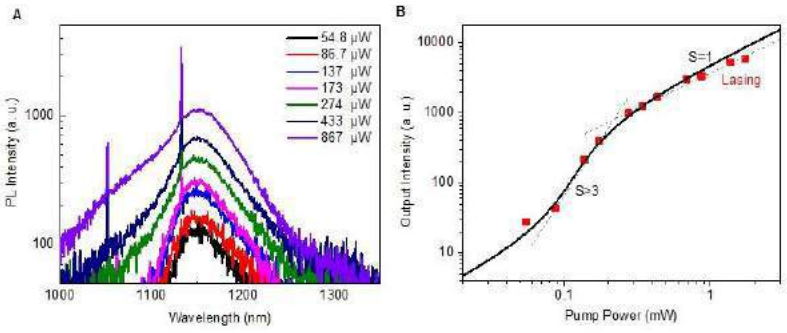

Figure 1 Photoluminescence spectra under different levels of optical excitation (A, left) and intensity output at the lasing peak vs. pumping power (B, right) showing a clear threshold behavior.
