Our recent efforts [6] in searching for a high Q cavity to be integrated with a 2D TMD gain material have led us to an interesting combination of a silicon nanobeam cavity and the monolayer of molybdenum ditelluride (MoTe2). Monolayer of MoTe2 is known to have a bandgap around ~1.72 eV, but an excitonic photoluminescence (PL) emission peak at ~1.1 eV,

which is about 50 meV below the silicon bandgap. This makes the MoTe2 a perfect gain material to be integrated with Si cavity structure. The high index of refraction and mature fabrication of Si has resulted in a high Q-cavity. As a result, room temperature operation was achieved under the pumping of a continuous wave laser. Examples of lasing behavior are shown in Figure 1. Details of device design, fabrication, and characterization will be presented, as well as updates about recent progress.

Abstract-Optical absorption and electron emission/collection are two key factors for improving photoelectric response based on plasmonic hot-electron. Here, we demonstrated plasmonic hot-electron photoresponse as high as 3.3mA/W at 1500nm achieved on a silicon platform by metamaterial absorber (MA) and omni-schottky junction. Furthermore, time-resolved photoresponse shows optical energy transferred to electricity through the photothermal mechanism distinct from the photoelectric process of hot electron.

Plasmonic effects were investigated in a myriad of applications such as biosensing, optoelectronics, thermal therapy, data storage and so on. In particular, the functionality of light harvesting at a nanoscale offers remarkable improvements of the quantum efficiency (QE) of photoelectric energy conversion in both valence-conduction transition [1] and internal photoemission (IPE) processes [2]. In the later one, metal absorbs photons and then generates hot electrons that may cross the metal-semiconductor junction resulting in photocurrent. There are two main limitations on the QE of IPE process, one is the spectral absorption and the other is the emission probability of hot electrons. Localized surface plasmon resonance (LSPR) of regular metal nanostructures only enhances light absorption in a narrow band and the device fabrication relies on the expensive high-resolution lithography technique like electron beam lithography [3]. The small junction area of metal-semiconductor interface limits hot electron emission. In this paper, we present our recent work addressing these two issues by combining both optical and electrical perspectives into the design of plasmonic photodetectors on silicon platform.

As shown in Figure 1, the proposed devices containing Au nanoparticles (NPs) which are sandwiched between two electron-accepting semiconductors (i.e. TiO_2 and silicon) allow high emission probability for the hot electrons due to the formation of the omnidirectional M-S junctions around these tiny plasmonic absorber/emitters. On the other hand, metamaterial perfect absorber (MPA) based optical enhancing scheme is incorporated by a MSM configuration, for the purpose of obtaining highly localized and perfect photon absorption in the mono-layered Au NPs. The measured photoresponse were shown in Figure 2, where we can see that random NPs provide broad band high absorption resulting in a much improved responsivity of the proposed device over the planar reference. The device with TiO2 intermediate layer also showed higher responsivity than the one with ITO layer, supporting the expected benefit for the omni-Schottky junction mechanism (no energy offset in conduction band between TiO_2 and silicon). The results of the time-resolved characterization of the devices differentiate the photoelectric and photothermal response, which will be presented at the conference.

*corresponding author: lanyc@mail.ncku.edu.tw

Abstract- A three-layered compact film with heat dissipation based on the method of passive radiation cooling for light emitting diode (LED) are developed and analyzed. Electromagnetic and heat diffusion simulations are accomplished to verify that the design of proposed film can effectively decrease the temperature of LED with various input powers.

This work develops and analyzes a three-layered (Si-Ni_3Si-Al) compact film with heat dissipation based on the method of passive radiation cooling for light emitting diode (LED). The proposed film is designed with the feature of high absorptance at atmospheric transmission region (i.e. 8 um – 13 um). According to Kirchhoff's law of thermal radiation, the emissivity of the film will be equal to its absorptivity at thermal equilibrium. The corresponding admittance diagram and absorption spectra are also explored to elucidate the reason of high absorption. Electromagnetic and heat diffusion simulations based on the finite element method (COMSOL) are accomplished to verify that the design of proposed film can effectively decrease the temperature of LED with various input powers. Considering the typical LED in work (e.g. 1 mm square surface area with heat generation of 1 watt), the proposed film can achieve lower temperature with significantly reduced size as compared to LED with traditional heat sink. Figure 1 plots the simulation temperature distribution for LED with the proposed three-layered film (t_1=570 nm, t_2=750 nm, t_3=150 nm) for heat dissipation. The interface temperature can achieve 326.07 K, which is lower than other heat dissipation designs. This work has potential applications in the field of thermal emitter, photovoltaic-based device and high power devices.

Abstract-Our experiment shows that the thermal emission of phonon can be controlled by magnetic resonance (MR) mode in a metasurface (MTS). Through changing the structural parameter of metasurface, the MR wavelength can be tuned to the phonon resonance wavelength. This introduces a strong coupling between phonon and MR, which results in an anticrossing phonon-plasmons mode. In the process, we can manipulate the polarization and angular radiation of thermal emission of phonon. Such metasurface provides a new kind of thermal emission structures for various thermal management applications. *n*

In recent years, the research interest of thermal emission in the infrared wavelength range is growing fast due to its important applications in thermaophotovoltaic (TPV) devices [1], radiative cooling [2,3], incandescent source [4], near-field heat transfer [5], and infrared spectroscopy [6]. Up to now, various structures and systems have been used to control thermal emission, such as gratings [7, 8], nanoantennas [9, 10], photonic crystals [11], surface plasmons [12-14], metamaterials [15-17] and metasurfaces (MTS) [18, 19]. Some properties of thermal emission, such as the emission bandwidth [20], coherent properties [7] and dynamics switching [21, 22, 23] are reported to be controlled in these systems.

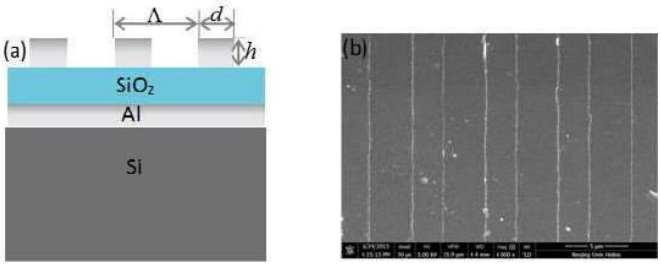

Figure 1 (color online) the sketch plot (a) and SEM top view (b) of sandwiched structure. In experiments, the periodic and height are fixed with $\Lambda = 6.5\mu m$ and $h = 0.05\mu m$, d is changed from 2.6 to 3.6 μm.

In this work, the MIM metasurface is used to control the emission of phonons. Using high temperature synthesized amorphous SiO2, we designed and fabricated the Al/SiO2/Al magnetic MTS with Al grating arrayed on the SiO2/Al film (see figure 1 (a)). The MTS grating width is adjusted to produce the strong coupling between MR and phonon inside SiO2. Differ from the precedent studies about the active optical phonons of silica at $\lambda = 10\mu m$, here, we focus our attention on the relatively inactive optical phonon at $\lambda = 12.5um$. The absorption and thermal emission spectra were measure by Fourier-transform infrared (FTIR) spectrometer in the wavelength range $11-16\mu m$. The anticrossing features in the spectra denoted that strong coupling between

phonon and magnetic resonance, albeit with big difference in radiation intensity of these two resonant states. Using commercial software FDTD solution and coupled mode theory, we analysed the coupling physical mechanism. The theoretical calculations agree with experiments quite well.

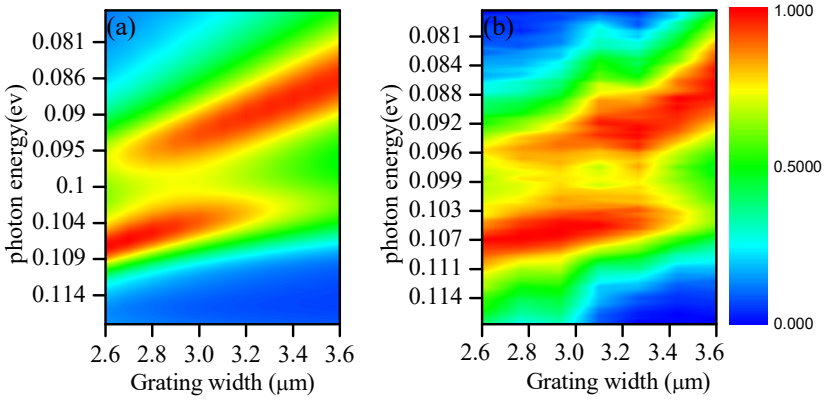

Figure 5. Simulated absorption (a) and measured emission (b) spectra versus photon energy and grating width d.

Abstract-We propose a novel mechanism to further enhance near-field radiative heat transfer (NFRHT) with the use of Si metasurfaces, which is based on the broad spectral bandwidth and the high tunability of the surface-plasmon polaritons that dominate NFRHT in these structures. We have shown that by an appropriate choice of the geometrical parameters, these metamaterials can exhibit room-temperature near-field radiative heat conductances higher than any existent or proposed structure.

Thermal radiation is one of the most ubiquitous physical phenomena. In recent years, there has been a renewed interest in this topic due to the confirmation of the long-standing prediction that radiative heat transfer can be drastically enhanced for bodies separated by small gaps [1]. This enhancement, which occurs when the gaps are smaller than the thermal wavelength (9.6 μm at room temperature), is due to the contribution of evanescent waves that dominate the near-field regime. The fact that this near-field radiative heat transfer (NFRHT) between closely spaced bodies can overcome the far-field limit set by the Stefan-Boltzmann law for black bodies has now been verified in a variety of experiments exploring different materials, geometrical shapes, and gaps ranging from micrometers to a few nanometers [2-4]. We demonstrate in this work that the use of metasurfaces provides a viable strategy to largely tune and enhance near-field radiative heat transfer between extended structures. In particular, using a rigorous coupled wave analysis, we predict that Si-based metasurfaces featuring two-dimensional periodic arrays of holes can exhibit a room-temperature near-field radiative heat conductance much larger than any unstructured material to date [5]. We show that this enhancement, which takes place in a broad range of separations, relies on the possibility to largely tune the properties of the surface plasmon polaritons that dominate the radiative heat transfer in the near-field regime.

Abstract- Photodetectors are typically based on photocurrent generation from electron-hole pairs in semiconductor structures and on bolometry for below bandgap absorption. We demonstrate subwavelength thermoelectric nanostructures designed for resonant spectrally selective absorption, which create localized temperature gradients with unfocused, spatially-uniform illumination to generate easily measureable thermoelectric voltages. We show that such structures are tunable with highly wavelength-specific detection, with responsivities up to 38 V/W, and bandwidths of 3 kHz, by combining resonant absorption at thermoelectric junctions, yielding a bandgap-independent photodetection mechanism.

Plasmon excitation enables extreme light confinement at the nanoscale, localizing energy in subwavelength volumes and thus can enable increased absorption in photovoltaic or photoconductive detectors[1]. Nonetheless, plasmon decay also results in energy transfer to the lattice as heat which is detrimental to photovoltaic detector performance[2]. However heat generation in resonant subwavelength nanostructures also represents an energy source for voltage generation, as we demonstrate here via design of resonant thermoelectric (TE) plasmonic absorbers for optical detection. Though TEs have been used to observe resonantly coupled surface plasmon polaritons in noble-metal thin films and microelectrodes[3,4] and have been explored theoretically for generation of ultrafast intense magnetic pulses in a dual-metal split ring resonator[5], they have not been employed as resonant absorbers in functional TE nanophotonic structures.

We demonstrate nanostructures composed of TE thermocouple junctions using established TE materials – chromel/alumel and bismuth telluride/antimony telluride – but patterned so as to support guided mode resonances with sharp absorption profiles, and which thus generate large thermal gradients upon optical excitation and localized heat generation in the TE material. Sample structure geometry and experimental data is shown in Figure 1. Unlike previous TE absorbers[6,7], our structures feature tunable narrowband absorption and measured single junction responsivities 4 times higher than the most similar (albeit broadband) graphene structures, with potential for much higher responsivities in thermopile architectures. For bismuth telluride – antimony telluride single thermocouple structures, we measure a maximum responsivity of 38 V/W, referenced to incident illumination power. We also find that the small heat capacity of optically resonant TE nanowires enables a fast, 3 kHz temporal response, 10-100 times faster than conventional TE detectors[8,9]. Additionally, the resonant TE nanowires exhibit noise only slightly above the Johnson noise level, suggestion a simple pathway for improving detectivity in future devices. We show that TE nanophotonic structures are tunable from the visible to the MIR, with small structure sizes of 50 microns x 100 micons. Our nanophotonic TE

structures are suspended on thin membranes to reduce substrate heat losses and improve thermal isolation between TE structures arranged in arrays suitable for imaging or spectroscopy. Whereas photoconductive and photovoltaic detectors are typically insensitive to sub-bandgap radiation, nanophotonic TEs can be designed to be sensitive to any specific wavelength dictated by nanoscale geometry, without bandgap wavelength cutoff limitations. From the point of view of imaging and spectroscopy, they enable integration of filter and photodetector functions into a single structure.

Functionalized Silk Fibroin Thin Films with Gold Nanoparticles as Ultrahigh Broadband Absorber

D. Wan*

[1]Institute of Biomedical Engineering, National Tsing Hua University, Taiwan

*corresponding author: dhwan@mx.nthu.edu.tw

Abstract- In this paper, the phenomenon of white-light-induced heating in silk fibroin (SF) films embedded with gold nanoparticles (Au NPs) is systematically investigated. As far as we are aware, this study is the first to employ Au NPs to develop an ultrahigh broadband absorber and also the first to use a white light source for photothermal generation. Also, the broadband absorptive film is coated on a simple Al/Si Schottky diode and displays a linear, significant, stable photo-thermo-electronic (PTE) response with varying light intensity.

There has been increasing interest in the unique physical and chemical properties of metal nanoparticles (NPs) because of their energy and biomedical applications. For example, metal NPs are attractive for their localized surface plasmon resonance (LSPR) properties. The strong interactions between metallic NPs and incident light originate from excitation of the collective oscillations of conduction electrons within these particles.[1] One of the amazing LSPR-related phenomena is the photothermal effect. When LSPR occurs, the plasmonic particles can efficiently convert optical energy to local heat and rapidly raise the temperature of the surroundings or themselves.

Light-activated Au NPs have been embedded in polymer matrix and widely used in material, biomedical, and photonic applications.[2] To further understand the photothermal process involved in the solid composites, a number of studies have investigated the light-induced heating of various polymers containing Au NPs.[3,4] Note that previous research has focused on the nanocomposites containing low Au contents (typically less than 1 wt%), which induced small temperature increases (few to few tenths °C). The low metal content might be attributed to the limitation of preparation methods or the poor solvent miscibility. In this case, the films exhibited a characteristic absorbance peak with a weak/moderate peak intensity and a narrow spectral bandwidth (ca. 50-100 nm), originated from the LSPR extinction of Au NPs dispersed in the polymer matrix. In other words, the nanocomposites can only absorb a small portion of the incident light energy near LSPR frequency, while most of the light energy within non-LSPR region will propagate through the film without any noticeable loss. This optical phenomenon restricts the choices of the light excitation sources for photoheating. Therefore, for the white-light-induced heat generation, a broadband optical absorber is strongly needed, which can completely trap the light energy over all wavelengths. To our best knowledge, however, no studies of the metallic NP/polymer nanocomposites with wide-range optical absorbance have been reported.

In this study, we fabricated homogeneous Au NP/silk fibroin (SF) composite films exhibiting ultrahigh broadband absorbance in the visible-near infrared (vis-NIR) range through a facile, simple solution process, and systematically investigated their optical properties and white-light-induced photothermal effects (see Figure1). Herein, SF was selected as host material due to a series of advantages: (i) high water solubility to prevent the

aggregation of Au NPs, especially at high colloid concentration; (ii) high T_g (ca. 180 °C) to avoid the heat dissipation induced from the phase change of polymeric matrix, and (iii) high transparency to reduce the light attenuation in the host material. By increasing the Au content in the composite films, the absorbance could be enhanced significantly around the LSPR wavelength and also raised dramatically at the non-LSPR wavelengths. The greater amount of absorbed light led to an increase in the photoheating rate. The optimized composite film exhibits an ultrahigh absorbance of ca. 95% over a wide spectral range of 350-750 nm, and moderate absorbance values (> 60%) in the longer wavelength range of 750-1000 nm. In this case, the composite film could absorb almost all of the incident light and accordingly convert the optical energy to local heat. Therefore, significant temperature increases on the order of ca. 100°C could be readily obtained when the composite film is irradiated by a LED or a halogen lamp. Moreover, the composite films also display a linear light-to-heat response with light intensity and a great photothermal stability. Finally, the broadband absorptive film is coated on a simple Al/Si Schottky diode and displays a linear, significant, stable photo-thermo-electronic (PTE) response with varying light intensity.

Superradiant and superscattering in thermal and light energy conversion

Zongfu Yu

University of Wisconsin Madison

When wave effects of thermal photons become significant, thermal emitters can exhibit intriguing coherent effects. Here, we show that the superradiant emission, which was originally found in quantum emitters, can be realized in resonant thermal emitters. Similar to the superradiance in quantum emitters, the in-phase oscillation of resonant emitters reduces the lifetime of thermal photons in the emitters. Unlike the atomic superradiance, one remarkable consequence of the thermal superradiance is the anomalous power scaling, where the emission power can scale inversely with the number of thermal emitters. More thermal emitters generate less power due to the coherent interference of thermal photons.

Fundamental electrodynamics dictates that the wavelength sets the length scale of the cross section in a resonant scattering process. Diverging cross sections can only be achieved around the DC frequency when the wavelength approaches infinity. Wely points, with a conic dispersion relation like that around the DC point, are shown to exhibit diverging cross sections, regardless of the wavelengths. The decoupling of the resonant cross section and the wavelength could allow, for example a nanoscale optical resonance to have a macroscopic cross section. Extraordinarily large cross section could be very useful for applications in optical energy conversion.

Abstract-Nanostructures enabled solar thermal conversion has aroused tremendous interest in the field of solar energy applications. Here we will report our progresses on the self-assembled plasmonic nanostructures assisted solar thermal conversion, which includes the design and fabrication of the most broadband plasmonic absorbers, tunability of absorption bandwidth, as well as the first plasmon enhanced solar desalination device. Our results may provide a competitive solution to the cost-effective and highly efficient solar desalination strategies for personalized applications.

Due to flexible tenability of absorption bandwidth, ability of subwavelength confinement of electromagnetic field and the related hot spots effect, plasmonic absorbers have aroused tremendous interest in solar thermal conversion processes [1,2]. Recently, we have demonstrated the three dimensional metallic nanoparticles as the broadband absorbers with the scalable self-assembled process (Fig. 1b).

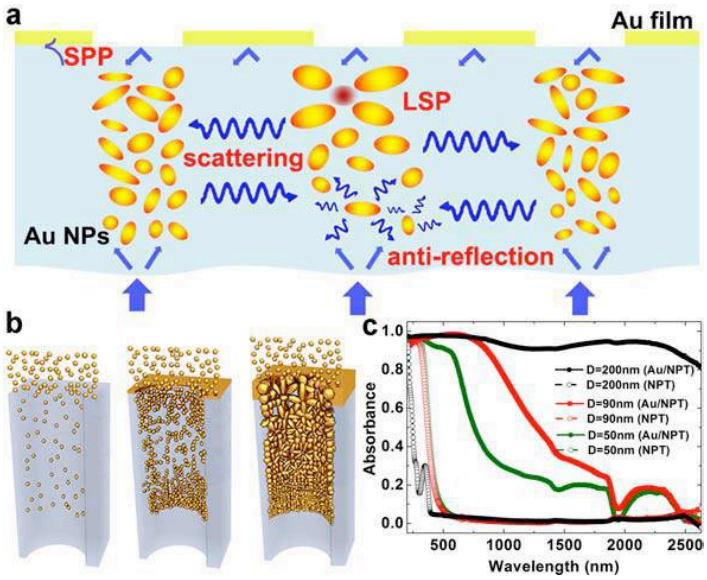

Fig. 1 Optical design (a), self-assembled fabrication (b) and absorption performance (c) for the broadband plasmonic absorbers.

Due to the unique close-packed and highly porous metallic nanoparticle assemblies, the nanostructure is ideal candidate for broadband absorbers due to high density of optical modes by plasmon hybridization, strong

scattering as well as antireflection effect (Fig. 1a) [3]. In addition, the absorption bandwidth can be flexibly tuned by the geometry parameters and/or deposition conditions [4], indicating potential applications for various solar thermal conversion applications. Finally, we for the first time employed the low cost 3D aluminum nanoparticles for the broadband solar absorbers and enabled the plasmon enhanced solar desalination device [5], by which the solar thermal efficiency ~ 90% and ~ 4 orders of magnitude of the ion concentration decrement were achieved. Our results would shed light on the low cost personalized solution for the solar desalination technologies.

Abstract— We investigate a *gap-free* thermophotovoltaic system whose engineered emitter is matched to the macroscopic layer of a particular material which has very low absorption at the operation band of the photovoltaic cell and relatively low thermal conductivity. We tailor the radiative heat transfer such that it is maximal and super-Planckian near the bandgap frequency of the photovoltaic cell, and reduced at other frequencies. Therefore, it gives rise to a high ultimate efficiency and high electric output. We believe that our study paves the way toward the new generation of efficient and feasible thermophotovoltaic systems for producing electricity from heat.

Thermophotovoltaics (TPVs) are systems which use a direct energy conversion method to generate electricity from heat. In fact, in TPVs (similar to solar cells) the radiating photons are absorbed by a photovoltaic (PV) cell that operates at room temperature. The absorbed photons are converted into electron-hole pairs and result in the electric current. However, in TPVs the radiating photons are emitted from a source which has a temperature much higher than the room temperature. Emitter and the PV cell are supposed to be separated by a vacuum gap in order to sustain the temperature difference between the emitter and the PV cell [1].

In designing efficient thermophotovoltaic systems, two main points should be taken into account. The first key point is that we have to obtain a super-Planckian radiative heat transfer in order to get a noticeable output power, and the second one is related to the efficiency of the system. Only photons which have higher energy than the bandgap energy of the PV cell ($E > \hbar\omega_{\mathrm{g}}$) can contribute in the generation of the electron-hole pairs. The low-energy photons cause thermal dissipation in the PV cell and may increase its temperature. The same senario is also true for the photons which have very high energy (since the excessive energy $\hbar(\omega\,!\;\;\omega_{\mathrm{g}})$ is not useful and it causes thermal dissipation). Hence, the radiative heat transfer must be frequency-selective such that it is maximum near ω_{g} and negligible at other frequencies [1].

In this conference paper, we introduce a new design of thermophotovoltaic systems which fulfills the above goals: frequency selectivity and super-Planckian radiative heat transfer. However, in contrast to the previous works (see, e.g. [2, 3, 4]) where super-Planckian radiative heat transfer was achieved by using hyperbolic metamaterials (wire media) or decreasing the width of the vacuum gap (to a few nanometres) to have a strong photon-tunelling effect, here, the super-Planckian radiative heat transfer is given by an intermediate material between the emitter and the PV cell. Indeed, the vacuum gap is replaced by the intermediate material which has a large thickness and it is matched to our particular emitter at the frequency near the bandgap frequency of the PV cell. Such a design resolves the difficulty of preserving the nanogap for the sufficient area of a few square centimetres, or fabrication of wire media.

Controlling the emissivity of a thermal emitter has attracted growing interest with a view towards a new generation of thermal emission devices. So far, all demonstrations have involved sustained external electric or thermal consumption to maintain a desired emissivity. In this invited talk, I will review our recent work on control over the emissivity of a thermal emitter consisting of a phase changing material Ge2Sb2Te5 (GST) film on top of a metal film [1]. This thermal emitter shows broad wavelength-selective spectral emissivity in the mid-infrared. The peak emissivity approaches the ideal blackbody maximum and a maximum extinction ratio of above 10dB is attainable by switching GST between the crystalline and amorphous phases. By controlling the intermediate phases, the emissivity can be continuously tuned. This switchable, tunable, wavelength-selective and thermally stable thermal emitter will pave the way towards the ultimate control of thermal emissivity in the field of fundamental science as well as for energy-harvesting and thermal control applications, including thermophotovoltaics, light sources, infrared imaging and radiative coolers.

Optical force has been widely utilized to manipulate microscopic objects, though mostly in vacuum or in liquids. Photophoretic force provides an alternative and effective way to transport light-absorbing particles in ambient gases. However, in most cases these forces work independently. Here, by employing the synergy of optical force and photophoretic force, we propose and experimentally demonstrate a configuration which can drive a micron-size metallic plate moving back and forth on a tapered fiber with supercontinuum light in ambient air [1].

Abstract- In order to tailor thermophotovoltaic emitters to match specific photovoltaic receivers we designed spectrally selective emitters that have close to black body emission at short wavelengths and substantially reduced emission at long wavelengths. We demonstrate selective band-edge emitters based on a W-HfO_2 refractive multilayer metamaterial and a ZrO_2 opal monolayer on tungsten both stable up to 1000°C. Conditions for improved selectivity and higher thermal stability will be presented as well.

The efficient thermophotovoltaic conversion requires emitters that demonstrate emissivity close to 1 at frequencies above the band gap frequency of the photovoltaic cell (short wavelengths) and emissivity close to zero for smaller frequencies (longer wavelengths). Two possible routes can be envisaged to produce the required type of the emission. The first is based on materials which have dielectric constants that are matched to vacuum at short wavelengths and are strongly mismatched and thus reflecting at longer wavelengths. The second option is based on structures on a surface that support critically coupled resonances at short wavelengths and no resonances at longer wavelengths.

We are presenting the results obtained by both routes. First we discuss results of a layered metamaterial from W and HfO_2 (Fig. 1a) [1]. The subwavelength combination of dielectric and metal allows shifting the hyperbolic transition of the metamaterial to the NIR. This way the metamaterial has close to one permittivity and thus close to one absorptivity and emissivity at short wavelengths. In the long wavelength range the metamaterial with low absorption has a hyperbolic equi-frequency surface and thus sustains thermally excited modes with only large wavevectors, none of which can couple out into vacuum. The structure shows up to 1000°C stability under

vacuum conditions of ~$2 \cdot 10^{-2}$ mbar. Even though the upper layer of tungsten was protected by 100 nm of HfO_2 the residual oxygen from vacuum leads to oxidation of this first layer of tungsten. The advantage of metamaterial is almost direction independent thermal emission which is connected to the fact that properties are defined by the effective parameters of the metamaterial and not by the accumulated phases. But the metamaterial still shows significant emission at longer wavelengths due to limited reflectivity. This is connected to the high imaginary permittivity of tungsten and large penetration of long wavelength fields into the metamaterial.

Better suppression of long wavelength emission can be obtained using dielectric resonators coupled to lossy metal. This was achieved by deposition of a monolayer of ZrO_2 spheres on a tungsten substrate protected by a thin layer of HfO_2 (Fig. 1b) [2]. The microspheres support resonances which are critically coupled to free space. The dense monolayer of spheres can be approximated and simulated as a PhC with a hexagonal lattice. The resonances of single spheres in this case present a tight-binding approximation of the PhC. The overlapping absorption of different resonances leads to a band of high emission at short wavelengths. At longer wavelength, where no resonances are present, the reflectivity is defined by the flat tungsten substrate. The penetration of the incident fields and thus the absorption is lower at longer wavelength than in the case of metamaterials. Presented PhC emitters have very good suppression of emission at longer wavelengths, but demonstrates angel dependent emission. The stability of this structure is also limited by oxidation of tungsten.

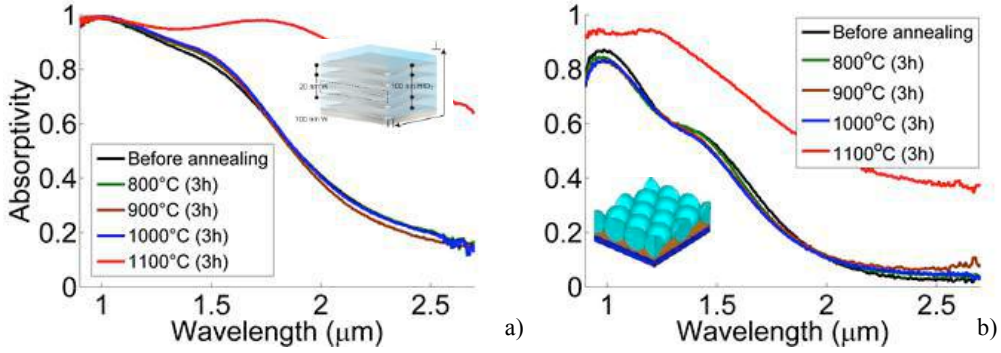

Figure 1: a) Absorptivity of the tungsten based metamaterial after tempering in vacuum ~$2 \cdot 10^{-2}$ mbar. Schematic inset shows the layered structure of W-HfO_2 (20 nm-100 nm) metamaterial. b) Absorptivity of the tungsten emitter coated by a monolayer of ZrO_2 microparticles (660 nm diameter) after tempering in vacuum. Schematic inset shows the structure geometry. (dark blue – W, orange – HfO_2, light blue – ZrO_2).

Abstract

We report on the thermoplasmonic energy conversion by self-assembled meta-structures of aluminum oxide nanostructures. We fabricate aluminum nanowire array, which has high optical transmission haze, and manipulate the optical characteristics by controlling sizes and morphologies. By depositing metal or metal oxide, the array structures absorb broadband light by plasmonic nanofocusing and the absorbed light is converted into the localized heat energy. The converted heat energy can be utilized for solar vapor generation and thermophotovoltaics.

Abstract- Nanojoining of nanomaterials opens up a new emerging set of applications in transparent conductors, thin-film solar cells, nanocatalysis, cancer therapy and nanoscale patterning. Single point nanojoining is highly demanded for building complex nanostructures. In this talk, I will show the precise control of single point nanojoining of silver nanowires in depth, where the nanojoining is laser-induced through the plasmonic resonance enhanced photothermal effect. single point nanojoining technique shows great potentials for high-performance electronic and photonic devices based on nanowires, such as nanoelectronic circuits and plasmonic nanodevices.

As the development of science and technology, integrated device tends gradually into micro-nano scale. For integrated devices based on nanowires elements, nanojoining (including nanowelding [1], nanosoldering [2] and nanobreaking [3]) have shown its necessity for manufacturing integrated nanodevices. In this talk, by taking advantage of photothermal effect of a 532 nm continuous-wave (CW) laser, nanojoining (including nanowelding, nanosoldering and nanobreaking) of nanowires can be achieved.

For the nanowelding and nanosoldering, we investigate the fusing property of a single metallic nanowire after irradiation and take advantage of the concept of match-end to implement nanowelding and nanosoldering. Moreover, we improve the method and test the electrical property after nanowelding. For the nanobreaking (Fig. 1), we study the morphological changes during fusing process and confirm that the critical power required for nanobreaking is much lower for perpendicular polarization than that for parallel polarization both in experiment and simulation. By controlling the polarization and the power of the irradiation laser for nanobreaking, the nanowires can be cut into segments with gap widths ranging from dozens of nanometers to several micrometers.

Abstract-Here, we experimentally demonstrate a multispectral metasurface that exhibits controlled inhomogeneous optical properties leading to a spatial modulation of the emissivity up to the wavelength scale in the infrared. A metasurface made of a non-periodic set of 100 million optical nano-antennas that spatially and spectrally control the emitted light up to the diffraction limit has been realized and studied. Each antenna acts as an independent deep subwavelength emitter for a given polarization and wavelength, and their juxtaposition at the wavelength scale can encode far field multispectral and polarized images. Other nanoantennas can be used, like the optical Helmholtz resonator, that allows to control the spectral bandwidth or the radiative losses.

Metasurfaces can be used to tailor the electromagnetic surface on various spectral bands. In particular, metal-insulator-metal (MIM) nanoantennas are known to modify the absorption of a surface due to a Fabry Perot resonance. Here, we first show how the infrared emissivity of a metallic surface, which is nearly zero can be turned into multiple quasi monochromatic emitters thanks to MIM nanoantennas. Then, we show that their subwavelength combination can be used to tailor more complex emissivity spectra, independently for both polarizations. Eventually, an inhomogeneous metasurface is made where the emissivity is spatially modulated at the wavelength scale.

The samples have been studied with a Fourier transform infrared spectrometer coupled to a high resolution cooled HgCdTe camera, and a polarizer.

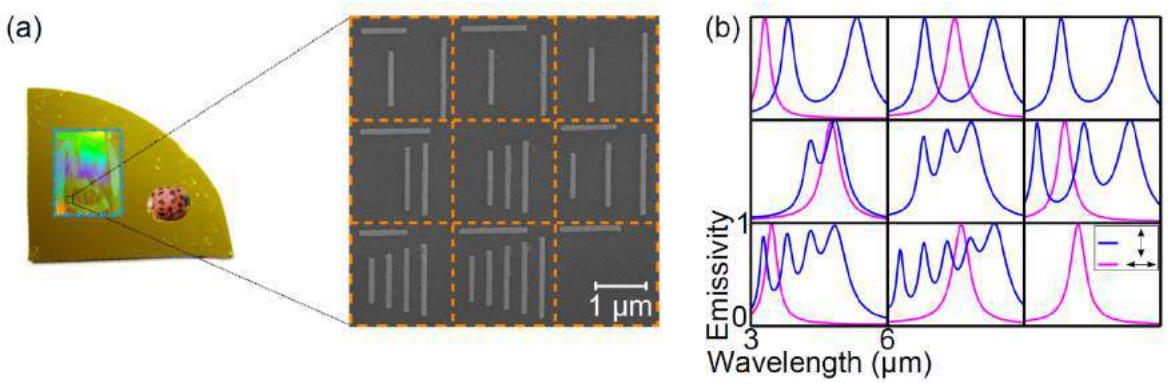

Figure 1: (a) Visible picture of the sample and SEM image of nine elementary cells, each containing various antennas. (b) Computed emissivity spectra for both polarization given for each elementary cell (practically consider as periodic for the computation).

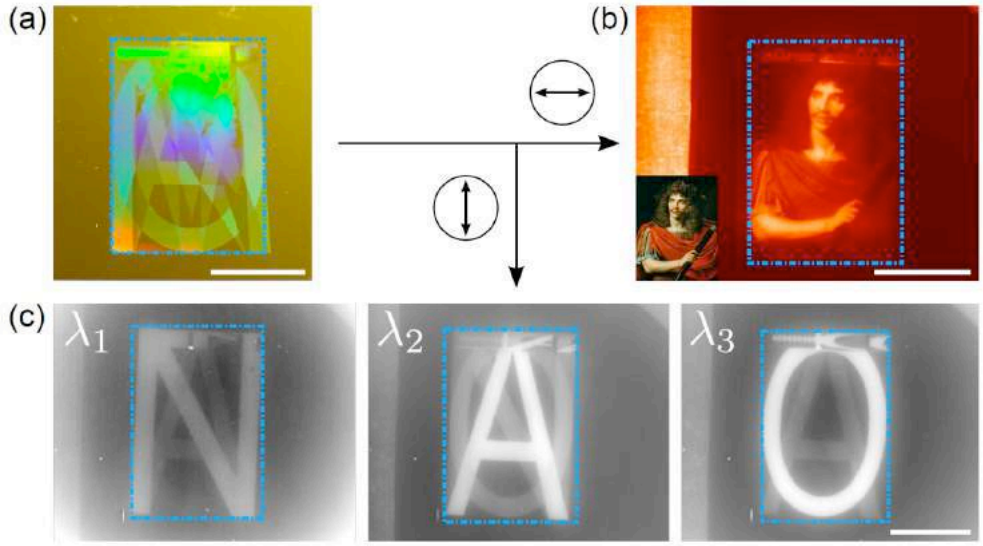

Figure 2: (a) Picture of the sample. (b) Infrared thermal emission on the 3-5 µm band of the sample heated at 100°C for the horizontal polarization. (c) Infrared emission for the vertical polarization, filters were added to select only a part of the emitted spectral band.

Abstract- By adequately designing their size and geometry, metal nano-structures offer highly efficient light/heat absorption with desired spectral features. We report our recent study on the design, fabrication, and characterization of spectrally selective narrow-band plasmonic metamaterial perfect absorbers for the effective applications in wavelength-selective thermal emitters, infrared detectors as well as high-sensitivity molecule-sensing.

Plasmonic metamaterial perfect absorbers can exhibit nearly 100% absorptivity at desired wavelengths, and also emit light at the same wavelengths when they are heated. It has been successfully demonstrated their use such as in wavelength-selective infrared thermal emitters and molecular vibrational sensors [1-4]. We present our recent study on the development of perfect absorbers based on the metal-insulator-metal structures [1-4]. By use of numerical electromagnetic simulations, we optimized the geometrical parameters of the perfect absorbers to have resonances at certain wavelengths depending on their applications from far-infrared to mid-infrared region. The fabricated perfect absorbers exhibit narrowband resonant absorption with efficiency higher than 97 %. We report applications of these devices such as for selective thermal emitters operated above 1273K [1,4], selective surface-enhanced vibrational spectroscopy for high-sensitivity molecular sensing [1,2], and wavelength selective IR detectors based on the combination with pyroelectric device and the metamaterial infrared absorbers [5].

Abstract- We show that a periodic array of hot nanoparticles embedded in resonant plasmonic antennas can produce thermal emission with an effective emissivity approaching unity.
This type of design allows to control thermal emission by designing the antennas. We expect to modulate thermal emission at a rate exceeding 10 MHz.

The goal of this presentation is to discuss how blackbody radiation can be tailored using nanoantennas. By tailoring blackbody radiation, we mean that the emitted spectrum, the directivity of the source, its polarization can be controlled thereby paving the way to a novel generation of IR sources. Furthermore, we aim at modulating the emitted intensity at a rate faster than 10 MHz.

In the last 15 years, many ideas have completely changed our perspective on what can be done with incandescent sources. Taking advantage of the existence of the spatial coherence of surface waves, highly directional sources have been demonstrated[1]. Taking advantage of the spectral resonances of plasmonic structures, quasimonochromatic sources have been fabricated[2]. Electrical modulation of the absorptivity of a stack of quantum wells has allowed modulating thermal emission at a rate of 600 kHz [3].

In this presentation, we introduce a novel approach. We start by introducing a generalized Kirchhoff law valid for anisothermal bodies. The idea is simple: Kirchhoff law can be extended to objects such as a hot graphene layer deposited on a cold substrate[4]. The power thermally emitted by a hot graphene layer on a cold substrate in a direction and at a given frequency is proportional to the power absorbed in the graphene layer only when illuminating this graphene layer in the same direction and at the same polarization.

The second ingredient of the presentation is to introduce a nanoantenna such as a half-wavelength antenna. By inserting a small hot volume of absorber in the gap of a dimer antenna, it is possible to enhance the power extracted from the small hot volume by more than three orders of magnitude. This can be achieved provided that the absorber has been properly designed in order to verify a critical coupling condition with the antenna. We will discuss in some detail the conditions required to optimize the absorption in a nanoantenna which differs from the maximum enhancement condition.

A key feature of this type of source is the small size of the heated volume. While usual incandescent sources cannot be modulated at high frequency due to their thermal inertia, nanovolumes can be cooled in a few tens of ns offering a new opportunity for high speed modulation. In order to produce a practical emitter, a periodic array of antennas can be fabricated which results in a metasurface for IR emission. Finally, by tuning the properties of the antennas, the metasurface can control the frequency, polarization and direction of emission.

Thermal emitters generally exhibit a broad spectrum and are widely used for various light sources from far-infrared to the visible range. However, in many applications involving non-dispersive infrared sensing and thermo-photovoltaics, only a specific spectral component that is much narrower than the original broad spectrum of thermal emitters is utilized, which reduces efficiency. Therefore, it is important to develop a single-mode narrow-bandwidth thermal emitter that achieves high emissivity at a target wavelength while suppressing it as much as possible at other wavelengths. To achieve such an ideal spectrum, we demonstrated mid-infrared thermal emitters by combining multiple quantum wells (MQWs) and two-dimensional photonic crystal (PC) slabs [1]. In our emitters, intersubband transitions of MQWs allow a strong interaction between light and matter around a target wavelength, and a Γ–point resonant effect of PCs further narrow down the thermal emission peak at a target wavelength and enable vertical emission. Ultrafast modulation (~MHz) of thermal emission without changing the temperature of emitters has been also realized by changing the electron density of MQWs using applied electric field [2]. We have also demonstrated near-infrared narrowband thermal emitters recently by using arrays of nano-rods made of intrinsic silicon [3], which can be utilized to increase the efficiency of thermo-photovoltaic power generation. In this emitter, an interband transition of intrinsic silicon emphasized light-matter interaction in the range shorter than the bandgap wavelength of silicon, and a rod-type resonator array with a small material filling factor suppressed the longer wavelength emission components. The details will be reported at the conference.

Abstract- We demonstrate an optically reconfigurable grating with enhanced transmission of TE polarized waves in the terahertz (THz) waveband. The grating is realized with periodical photoexcited free carriers strips on a thin Si wafer. For TE polarized THz incident wave, the strips behaviors like metal, resonances between the strips happen and cause the enhanced transmission. The frequency of the transmission peak could be tuned through changing the period and duty cycle of the photoinduced grating.

A pattern with illuminated and dark regions was projected onto a Si wafer with thickness of 10μm. In the illuminated region, carriers are created by photoexcitation. Owing to the fact that the skin depth of Si is 12.2 μm at a wavelength of 800 nm[1], the photoinduced carriers form a freestanding grating, which can be regarded as a metallic wire grating embedded in the Si wafer. Then, a THz beam is incident onto the grating and the transmission spectra are measured with a terahertz time-domain spectroscopy system.

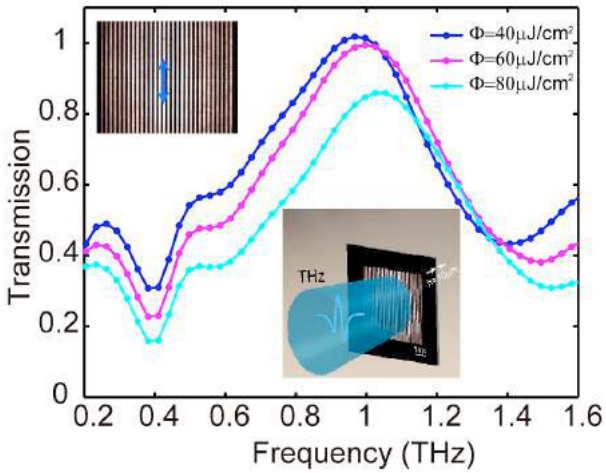

Figure 1 Experimental transmission spectra of the photoinduced grating (P = 200 μm, D = 0.5) for a series of excitation fluences, when the incident THz electric field is TE-polarized.

Extraordinary optical transmission (EOT) through such photoinduced grating is observed for TE-polarized THz incident wave, which is different from the former reports where the incident light is usually TM-polarized [2,3]. In order to verify the measured results, we performed realistic simulations of the photoinduced grating using a commercial software package (FDTD Solutions) based on the FDTD method. The dielectric function of the photoexcited Si wafer is calculated using the Drude model. The physical explanation on the EOT phenomenon with TE-polarized THz incident wave is cavity resonance, which is a rather different process from the excitation of surface plasmons (SPs) that occurs for TM polarization. The field is able to couple in the dielectric and is strongly enhanced in the region between photocarrier strips. The resonator length is determined by the width of the spacing. Thus, the position of the resonance peak shifts towards longer wavelengths when the spacing between the photoinduced stripes increases.

This kind of reconfigurable terahertz grating can be used as a tunable polarization-independent THz filter to avoid the processing of traditional samples and provides flexibility to adjust the structural parameters of the sample. Furthermore, this technique could also be used to produce THz diffractive elements with reconfigurable functionality for more applications.

Abstract-We report the excitation of extremely high quality-factor (Q-factor) dark mode resonances in metamaterials composed of mirror-asymmetric split ring resonators (MASRRs) in the terahertz region. Breaking the symmetry of the mirror-arranged SRR leads to the occurrence of two distinct otherwise inaccessible ultrahigh Q-factor dark modes. The numerical simulations indicate that the highest Q-factor of the dark mode resonance was 60, which is more than one order of magnitude larger than that of conventional metamaterials.

Metamaterials have attracted tremendous of research interest due to their unusual and exotic electromagnetic properties and functionalities that are not encountered in naturally occurring materials. The unique properties of metamaterials are based on the resonant responses of the constituent building blocks and arrangement. High Q-factor resonances in metamaterials are of particular importance, as they can be utilized to realize slow light devices[1,2], narrow-band filters[3,4], and ultrasensitive sensors[5,6]. However, the performance of conventional metamaterials typically suffer from low Q-factor (<~10)[3,4,6] due to radiative and ohmic losses, which hinder the development of the metamaterial-based devices.

In this paper, we theoretically and experimentally demonstrate a metamaterial composed of mirror asymmetric split ring resonators that sustain multiple high Q-factor resonances. The excitation of sub-radiant dark modes with highly suppressed radiation losses result in the high-Q factor. The metamaterial samples were fabricated using high-resolution electron-beam lithography method, and characterized by terahertz time domain spectroscopy (THz-TDS). The corresponding theoretical calculations were performed by FDTD algorithm. The experimental and simulated results manifest that two extremely sharp resonances appears at ω_1=0.5 THz and ω_2=1.3 THz, respectively. The calculated Q-factor for dark mode ω_1 and ω_2 are 60 and 30, respectively.

This mirror-asymmetric metamaterial supporting multiple high Q-factor resonances may well enable great advances in designing and realization of high-performance photonic devices to overcome the technologically difficulty in terahertz regime.

3D Lantern-like metamaterial

S. Hu[1], R. H. Pan[1], Z. Liu[1], S. Y. Yang[1], J. J. Li[1*], and C. Z. Gu[1,2*]

Abstract-This work presents a 3D metamaterial based on stress induced bending of bilayer or multilayer film. Take advantage of traditional planar process, the lantern-like metamaterial contains a flat pad supported by the substrate and a number of arms connecting to the pad. By changing the number of arms, the transmission spectrum changes correspondingly, and an EIT-like resonance appears when the arm number is above 6 due to the coupling between different arms.

Plasmonic induced transparency (PIT) is an optical phenomenon based on the interference between "dark mode" and "bright mode" of metamaterials, by which a transparency peak appears in the absorption region of the spectrum[1-3]. This phenomenon has great potentials in the application of slow-light devices and sensors. 3D metamaterials usually perform better than 2D structures due to larger degree of freedom and more ways of light-structure interaction. However, up to now, the fabrication of 3D metamaterials is still limited by the existing planar micro/nano-fabrication technique in visible and infrared region, which restricts its application on high frequency EIT devices.

In this work, planar fabrication process including electron beam lithography (EBL), reaction ion etching and metal film deposition was used, and the schematic of 3D structure is shown in figure 1. After released from the substrate, the residual stress and modulus differences between two layers result in the bending of cantilevers[4,5]. This method can flexibly control the structure configuration and different materials can be applied including metal, dielectric and semiconductor. Lantern-like metamaterials were fabricated by this method, and the radius of the curved cantilever is tunable by controlling the thickness and material type of the bilayer film. A series of structures with different numbers of arms were simulated and the transmission spectra are shown in figure 2. The peak at 2 THz is a fundamental mode of the LC resonance in the ring, and at about 6 THz coupling between different arms happens. When the arm number is less than 4, there is only one resonance peak at 6 THz; as the arm number is over 6, a transparent peak appears in the absorption region, which comes from the hybridized coupling effect.

Abstract- We suggest that terahertz (THz) metamaterials can be used to measure the dielectric constant of various dielectric materials. We successfully measure the dielectric constant of various polymers and polar liquid using THz metamaterial devices. Our experimental results were confirmed by finite-difference time-domain simulation.

Recently, we found that THz metamaterial can be used as a sensitive biosensor, enabling us to detect the low-density microorganisms although their scattering cross-section is extremely low against THz waves [1]. This was possible because the detection volume of THz metamaterial is highly confined near the surface, in particular, in the gap area. The vertical range of the detection volume has been estimated to be 3–4 μm, depending of the detailed geometry of the pattern [2]. Therefore, it is highly desirable to use metamaterials to address the dielectric constants of the thin films without necessitating large amount of the materials. More importantly, the narrow detection range will enable us to study the dielectric properties of various polar liquids that attenuate the THz waves substantially.

Here, we introduce a novel method to extract the dielectric constants of the thin polymer film and the polar liquid solution by using THz metamaterial sensors through THz time-domain spectroscopy (THz-TDS) [3]. We demonstrate the dielectric constant measurements of thin polymer films and polar liquid solutions by using THz metamaterial sensors. The resonance shift of the metamaterials exhibits the saturation behavior with the increased film thickness of deposited target material. We found that the saturation frequency shift varies linearly with the real part of the dielectric constant and extracted their correlation explicitly for the particular metamaterials pattern we used. This approach could be very useful to determine the dielectric constants of various materials, without necessitating the large amount of the target materials.

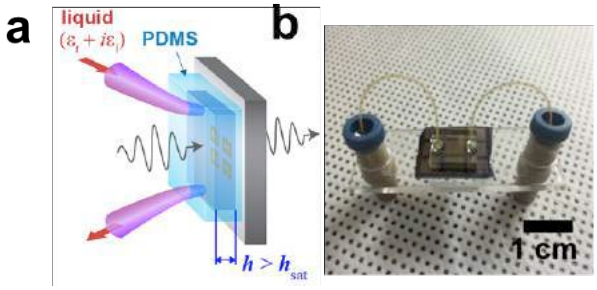

Figure 1. (a) Schematic of the fluidic THz metamaterial device for the sensing of aqueous solutions. (b) Photograph of the fluidic metamaterial device.

More importantly, we were able to measure the dielectric constant of the polar liquids such as distilled water, methanol, and ethanol as schematically shown in Fig. 1. This was possible due to the unique properties of metamaterials whose detection volume is strongly localized at the surface. In other words, the metamaterials allow us to address the THz optical constants without suffering from the large attenuation effects in the polar liquids. In addition, we found that the resonance shift does not depends critically on the imaginary part of the dielectric constants, making our approach a universal technique regardless whether the target specimens are transparent or conductive materials. The results from the FDTD simulation are in good agreement with our experimental results both in the thin film and the liquid cases. We also found that the metamaterial fluidic devices can work as an efficient ion sensor, because the dielectric constant of ionic solutions (such as KCl and NaCl solutions) changes with ionic concentration as shown in Fig. 2(c). For instance, the sensitivity in terms of the molar concentrations of the KCl solutions yielded 10 GHz per M. Our work will contribute to the qualitative and quantitative study on the dielectric properties of various types of materials in THz frequency range as well as to the development of effective future biological and chemical sensors.

Development of terahertz nano-gap metamaterials for low-density virus detection

S. J. Park[1], G. A. Shin[2] and Y. H. Ahn[1*]

[1]Department of Physics, Department of Energy Systems Research, Ajou University, Suwon 16499, Korea

Abstract- We developed terahertz metamaterials with micro- and nano-gaps for the sensitive detection of viruses. Red-shift of resonant frequency occurs as we deposit low-density viruses such as PRD1 and MS2 on the metamaterials due to the change of the effective dielectric constant of the gap structure. Sensitivity increases as we reduce the gap size in the metamaterials, which is due to the size compatibility and the strong field confinement effect in the gap area.

Metamaterials operating in THz frequency range have proven to be an efficient future platform for sensing low-density microorganisms such as fungi and bacteria (with the typical sizes of 1–2 μm). Although their scattering cross-section is extremely low against THz waves, the field-enhancement effects in the gap area enable us to detect the low-density microorganisms [1]. On the other hand, sensing of viruses is still very challenging because their typical sizes ranges ~ 50 nm, which scales only ~λ/10,000 with respect to the incident THz waves. In this work, we used THz metamaterials for sensing low-density viruses and improved the sensitivity by introducing nano-gaps in the metamaterials.

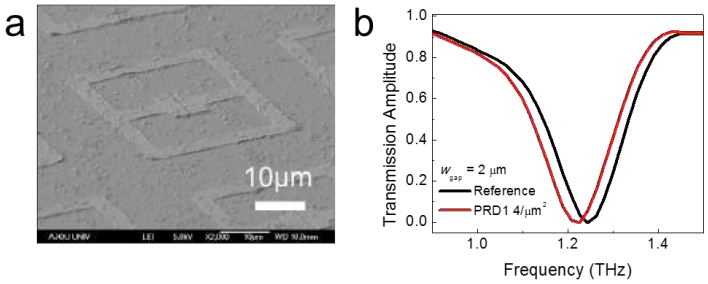

Figure 1. (a) SEM image of metamaterials (with a gap width of 200 nm) coated with PRD1 viruses. (b) THz metamaterials resonances measured before (black line) and after (red line) the deposition.

Our metamaterials consist of split-ring resonators fabricated using conventional e-beam lithography techniques (Fig. 1(a)). We deposited two types of viruses (PRD1 and MS2) on the metamaterials surface from a solution, followed by a drying process in an oven for 5 min at 85 °C. A representative result is shown in Fig. 1(b) for the metamaterial devices with the gap width of 2 μm, for the PRD1 viruses with the surface density of 4/μm^2. The resonant frequency red-shifts as we deposit the viruses and the frequency shift (Δf) increases with an increase in number density. The red-shift in the resonance is due to the change in the effective dielectric constant

of the gap area, consistent with the measured dielectric constant of PRD1 viruses ($\varepsilon_{PRD1} \sim 4.1$, $\varepsilon_{MS2} \sim 3.9$).

More importantly, the sensitivity of THz metamaterials can be improved by reducing the gap width (w_{gap}). In general, THz metamaterials have gap structures typically with the size of ~μm which is compatible with the sizes of the bacteria. In order to optimize the sensitivity, it is highly desirable to develop the metamaterials with the nano-gap, compatible with the size of viruses. In Fig. 2(a), Δf is plotted as a function of PRD1 density for the different w_{gap}'s of 200 nm – 2 μm. Clear saturation behavior was found as the surface density increased and we found that the saturation density is reached at the lower density for the metamaterials with the smaller gaps. We plotted the sensitivity of the metamaterials sensors as a function of w_{gap} in Fig. 2(b). The sensitivity increases by about 8 times for w_{gap} = 200 nm as compared to the case of w_{gap} = 2 μm. The enhanced sensitivity in the nano-gap metamaterials is attributable to the size compatibility between the target substances and the gap size, accompanied by the large field enhancement effects in the gap area [2].

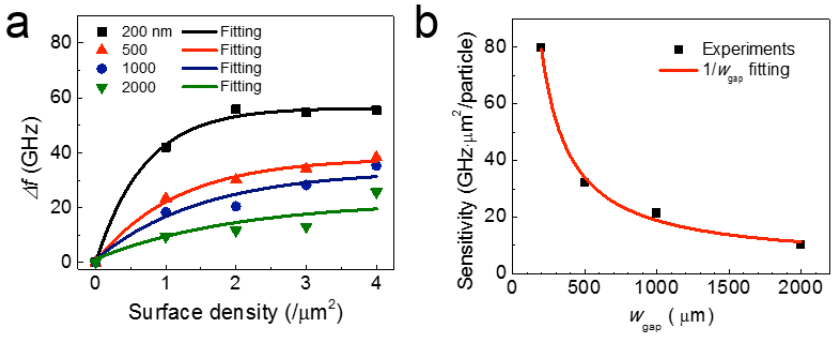

Figure 2. (a) Resonance frequency shift as a function of the surface density of viruses for metamaterials with different gap width (b) The sensitivity of metamaterials sensor as a function of gap width (w_{gap}).

Interaction mechanisms in ensembles of planar meta-atoms

M. Wenclawiak[1*], C. Derntl[1], K. Unterrainer[1], and J. Darmo[1]
[1]TU Wien, Institut für Photonik, Gußhausstraße 27-29, 1040 – Vienna, Austria

Abstract-In this contribution we demonstrate the substantial influence of meta-atoms in the terahertz regime on the radiation efficiency when being arranged in a confined environment. The meta-atoms, as the elementary structures of a metasurface, are thereby arranged in separated super cells with varying element density. For such meta-atom ensembles we find a radiative lifetime effect comparable to that known for an ensemble of excited atoms in a sub-wavelength volume.

In the past decades, there have been numerous investigations of the rising phenomena for ensembles of atoms in a confined volume. In 1954, Dicke published a theoretical paper describing a modification of the radiative lifetime for two level atoms confined in a volume smaller than the cubed wavelength corresponding to the optical transition[1]. These effects have later been proven in a variety of experiments, e.g. in gas[2] and as well in solid state[3] environments. Here, we describe a comparable experiment with meta-atoms, structures featuring dimensions shorter than the interacting wavelength. These structures gained a lot of attention in the last years starting with the pioneering experimental work of Pendry *et al.* including phenomena like negative refractive index materials and perfect lensing[4,5].

Our investigation focuses on the radiative lifetime of plasmonic resonators in the terahertz (THz) frequency regime. The used meta-atoms can be regarded as a system of two conductively coupled dipoles oscillating in phase. We measure the transmission properties of various metasurface arrangements by means of time-domain-spectroscopy and extract the resonance frequency and linewidth out of the fitted spectra. Hereby, the frequency position can be compared to a simple analytical model for estimating the resonance behavior of conductively coupled dipoles. The different number of meta-atoms is arranged *randomly* in separated super cells (see Fig.1 (a)) in order to prevent the formation of so called "lattice-modes" due to diffraction of the impinging radiation, which can influence the linewidth of the plasmonic resonators[6].

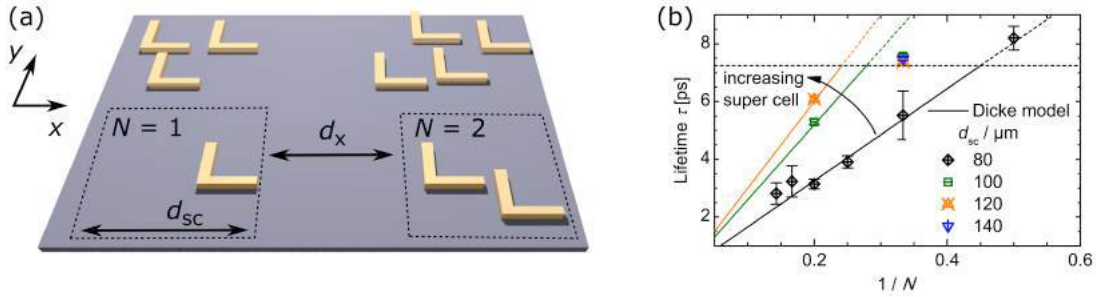

Figure 1: (a) Schematic drawing of the super cell geometry with varying number of randomly arranged meta-atoms. **(b)** Radiative lifetime extracted out of transmission measurements for varying super cell sizes containing an increasing number of meta-atoms.

The radiative lifetime is plotted as a function of the inverse number of confined meta-atoms in one super cell in Fig.1 (b) as it reflects the behavior of the two-level atoms predicted by Dicke. As a result we obtain a proportional dependence between the two parameters restricted only by a critical number of elements in one super cell geometry. In order to confirm the observed behavior, in a subsequent experiment, we change the size of the super cells by keeping the number of elements fixed in order to investigate the critical density showing a modified radiative lifetime response. As schematically shown in the viewgraph of Fig.1 (b), the effect on the radiative lifetime is restricted only to very dense ensembles of meta-atoms.

In the terahertz frequency range, only a few dense meta-atoms already show a strong modification of the radiative lifetime and therefore, influence the rate at which the stored energy is lost.

Abstract— Metamaterial designs combining graded arrays of resonators and elastic wave excitation are opening new possibilities to broadband control the propagation of mechanical waves in solid media. In this presentation we report on the recent development of a graded metasurface that supports a variety of phenomena including wave focusing, re-routing, rainbow trapping and mode conversion. Applications of this metamaterial can be envisaged in several fields and lengthscales.

Recent years have witnessed an increasing popularity of metamaterial concepts, based on the so-called local resonance phenomenon, to control the propagation of electromagnetic, acoustics and elastic waves in artificially engineered media. While the momentum initially focused on the subwavelength bandgaps generated by the resonance, the research is now shifting towards more complete forms of control, encompassing tailored graded designs to obtain spatially varying refraction index, wide bandgaps and mode conversion. In the field of photonics and acoustic for instance, this transition has already taken place and new graded design allows a tailored control of the propagation of light, micro-waves and sound. Elastic waves, as opposed to acoustic and electromagnetic waves, are characterized by different compressional and shear wave speeds resulting in mode conversions at the interfaces. On the one hand this makes elastic metamaterials complex to model and the use of computational elastodynamics technique mandatory, on the other hand it offers new control possibilities not achievable in the electromagnetic or acoustic case (e.g. Fig. 1).

In this talk, after a brief introduction on resonant elastic metamaterials, we will discuss few modeling strategies that allow tackling the complexity of the elastodynamic problem. Then, with the help of parallel numerical simulations and ultrasonic experiments, we will explore the physics and the capacities of a recently developed metasurface made of a cluster of rods on an elastic substrate [1, 2]. The metasurface interacts and indeed controls the propagation of flexural waves in plates and Rayleigh waves in halfspaces. Through an appropriate engineering of the resonator's length, we will show how to design a "resonant metalens" for wave focusing and re-routing and a "resonant metawedge" that features not only rainbow trapping capacities but also Rayleigh to shear waves conversion.

To conclude, we will discuss the potential engineering areas, such as geophysics (large-scale), mechanical engineering (micro-scale) and acoustic imaging (nano-scale), where elastic metasurfaces can find application.

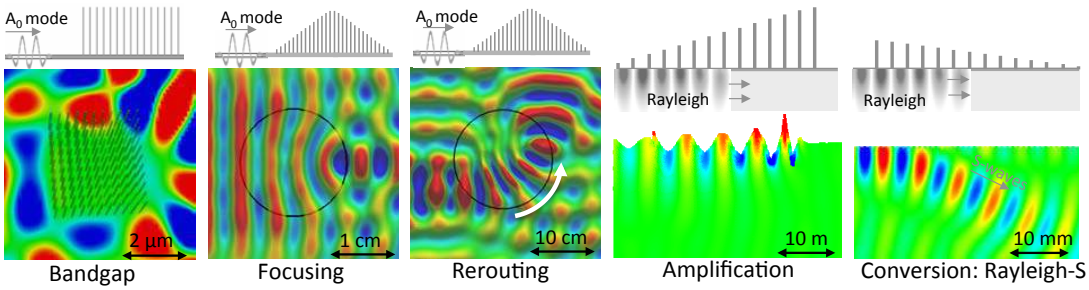

Figure 1: Example of control achieved through one of the discussed resonant metamaterial for different type of waves (Flexural or Rayleigh) and lengthscale.

Asymptotic analogies for closely packed photonic and phononic crystals

A. L. Vanel, O. Schnitzer, and R. V. Craster

Department of Mathematics, Imperial College London SW7 2AZ, UK
alice.vanel13@ic.ac.uk

Abstract— Mechanical waves through periodic mass-spring lattices, as developed by Brillouin and others as models in solid state physics, have long acted to motivate, and gain qualitative intuition, about waves through continua containing periodic arrays of inclusions such as photonic and phononic crystals. Our aim here, in the limit of closely arranged inclusions, is to make the qualitative analogy precise, and quantitative, particularly in terms of the band diagrams commonly used for dispersion analysis. Techniques based upon matched asymptotic expansions use the non-dimensional narrow gap between the inclusions, h, as a natural small parameter and allow us to replace a photonic crystal by an effective mass-spring lattice for the whole acoustic band, extract scalings for the frequency variation with gap width, and extend these ideas to higher branches; ultimately a versatile semi-analytic methodology is developed for general inclusion shapes and we illustrate this by comparison with numerical simulations.

One vital task in the design and optimisation of any photonic crystal is the accurate and rapid identification of the dispersion bands, or band surfaces, so that features such as stop-bands, Dirac-like points and local behaviour at stop band edges, can be tuned to enhance specific effects; often this can involve altering material properties, geometric shape or lattice parameters. There are well developed numerical methods for finding band diagrams such as multipole methods for cylindrical and spherical inclusions, plane wave expansion methods and finite element (FE) schemes; in practice many practitioners simply use general purpose commercial FE packages such as COMSOL. Although numerical schemes are highly useful, they provide little physical insight, and can be computationally expensive particularly when resolving the limit of closely spaced inclusions that we treat here. Here we develop an asymptotic theory based entirely upon exploiting the thinness of the gap between inclusions, to be precise we will assume that the inclusions are smooth (with their geometry locally quadratic near the thin gap) and that they have Neumann boundary conditions upon them. We show an illustration of a typical geometry, closely packed cylinders placed on a square array, in Fig. 1. Our aim here is to arrive at an asymptotic description of the closely-packed system and to be able to replace the physical system of Fig. 1(b) with an idealised mass-spring system as in 1(d). Natural questions that arise are how the frequencies at the band-gap edges, or the dispersion curves themselves, scale with the gap width, whether there are analytic formulae for the dispersion curves and, if so, what is the physics behind this. By developing an asymptotic understanding of this thin-gap material we are led to very rapid semi-analytic methods for generating band diagrams that are almost immediate and do not require sophisticated numerical methods and so we anticipate this being a useful alternative to numerical modelling.

The first part of the talk will be an intuitive description of the physics, we do so in terms of the acoustics of a phononic crystal of rigid cylinders in an ideal gas, inspired by Rayleigh 1896. We then proceed formally, using the language of matched asymptotic expansions, to obtain a completely analytical formula for the acoutic branch. We move to analysing the higher branches using coupled modes theory. Finaly, we show that this analysis is not limited to cylindrical inclusions, nor is it limited to a square lattice and the approach is very versatile.

[*]corresponding author: yykim@snu.ac.kr

Abstract-This work presents a newly-discovered elastic wave mode conversion mechanism called the transmodal Fabry-Pérot resonance (TFPR) which occurs through a special anisotropic medium. When the TFPR occurs at the TFPR frequencies, an incident longitudinal wave becomes maximally transmitted to a transverse wave. The theory of the TFPR phenomenon is presented and the anisotropic medium is realized by elastic metamaterials. Numerical and experimental results show the unique transmodal resonance that maximally transmits an incident wave mode to another without transmitting the incident mode.

When a layer of material of certain size is placed between waveguides, 100% wave transmission through the layer can be possible at certain frequencies. This phenomenon is the well-known Fabry-Pérot resonance [1-2]. This resonance phenomenon has been applied to various wave fields such as wave interferometers and spectroscopes. At the resonance, an incident longitudinal (or transverse) wave is transmitted to a longitudinal (or transverse) wave; the mode at the inlet and the mode at the outlet are identical without mode conversion. When the inserted material is not isotropic, however, an incident longitudinal or transverse wave is transmitted to both longitudinal and transverse waves. On the other hand, we aim to investigate if an incident longitudinal (or transverse) wave can be transmitted only to a transverse (or longitudinal) wave. This transmodal transmission can be extremely useful for generating transverse waves efficiently by using common transducers generating a longitudinal wave.

In this presentation, we report a new type of resonance phenomenon, which is referred to as the transmodal Fabry-Pérot resonance (TFPR) at which an incident longitudinal (or transverse) wave is converted only to a transverse (or longitudinal) wave with highly-efficient transmission through a special anisotropic medium. To reveal this new phenomenon, we establish a simple theoretical model to describe the wave physics in the anisotropic medium and show that inside the medium, longitudinal and shear waves are coupled in a special manner. For the wave analysis, the transfer matrix approach was used [3]. To realize the desired anisotropic medium exhibiting TFPR's, a single-phase elastic metamaterial is designed. Finally, the transmodal conversion mechanism was experimentally confirmed in a plate waveguide, and wave excitation and measurement were done with magnetostrictive patch transducers [3,4].

Elastic metasurface for high transmission anomalous beam refraction

Hyuk Lee[1], Jun Kyu Lee[1], and Yoon Young Kim[1*]
[1]School of Mechanical and Aerospace Engineering, Seoul National University, Korea
[*]corresponding author: yykim@snu.ac.kr

Abstract-In this work, we realize an elastic metasurface capable of anomalously manipulating the refracted ultrasonic beam with almost full transmission. After the underlying mechanism involving the longitudinal elastic wave motion by the developed mass-spring model is presented, the design of the unique unit cell structure is proposed. For simulation and test, the metasurface is embedded in a thin plate and the anomalous refracting and focusing of the lowest-symmetric Lamb mode within its subwavelength thickness (<0.5λ) are demonstrated.

In order to maximize practicality of the metamaterial devices, bulky metamaterials may need to be miniaturized to compact and thin devices. In this respect, numerous studies on the concept of the metasurface based on the generalized Snell's law [1] have been developed. Compared with vast works performed on optics and acoustics, however, the elastic counterpart has been very rare due to lack of a concrete methodology to control both the transmission and phase especially regarding only a single elastic mode. Our aim is to overcome this limitation by developing an elastic metasurface for high-transmission anomalous beam refraction. As in the electromagnetic and acoustic field, the elastic metasurface can be a powerful tool in solid mechanics as it may be used for non-destructive evaluation and biomedical screening.

We design our elastic metasurface by using a single-phase medium (here, aluminum) to facilitate its fabrication [2, 3]. Relying on our explicit analysis with mass-spring model, we can accurately estimate the transmission coefficient and phase shift through the metasurface structure. By delicately designing the layout and dimension of the unit cell of the elastic metasurface, it was possible to find the proper unit cell configuration realizing both high transmission and the full phase span over 2π. Numerical simulations and experimental results are presented to show how well the propoposed metasurface works.

Nonlinear magneto-granular phononic metawaveguides

F. Allein, V. Tournat, V. Gusev, and G. Theocharis

LAUM, UMR CNRS 6613, Université du Maine, Le Mans, France
florian.allein@univ-lemans.fr

Abstract— We report on the design and operation of magneto-granular phononic structures in two different configurations, line and Γ shaped waveguides. These metawaveguides are composed of steel spherical beads in a properly designed magnetic field, the strength of which induces tunability in their dynamic response. Experimental results reveal the existence of coupled transversal-rotational modes and conversion from longitudinal to transversal-rotational modes. These observations are well supported by a proposed model taking into account all degrees of freedom in translations and rotations. In addition, nonlinearity originated from contact deformations gives rise to nonlinear processes such as amplitude dependent transmission, filtering and conversion to second harmonic frequency. The combination of the non-contact tunability with the potentially strong nonlinear behavior of the granular systems, makes magneto-granular crystals suitable nonlinear tunable mechanical metamaterials for the control of elastic wave propagation.

Granular crystals are periodic arrangements of elastic particles in contact in which the rotational degree of freedom can play an important role on the wave propagation [1]. Here, we present the theoretical and experimental study of 1D magneto-granular metawaveguides composed of steel spherical beads inside a properly designed magnetic field. The latter is induced by an array of permanent magnets. A schematic of the proposed magneto-granular chain is shown on Fig. 1(a). This configuration allows us to tune the dynamic response of the chain by modifying the magnetic strength of the magnets. Tunability of such system have been demonstrated in Ref [2]. As long as the frequency is much below the individual resonances of the beads, the phononic band structure of the granular crystals can be obtained by discrete lattice models, in which the contact deformations are modeled by springs. Due to the finite size of the particles and the friction between them, one should consider not only the normal contact stiffness but also the tangential and torsional ones. Thus, rotational degrees of freedom should be included in the analysis [3].

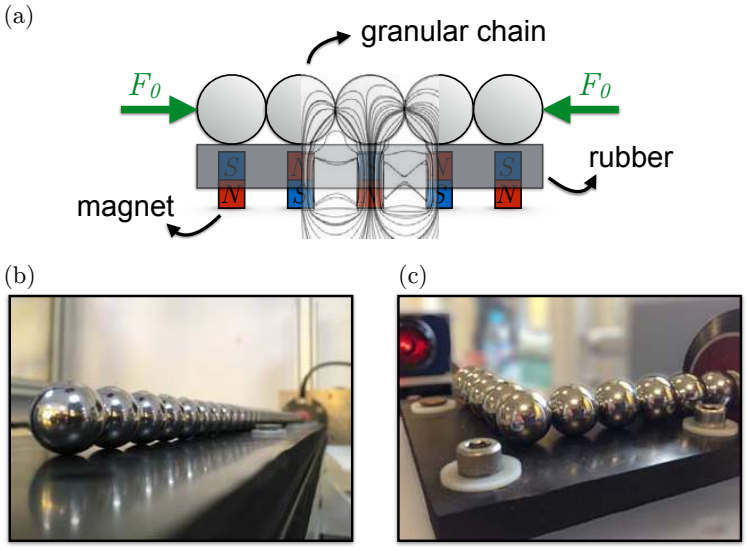

Figure 1: (a) Schematic diagram of the granular waveguide on top of permanent magnets within a rubber. Forces and magnetic flux lines induced by the magnetic field have been superimposed. Photography of (b) the line and (c) Γ-shaped waveguides.

Moreover, a key feature of granular media is the strong nonlinearities at the contact that enable a plethora of nonlinear processes. Granular phononic crystals have recently played a important role in the study of fundamental nonlinear wave phenomena, including harmonic generation [4] and discrete breathers [5]. They have been also applied in various engineering devices, including acoustic lenses [6], and acoustic rectifiers [7, 8].

Here, we intend to design an acoustic device to control the elastic wave propagation taking advantage of the strong contact nonlinearities and geometry. The line-shaped metawaveguide supports the generation of second harmonic for longitudinal motion. The experimental beating in amplitude of this second harmonic is demonstrated in such system. Adding a second chain perpendicular to the first one linked at its extremities gives us a Γ-shaped metawaveguide, see Fig. 1(c). The experimental setup using external magnetic field to create precompression into the chain allows to easily build a two dimensional configuration avoiding mechanical boundary to constrain the system. This system allows mode conversion from longitudinal to transverse-rotational modes. Taking advantage of the nonlinearity, this system supports also amplitude dependent transmission and filtering of harmonics.

To conclude, we have presented the realization and dynamics analysis of magneto-granular metawaveguides composed of spherical steel spheres in contact in the presence of a properly designed magnetic field. The latter can be used to tune the dynamics of the structure. Evidence of conversion from longitudinal to tranverse-rotational modes have been presented in a Γ-shaped waveguides. In addition, nonlinear processes are experimentally shown such as the beating in amplitude of the second harmonic and filtering of harmonics. The combination of the non-contact tunability and the potential strong nonlinear behavior opens the way for the construction of novel nonlinear tunable mechanical metamaterials for the control of elastic wave propagation.

Measurement and Analysis of Lamb Wave Propagating on Plates with Periodic Structures

I-Ling Chang[1*], **Guan-Hua Huang**[1] **and Yun-Chun Lee**[1]
[1] Department of Mechanical Engineering, National Cheng Kung University, Taiwan
[*]corresponding author: ilchang@mail.ncku.edu.tw

Abstract-Both experiment and numerical simulation were carried out to investigate the Lamb wave propagation behavior on phononic crystal plates. The considered periodic structures on the plate are holes and pillars. The dispersion relations of symmetric and antisymmetric Lamb waves extracted from experimental measurement agreed quite well with the numerical results. It was found that the band gaps of the phononic crystal plates with pillars was easier to observe experimentally and narrow banded, which were caused by the local resonance.

In this study, we discussed the behaviors of Lamb wave propagating on the plate with periodic structures, which are so-called phononic crystal plates. Two kinds of periodic structures were considered on the plate, which are "hole-type" and "pillar-type", respectively. We employed finite element method and plane wave expansion approach to investigate the special wave propagating phenomena of the phononic crystal plates, such as band gaps and changes of wave velocity. The effects of the periodic structures, such as the lattice constant, filling ratio, periodic pattern and plate thickness, on the wave propagating behaviors were studied and the band gap mechanisms were also examined. Different Lamb waves, i.e., symmetric and antisymmetric, could be identified from the vibrating mode characteristic.

Then, we utilized PVDF line-focus transducer to experimentally measure the Lamb wave propagating on the phononic crystal plates. The line-focus transducer serves as signal generator and receiver. And the whole experiment was carried out under water. The transducer was first focus on the 50μm thick stainless steel plate with impulse signal and proceeded to a series of de-focusing measurements. After signal processing and data analysis, the dispersion curve could be extracted from a series of receiving signals and the band gap could be identified. Various plate samples with different periodic structures were prepared and measured. The dispersion relations from both experiments and numerical simulations were compared and found good agreement. However due to the design of the transducer, the in-plane shear wave could not be excited. It was found that the band gaps of the phononic crystal plates with pillars was easier to observe experimentally and narrow banded, which were caused by the local resonance.

Omnidirectional Source Illusions of Guided Elastic Waves in Plates using Metasurfaces

Yongquan Liu[1], Zixian Liang[2], Fu Liu[1], Owen Diba[1], Alistair Lamb[1], and Jensen Li[1*]

[1] School of Physics and Astronomy, University of Birmingham, Birmingham B15 2TT, United Kingdom

[*]corresponding author: j.li@bham.ac.uk

Abstract-We demonstrate source illusion devices to manipulate guided elastic waves using metasurfaces. A source shifter, a transformer and a splitter are proposed, then measured to be broadband and robust against change of source positions. The approach is potentially useful for non-destructive testing, ultrasonography and advanced signal modulation.

The transformation method[1], together with metamaterials, is a powerful tool to achieve invisible cloaking and other illusion effects for electromagnetic waves, acoustic waves, heat flows, and matter waves. However, this approach is non-universal to manipulate elastic waves, as the governing equation in elastodynamics cannot keep its form under a general coordinate transformation, unless further approximations are applied or Willis media are employed. In consequence, the design of generic illusion devices for elastic waves is a challenging task. On the other hand, metasurface[2] has been demonstrated as an effective way to manipulate wavefront in optics and acoustics due to the simplicity in fabrication with low-loss, compact structures, but without losing the extreme functionality of bulk metamaterials. Zhu and Semperlotti[3] presented the first elastic metasurface to achieve anomalous refraction of guided waves in solids recently. Inspired by demonstrations of metasurfaces in achieving reduced versions of electromagnetic cloaks[4], here we develop a theoretical framework and experimental realizations of source illusion devices for flexural waves in plates using elastic metasurfaces. Our approach requires neither the form-invariance of elastodynamics nor bulk metamaterials with negative indices, yet allows us to demonstrate a series of all-angle elastic illusion effects.

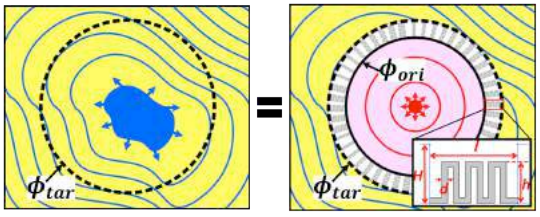

Fig. 1. Schematic of making illusions using metasurfaces. The unit cell is zoomed in the right part.

Fig. 1 shows the schematic diagram of the design strategy. Suppose that we have an original source, with wave field characterized by its phase $\phi_{\text{ori}}(x,y)$, a ring-type metasurface with the phase discontinuity of ϕ_{tar}-ϕ_{ori}, being evaluated at the location of metasurface, will turn this original incident field into an arbitrary target profile $\phi_{\text{tar}}(x,y)$. By doing this, an observer outside the metasurface (the black dashed circle) finds the same target field pattern in the physical space. Next, the phase discontinuity can be achieved by a ring-type metasurface. Each unit cell consists of a curved thin bar with identical width d and height of turns h. Then the wave is restricted to propagate along a zigzag path shaped by the unit cell. Due to the increase of total path length, we can increase the phase discontinuity of transmitted waves.

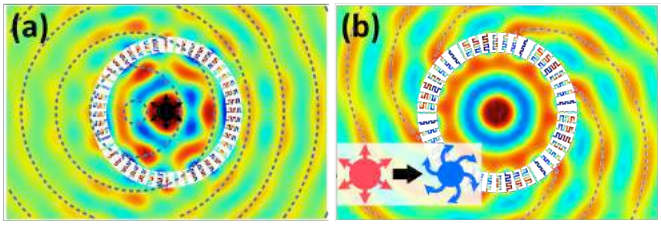

Figure 2 (a) Normalized amplitude of the A0 wave field for the source shifter at 12 kHz. (b) Simulated results for the source transformer at 8 kHz.

A source shifter is firstly proposed to shift the position of a wave source at origin (0,0) horizontally by a distance ΔS to the left. Fig. 2(a) shows the simulated out-of-plane velocity field at 12 kHz. The circular wave fronts are expected from the point source in the metasurface. Out of the metasurface, circular wave fronts are also obtained, centred at about ΔS on the left of the origin. Our elastic metasurfaces can also be used to transform a point source to a prescribed target wavefront. For example, we can impart an additional angular momentum[2] to the point source. The observer outside perceives it is a point source with spiral wave front. As shown in Fig. 2(b), the cylindrical wave shapes into a spiral with evenly-distributed six branches outside metasurface.

In order to validate the present method, we performed experimental investigations for the illusion devices. They all coincide with numerical simulations and theoretical analysis. The proposed approach paves the way to a much wider range of applications of metasurface. For example, the source splitter can be used as compact devices with phased array sources for non-destructive testing, the source transformer with angular momentum provides an additional degree of freedom for signal modulation.

Abstract. Many biological systems show extremely efficient structural as well as dynamic properties achieved through their structure, which is often hierarchical. In this study, a hierarchical architecture is introduced in ordinary phononic crystals (PCs) and acoustic metamaterials (AMMs) to investigate modifications of the dispersion diagrams due to increasing structural complexity at different scale levels.

Introduction. Hierarchical structures with constituents over multiple length scales are found in various natural materials like bones, shells, spider silk and others, all of which display enhanced quasi-static mechanical properties, such as high specific strength, stiffness and toughness, attributed to hierarchy[1-3]. At the same time, the role of hierarchy on the dynamic behavior of phononic crystals (PCs) and acoustic metamaterials (AMMs) remains largely unexplored. This study assesses the effect of bio-inspired hierarchical organization as well as of the material viscoelasticity on the wave attenuation properties of continuous mechanical metamaterials[4].

Although optimized ordinary PC and AMM configurations have been proposed so far[5,6], light-weight, practically oriented metastructures with multi-scale wave attenuation abilities remain an open field of research. Indeed, ordinary elementary unit cells comprising single inclusions or cavities, often results into limited frequency band gaps (BGs).

Unit cell organization. One way to potentially overcome this limitation is to exploit fractal-like and bio-inspired structural hierarchy. Structural hierarchy is here understood in the sense that a representative unit cell comprises multiple arrangements of inhomogeneities at various size scales. If the same arrangement occurs at every scale, the pattern is called self-similar. We consider single-phase structures formed by self-similar unit cells with different hierarchical levels and types of hierarchy, as presented in Fig. 1.

Results. The influence of bio-inspired hierarchical organization and material viscoelasticity on wave dispersion in metamaterials with self-similar constituents at various spatial scales (see Figs. 1a and 1b) is numerically and experimentally investigated. Contrary to previous approaches[7,8], our study focuses on porous hierarchical structures, whereby increasing hierarchy entails a weight reduction. Results highlight a number of advantages, such as: (i) conservation of most of the BGs induced by the constitutive regular geometries, in the presence of material damping (we show that even small viscoelastic effects, not treated in the current literature,

are essential in determining this behaviour); (ii) nucleation of additional "hierarchically-induced" BGs and the tuning of the band gap frequencies of regular metamaterial to lower frequencies according to the spatial scale of the hierarchy, with a simultaneous significant reduction of the global structural weight; (iii) similar wave dynamics at low frequencies for hierarchical and corresponding regular structures.

The physical mechanism for the occurrence of the hierarchically induced BGs is discussed and the generality of the observed behavior, which is not limited to a specific configuration, is experimentally proved. A simple equivalent mass-spring model has been developed to predict the observed BG shift to lower frequencies.

In conclusion, this work provides insights on the crucial role of hierarchical structure on the dynamic behavior of metamaterials and reveals that the principles of bio-inspired hierarchical organization can lead to light-weight metamaterials with advanced multi-frequency attenuation properties, providing useful design principles for further practical applications.

Abstract-We propose and realize a new elastic metamaterial having extreme broad low frequency stop band. The stop band achieved with the proposed elastic metamaterial is from 235 to 4520 Hz. To achieve the extreme broad low frequency stop band, we developed a new idea of near-zero rotational stiffness, which is a different mechanism compared with phononic crystals or resonance based metamaterials. We expect that the proposed elastic metamaterial can open a new way in various vibration devices.

Achieving extreme broad stop band at low frequency range, around ~100 Hz, has been a big challenge in the field in elastic metamaterial. If the extreme broad low frequency stop band can be achieved, one can break-through the well-known mass law and realize new vibration shielding devices. Previously, two major physics have been mainly considered to achieve a stop band metamaterial; one is the phononic crystal utilizing Bragg scattering from the crystal's periodicity[1,2], and the other one is the resonance based metamaterial utilizing internal resonance phenomena[3]. However, these two methods have shown a critical limit that they are hard to be applied in achieving the extreme broad stop band at low frequency. The stop band achieved with phononic crystals were generally formed at too high frequency ranges. On the other hand, the stop band achieved with resonance based metamaterials were formed at low frequencies, but they suffered from narrow band width.

In this work, we propose and realize a new elastic metamaterial having the extreme broad stop band at low frequency range. Fig. 1 (a) shows the wave dispersion curve of the proposed elastic metamaterial. In Fig. 1 (a), the stop band is formed from 235 to 4520 Hz, which is not only broad but also very low that covers almost all vibration frequencies. As explained above, such a broad low frequency stop band cannot be achieved by the well-known phononic crystals or the resonance based metamaterials. Here, we developed a new method, called 'near-zero rotational stiffness' method, to achieve extreme broad stop band at low frequency range. As well known, flexural elastic wave is governed by two kinds of stiffness – vertical and rotational stiffness[4]. We found that by lowering the rotational stiffness and increasing the vertical stiffness, one can achieve extreme broad low frequency stop band. Detailed physics and the actual metamaterial design to achieve this will be presented.

Fig. 1 (b) shows the numerically and experimentally measured vibration transmission of the proposed elastic metamaterial structure. As can be seen in Fig. 1 (b), extremely effective vibration shielding from 235 to 4520 Hz can be achieved with the proposed metamaterial. These investigations clearly supports that the proposed elastic metamaterial indeed has the extreme broad low frequency stop band.

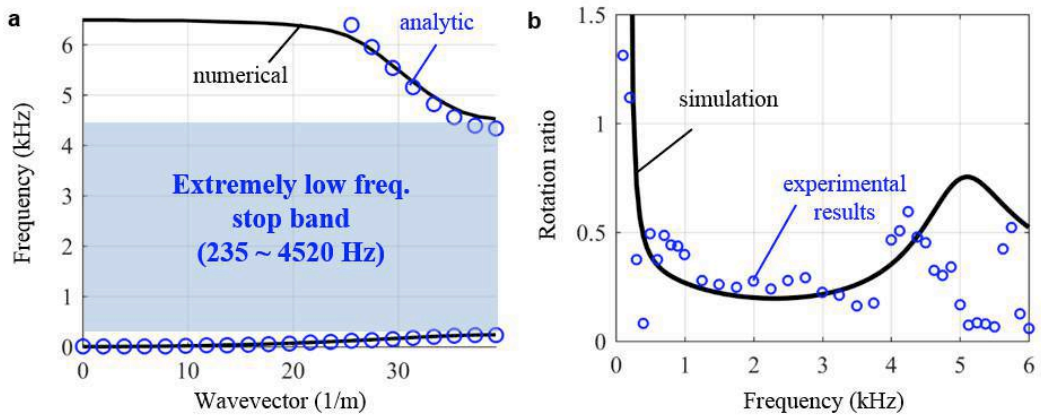

Figure 1 (a) Wave dispersion curve of the proposed elastic metamaterial, (b) numerically and experimentally measured vibration transmission of the proposed elastic metamaterial

This work suggested that by using a new idea of 'near-zero rotational stiffness metamaterial', one can achieve extreme broad stop band at very low frequency ranges. This approach, and the proposed elastic metamaterial structure, can open a new way in vibration devices.

Abstract

Phononic crystals (PnC) were known for acoustic band gaps and applied as filters and reflective gratings for acoustic waves. In this paper, another important property of PnCs, the anisotropic propagation, was studied. A PnC made of circular tungsten films on a lithium niobate substrate was analyzed. Dispersion curves and equal frequency contours of surface acoustic wave were calculated to show the anisotropy. Then negative refraction of group velocity can be observed and used to suppress diffraction of surface waves.

1. Introduction

Phononic crystal (PnC) is an artificial composite for acoustic waves. PnC consists of periodically-arranged elastic materials or geometric structures in a background media. While acoustic waves propagate in PnCs, there are some special phenomena. One is the band gap which can block waves in a frequency range [1-5], and the other one is anisotropic propagation which allows the phase and group velocities aiming at different directions [6-10]. These properties allowed several applications of PnCs. Based on band gaps, PnC were used as the gratings in surface acoustic wave (SAW) device used in SAW resonators, filters and sensors [11-16]. Further, a hybrid design of inter-digital transducers (IDT) and PnCs was proposed to reduce the acoustic loss in SAW devices [17, 18]. On the other hand, PnCs with anisotropic propagation were used as a lens to bend the propagating waves and to focus waves at a certain area [19-21]. Negative refraction of waves in PnC were also reported [22, 23].

In this paper, we analyzed Rayleigh waves in a square lattice PnCs made of circular tungsten films on a piezoelectric substrate. The band structures and equal frequency contours (EFCs) were analyzed. By applying the anisotropic propagation, negative refraction of group velocity were observed at some frequency. Then using the PnC as an acoustic lens to suppress diffraction were demonstrated.

2. Surface acoustic waves in tungsten/lithium niobate PnC

In this paper, the 128˚Y-cut lithium niobate was chosen as the matrix material and a square lattice PnC was formed by circular tungsten films covering on the substrate. We used the finite element method (FEM) to calculate the band structures and EFCs of the PnC [11]. The lattice constant a of unit cell was set as 4 μm, thickness of metal film h is 400 nm and radius r is $0.4a$. The thickness h was chosen by considering the feasibility of fabrication, and a large radius allows more obvious dispersive bands. In order to enhance the anisotropic propagation, we set the x axis of material coordinate toward the ΓM direction of the square lattice coordinate, as the inset shown in Fig. 1.

The dispersion curves of Rayleigh waves, Loves, and high order SAW in the first Brillouin zone were shown in Fig. 1. The irreducible are in the Brillouin zone is the area Γ-M_1-Y-M_2-Γshown in the inset. There are partial band gaps in the ΓY direction while SAW can propagate in ΓM direction. The frequency range from 370 MHz to 460 MHz is the partial band gap of Rayleigh waves, and the range from 385 MHz to 430 MHz is the partial band gap of Love waves. Using the partial band gap, the direction around ΓY is the non-propagation direction to block energy.

The eigenmodes of all wave vectors within the first Brillouin zone formed a dispersive surface SAWs. Then EFCs were determined by cutting three-dimensional band structures at a chosen frequency. EFCs are equivalent to slowness curves. These curves show the relation of propagation property of waves in different directions. Fig 2 showed the EFCs of 445-MHz SAW in 128˚Y-cut $LiNbO_3$ and the W/$LiNbO_3$ PnC. In Fig. 2(a), the EFC is non-circular for SAW in $LiNbO_3$ which present the anisotropy of the piezoelectric materials. By adding the square-lattice tungsten films on $LiNbO_3$ substrate, the anisotropic wave propagation can be enhanced. As shown in Fig. 2(b), partial band gaps for SAWs appeared at the same frequency (445 MHz). We also analyzed another PnC in which the square-lattice pattern rotated 45˚ and the EFC shows more circular contours. Thus the alignment of the PnC can be used to enhance or reduce the anisotropic propagation of SAW in piezoelectric materials.

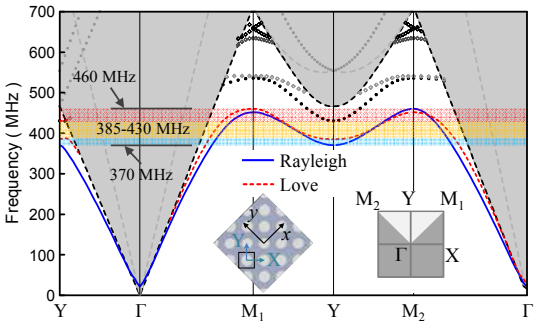

Figure 1: Band structures of W/LiNbO$_3$ PnC (a=4 μm, h = 400 nm, r = 0.4a).

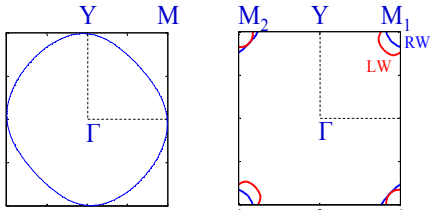

Figure 2: EFCs of 445 MHz SAWs in (a) 128˚Y-cut LiNbO$_3$ and (b) W/LiNbO$_3$ PnC.

The directions of wave propagation were observed from the EFC figures. The direction form the origin to one point on the EFC means the direction of phase velocity, the direction normal to the EFC at the point presented the group velocity (energy velocity). Considering the SAW passing the interface of LiNbO$_3$ area and PnC in Fig. 3, we determined the angle of refraction by the Snell's law. The typical value were list in Table 1. The curve of SAWs in the PnC is concave near the M$_1$ and M$_2$ points in the first Brillouin zone. The directions of group velocity Rayleigh waves were refracted to negative angles near the M$_1$ and M$_2$ points. At the 445 MHz, the refraction angle of group velocity is the minimum -24˚ near M$_1$ point. The result showed that Rayleigh wave at ΓM$_1$ direction has stronger self-collimation effect when passing the LiNbO$_3$-PnC interface. Thus ΓM$_1$ direction, which is parallel to the x axis, was specified in the development of using PnC to suppress diffraction of surface waves.

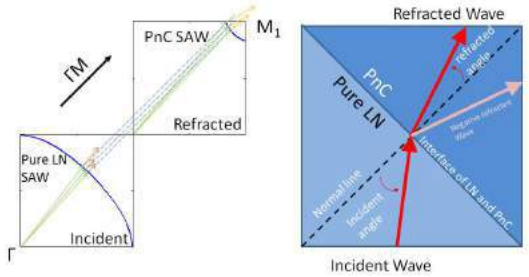

Figure 3: Directions of incident waves and refracted waves at the interface of LiNbO$_3$ and PnC regions.

Table 1: Typical incident and refraction angles of 445 MHz Rayleigh waves. The normal direction of the interface aligns with the ΓM$_1$ direction.

Incident angle in LiNbO$_3$		Angle of refraction in PnC	
θ_{phase}	θ_{group}	θ_{phase}	θ_{group}
7.75˚	4.15˚	5.30˚	-24.0˚
5.00˚	3.00˚	3.50˚	-16.5˚
3.00˚	1.90˚	2.05˚	-8.5˚

3. Lowering diffraction by phononic lens

3.1. Wave trajectory

The negative refraction of energy velocities in the interface supports the development of a PnC lens. Ray trajectories of energy were obtained by calculating the direction of the energy velocity from different incident angles as listed in Table 1. A PnC lens is a simple rectangular PnC. The energy velocity performed negative refraction while entered and leaved a PnC lens, and thus the thickness (the number of layers) of the PnC lens determined the focal area of energy. Fig. 4 showed the directions of wave energy form a point source. Along the ΓM$_1$ direction, rays were converged inside PnC structure due to the negative refraction of energy velocity. When thickness of lens is large enough, rays focused within PnCs, and a secondary focal region outside the lens appears. For different layers of PnCs, the focal length of the secondary focal points changed with the lens thickness, the distance of two boundaries of the lens. In the Fig. 4, there is no focal point behind lens at an 8-layer PnC lens. The focal length is around 11λ if the thickness of lens is 15 layers; the focal length is around 22λ for the 21-layer PnC lens. The focal points are the intersection of ray trajectory of energy velocity and the concentrated energy around those points performed larger displacement.

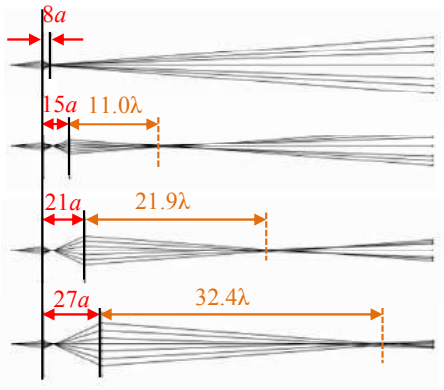

Figure 4: Trajectory of SAW passing PnC lens in different layers.

3.2. SAW passing a phononic lens

To design a lens, the transmission of waves passing the PnC lens was considered. The PnC lens contained lots of tungsten films which may scatter waves, and thus the attenuation of wave inside the PnC lens were calculated. The PnC lens with different thickness was set in FEM model and the amplitude of wave passing the lens was recorded to be compared with the incident waves. The transmission was shown as the dashed line (the standard PnC) in Fig. 5. The transmission did not show a simple trend. This should resulted from the multi-reflection of SAW inside the PnC. According to the theory of matching layer for the equivalent pure material, the transmission can reach to highest value while thickness of lens is an integral number of half wavelength.

The transmission of wave passing a standard PnC lens showed a noticeable energy loss. Thus tapered PnC region was proposed to the design of PnC lens. Tapered structure attached at the boundaries of PnC lens reduced the mismatch of acoustic impedance and discontinuity. A two-layer tapered PnC was defined by adding two-row tungsten film with smaller radii (0.27*a* and 0.35*a*). The radii of the three-layer tapered PnC are 0.23*a*, 0.32*a* and 0.37*a*, respectively. Fig. 5 showed that the tapered structure raised the transmission effectively. The transmission raised from 80% to 95%. Thus the PnC lens was designed with the three-layer tapered structures in the following studies.

The numerical simulation of SAW passing through a PnC lens in a three-dimensional model was present in this section. The PnC lens was designed for the 445 MHz Rayleigh wave. The first case considered the SAW generated by a point source in front of the PnC lens. The amplitude of out-of-plan displacement field was recorded to evaluate the PnC lens. Fig. 6(a) showed the amplitude filed of the SAW in the pure $LiNbO_3$ substrate without a PnC lens. Fig. 6(b) is the result which a 15-layer PnC lens was set. The amplitude fields along the central line were plotted in Fig. 6(c). By comparing these two cases, we observed that the energy was concentrated when SAW through the PnC lens. Thus PnC lens could help to suppress the diffraction of waves.

Further, the SAW launched by line sources were considered and shown in Fig. 7. The length of line source is 3λ, and the thickness of PnC lens is 21-layer. Fig. 7(a) is the displacement amplitude without passing the lens. In the simulation, the SAW from a line source propagated a longer distance before the amplitude field spread because the diffraction occurs mainly at the end points of the line. Therefore, the longer of the source line is, the lower percentage of the energy loss. Thus the effect of suppressing diffraction waves was not as obvious as in the case of point source. In Fig. 7(b), the PnC still converged the energy. Fig. 7(c) showed the amplitude along the central line. The PnC lens did help keep the energy in the central line. These cases with PnC lens really showed low diffraction, and the decrease of energy in the 21-layer PnC lens is lower. The result concluded that PnC could be used in the SAW device to lower the diffraction of surface waves.

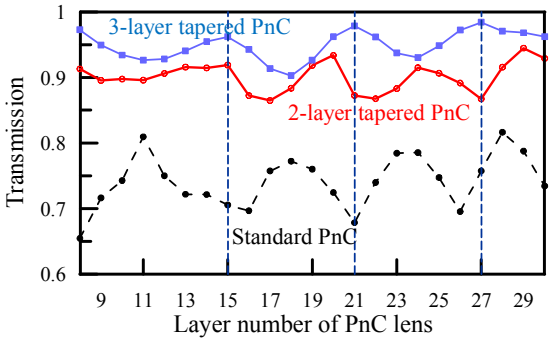

Figure 5: Transmission of SAW passing through three-type PnC lenses of different layers.

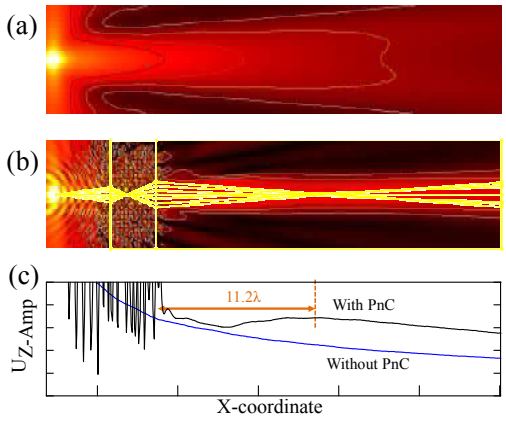

Figure 6: The SAW amplitude fields excited by a point source: (a) without a PnC lens; (b)with a 15 layers PnC lens. (c) Amplitude distribution of cases (a) and (b).

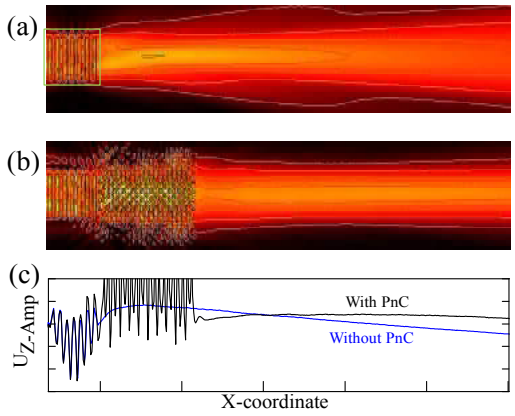

Figure 7: The SAW amplitude fields excited by a IDT: (a) without PnC lens; (b)with a 21 layers PnC lens. (c) Amplitude distribution of cases (a) and (b)

4. Conclusions

In this study, the tungsten/lithium niobate PnCs was analyzed to understand the anisotropic propagation of SAW. The band structure of the PnCs was analyzed the partial band gap and negative reflection of energy velocity were concluded. The PnC was used to be an acoustic lens to suppress diffraction of surface waves at 445MHz along the ΓM1 direction. Considering the energy attenuate inside PnC, three-layer tapered PnCs were proposed to be placed at the interface of PnC lens, and raise the transmission over 90% and the thickness of PnC lens was chosen for higher transmission. Ray trajectory from energy velocity was plotted to predict the distribution of focal points. According to this result, the diffraction of surface waves was suppressed effectively, and this PnC lens could be used to make the low-diffraction SAW device.

Metamaterials in Communication Systems

Dynamic parameter control of magnet-less non-reciprocal metamaterial (MNM) for adaptive electromagnetic material

Toshiro Kodera
Meisei University, Tokyo Japan
kodera2t@ieee.org

Abstract- Adaptive electromagnetic response control of metamaterial is quite attractive for realizing environment adaptive metamaterial. The magnetic loss of magneto-less non-reciprocal metamaterial (MNM) corresponds to Q-factor of resonant particle and it can be dynamically controlled by the bias condition of the unidirectional active component. In this talk, a precise Q-factor evaluation of MNM is presented and its results are compared to actual prototype device.

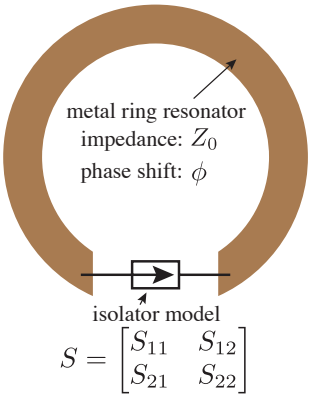

Fig. 1 Simplified MNM model

The magneto-less non-reciprocal matermaterial (MNM)[1] provides an artificial creation of gyrotrpic magnetic response in RF regime, which enables non-reciprocal device realization as same as ferrite material[2].

Figure 1 shows a simplified MNM model consists of metal ring resonator with characteristic impedance Zo with phase shift ϕ and isolator model. Assuming perfect-matched ideal isolator, Q-factor of this model can be derived as [3],

$$Q = \frac{(2n-1)\pi}{2} \left| \frac{2Y_0 R_x S_{21}}{2Y_0 R_x (1+S_{21})+1} \right| \quad (1)$$

, where n is the resonance order and Rx is the loading resistance which corresponds to energy dissipation by electromagnetic coupling with resonator surroundings. The infinite Q-factor leads to oscillation (instability) of MNM and, if S21 has a smaller value than unity, this situation arises only for Rx has infinity value (load-pull situation). The exact magnetic loss of MNM can be estimated by the relation between Q-factor and half-value of magnetic resonance (ΔH). This design guideline will provide the dynamic magnet-loss control of MNM leading to environment adaptive metamaterial.

Translation of Metamaterial Concepts to Low-Profile Broadband Microwave Antenna Technology (Invited)

Zhi Ning Chen[1*], **Wei Liu**[1], **and Xianming Qing**[2]
[1]Department of Electrical and Computer Engineering, National University of Singapore (NUS), Singapore
[2]Institute for Infocomm Research (I^2R), Agency of Science, Technology and Research, Singapore

Abstract-This paper updates the progress in the applications of metamaterials in the designs of low-profile and broadband microwave antennas. First, the development of metamaterials-based antenna technologies is introduced in the designs of artificial magnetic conductor (AMC) loaded substrate-integrated Fabry-Perot cavity antenna, AMC-loaded ultra-high frequency (UHF) radio frequency identification (RFID) reader antenna, high-permittivity meta-slab loaded high gain antenna arrays for 2.5G/3G/LTE cellular base-stations. Then, as an example, the design of a metamaterial-based broadband low-profile mushroom antenna is presented in detail.

As one type of artificially made electromagnetic structures, metamaterials feature the unique electromagnetic properties which have never been found in any nature materials. The important impact of the research into metamaterials is to control the electromagnetic waves and fields in an unusual way. In the past 18 years, the theoretical research into new physical concepts and phenomena has led to many new scientific findings [1–3]. However, translation the scientific findings to engineering technologies for practical applications is critical challenge. So far, more and more metamaterial-based designs have been applied to control the electromagnetic wave transmission and reflection, while we have hardly seen success stories in practical engineering applications of metamaterial-based antenna deigns because of the challenging requirements of antennas, in particular low ohmic loss, wide operating bandwidth, and simple structure for low fabrication cost and ease installation.

The team from NUS and I^2R has paid much effort to translate the physical concepts of metamaterials to antenna engineering technologies in the past ten years. So far, we have developed many solutions for enhancing antenna performance for RFID, WLAN/WiFi, cellular base-stations, radar systems, and so on. Here, we will update the progress in the applications of metamaterials in ultra-low-profile broadband antenna technologies.

A. AMC-loaded substrate-integrated Fabry-Perot cavity antenna and UHF RFID reader antenna

An AMC-based partially reflective sheet and a ground plane are used as the two reflectors of the Fabry-Perot resonant cavity for an ultra-thin design where the cavity is fully dielectric filled as shown in Figure 1(a). With a microstrip patch antenna as a feed, the antenna operating at 10 GHz achieved the high gain of 12.5 dBi with an aperture of $2\lambda \times 2\lambda$ and much reduced thickness of $\lambda/9$ (where λ is the operating wavelength in free space) [4].

Figure 1(b) shows an AMC-loaded UHF RFID reader antenna. The zero-phase-shift-line loop antenna operating at 915 MHz is able to be positioned close to the AMC to achieve directional magnetic field distribution. The ultra-low-profile antenna is with a thickness of less than $\lambda/8$ and enhanced magnetic field intensity.

B. High-permittivity meta-slab loaded high gain antenna

A double layer electromagnetic band gap (EBG) structure with high effective permittivity was loaded in a dipole antenna to achieve wideband high-gain low-profile antenna [5]. The high-permittivity meta-slab loaded

This work was supported by National University of Singapore under Research Grant R-263-000-B62-112.

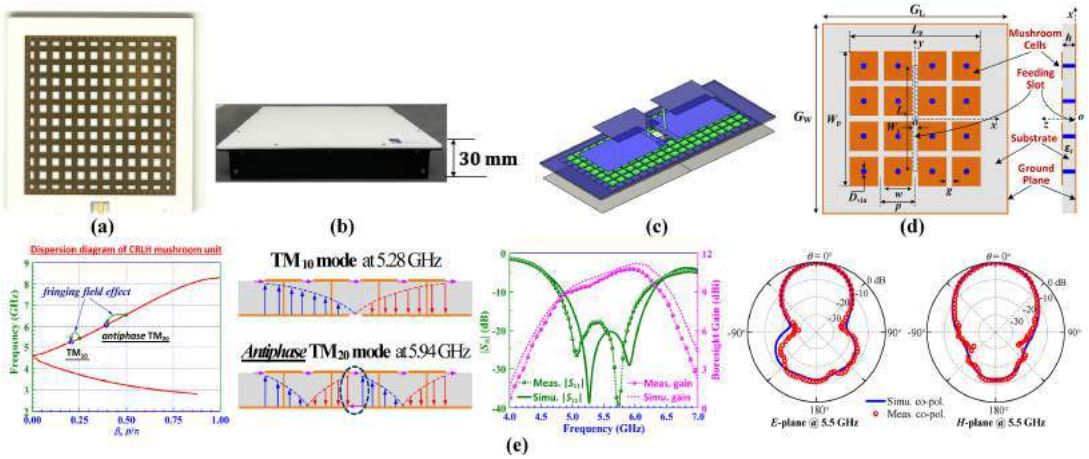

Figure 1. Metamaterial-based antennas

dipole antenna was further developed to realize a maximum gain of 14.2 dBi with aperture efficiency of 94%, and stable radiation patterns over a wide impedance bandwidth of 44.4% (1.67–2.69 GHz) as shown in Figure 1(c). Later, the technology was used to design the cellular base-station antenna with radiation efficiency of >90%, half-power beamwidth of >55±5°, port isolation of >25dB over the bandwidth of ~45% (1710–2690 MHz) at an overall thickness of 20 mm.

C. Metamaterial-based broadband low-profile mushroom antenna

Figure 1(d) shows the metamaterial-based broadband low-profile mushroom antenna fed by a microstrip line thru an aperture on a ground plane [6]. The antenna printed on Rogers RO4003C (ε_r = 3.38, $tan\delta$ = 0.0027) has a patch area of 0.72λ×0.72λ and a thickness of 0.06λ (λ is the free-space wavelength at the center frequency of 5.5 GHz). Figure 1(e) illustrates the dispersion diagram of the mushroom unit cell, sketched electric fields of the dual operating modes, $|S_{11}|$ and gain, radiation patterns of the antenna. Due to the unique composite right/left-handed (CRLH) dispersion of the metamaterial mushroom unit and the feeding scheme, both the adjacent TM_{10} and the antiphase TM_{20} modes are generated for consistent boresight radiation over a wide bandwidth. The achieved bandwidth for $|S_{11}|$<−10 dB is 4.85–6.28 GHz or 26%. The measured average realized boresight gain is 10.2 dBi with consistent radiation patterns over the bandwidth.

Abstract-Characteristics of surface plasmon modes, in particular the leaky modes, propagating on dielectric-substrate supported silver nanowires of circular and pentagonal cross-sections are numerically investigated using a finite-element method over the wavelength range covering the optical communication band. Leaky modes are with electric-field guided mainly at the top air-silver interface and with field leakage in the substrate, which are clearly revealed based on high-resolution numerical analysis. Higher order leaky modes are determined for both circular and pentagonal nanowires with their dispersions, cutoff wavelengths, and propagation losses compared.

This work concerns surface plasmon polariton (SPP) modes propagating along a chemically synthesized silver nanowire, in particular for that supported by a dielectric substrate, as depicted in Fig. 1(a). Such nanowires have been investigated for possible applications in optical sensing, optical coupling with nanophotonic components and circuits, interaction with single-photon emitters, etc., and in many related experiments the nanowires often appeared as falling on a dielectric substrate [1, 2]. From the viewpoint of solving electromagnetic modes, the appearance of the substrate results in a more complicated boundary-value problem. Recently, detailed guided-mode solutions based on a finite-element method have been reported for circular-cylinder nanowires with emphasis on single-guiding-mode operation [2, 3]. We have recently conducted mode analysis of similar circular-cylinder silver nanowires using an in-house developed full-vector finite-element imaginary-distance beam propagation method (FV-FE-IDBPM) [4] and disclosed, in addition to the "single-guiding mode" for which the mode fields are mainly guided near the nanowire-substrate interface, the existence of a leaky mode with major electric-field distributions on top of the air-nanowire interface [5]. This analysis method has recently been used to provide high-resolution modal characteristics and detailed modal profiles of leaky modes on a metal stripe plasmonic waveguide with a metal stripe fabricated on top of a substrate [4]. And the possible existence of the leaky mode on the structure of Fig. 1(a) can be understood from the characteristics of the stripe waveguide [5].

The chemically synthesized silver nanowire can possess pentagonal cross-sectional shape [6], as depicted in Fig. 1(b), with the circular cross-sectional shape being an approximation. This paper presents our recent studies of the modal dispersions and propagation losses for silver nanowires of both cross-sectional shapes with the considered wavelength range from 500 nm to 2000 nm, covering the optical communication wavelength band so that waveguiding applications in future photonic circuits can be evaluated [2]. New results include obtaining the higher order leaky modes in addition to the fundamental leaky mode reported in [4]. Possible application in mode-division multiplexing for increasing data transmission channels along a pentagonal nanowire through the existence of multiple leaky plasmon modes was proposed in [6]. Here we are interested in comparing modal characteristics between the circular and pentagonal nanowires. Fig. 1(c) shows the Re[E_y] profile of the first

leaky mode at the wavelength λ = 500 nm when the radius of the circular silver nanowire (*r*) is 400 nm. When the *r* = 400 nm circle is just tangentially surrounded by the five sides of a pentagon, the Re[E_y] profile of the first leaky mode at the wavelength λ = 532 nm of the corresponding pentagonal nanowire is shown in Fig. 1(d). In both Fig. 1(c) and (d), the modal electric field is mainly localized on the top of the nanowire in the air along with down-propagating leakage field in the substrate. For the *r* = 400 nm circular nanowire structure in the considered wavelength range, four leaky modes were found and their propagation length versus wavelength results are shown in Fig. 1(e), where "AML" means "air-metal-leaky" with the subscript specifying the order number. The results show the cutoff wavelength of the AML_1 mode is longer than 1550 nm with the propagation distance larger than 25 μm. The result corresponding to the Fig. 1(d) case is also shown in Fig. 1(e) from which longer cutoff wavelength and larger propagation length are seen. The enough long propagation lengths give the message that such leaky modes can play roles in practical applications.

Plasmonic Sensor for Biomedical Device

CMOS spoof-SPP optical filter for fluorescence detection

Xiaojian Fu, Yu Jiang and Hao Yu*
School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore 639798
*corresponding author: haoyu@ntu.edu.sg

Abstract-In this work, an optical filter is designed based on spoof surface plasmon polariton resonant cavity constructed by nanoscaled metallic line array. As for fluorescence detection, the numerical results show that the 400~450 nm excitation light is almost 100% absorbed and the 750~850 nm fluorescence is highly transparent. The transmission difference between 400 nm and 800 nm reaches 64dB. Thus, an on-chip high SNR fluorescence detector can be achieved by combining this filter and a high sensitive photon detector.

Fluorescence detection has attracted lots of research interests due to application in materials science and biomedical such as DNA fluorescence detection for early diagnosis of genetic decreases. However, complicated instrument such as fluorescence microscopy is usually employed for traditional fluorescence detection technology. In this work, a kind of novel on-chip plasmonic filter is developed for fluorescence detection. Specifically, a broadband filter is designed based on spoof surface plasmon polariton (spoof-SPP) resonant cavity constructed by nanoscaled metallic line array. As for fluorescence detection, the short-wavelength excitation light will be absorbed by the filter, while the long-wavelength fluorescence beam will have a high transparency. Take the quantum dot source as an example, we estimate the performance of the fluorescence detector using the numerical simulation method. Both the transmission parameter and near-field distribution results show that the 400~450 nm excitation light is almost 100% absorbed and the 750~850 nm fluorescence is highly transparent. The transmission difference between 400 nm and 800 nm reaches up to 64dB. Thus, a broad operating band and high SNR fluorescence detector can be achieved by combining the spoof-SPP based filter and a high sensitive photon detector.

Alternative plasmonic materials

Metal Alloys as Alternative Materials for Plasmonics

Marina S. Leite
Department of Materials Science and Engineering
Institute for Research in Electronics and Applied Physics
University of Maryland – College Park

Steel is an alloy primarily formed by iron, carbon and chromium that have transformed our society. Today, steel is widely in a variety of applications, ranging from building construction to surgical tools, all possible because alloying provides a low-cost material with improved mechanical properties. In the realm of plasmonics, there is still a pressing need to identify materials with superior optical response. Here, we present how the alloying of metals (Ag, Au, Cu, Al) provides materials with permittivity values not found in its pure counterparts. We overcome the constraint imposed by the pre-defined permittivity of noble metals by alloying, where we have recently developed a library of their optical properties [1]. Further, we implement a scalable method for the fabrication of alloyed nanostructures with *on demand* optical response [2]. We resolve the light-alloyed nanostructures interactions by near-field scanning optical microscopy and 3D full-field simulations. We demonstrate that perfect absorbers with superior performance can be obtained by using Al-Cu/semiconductor, where we find near-unity absorption in the visible and NIR range of the spectrum, not possible by using conventional metals [3]. We expect alloyed metals to become a novel platform for the design and fabrication of building blocks for nanophotonics, for applications ranging from metamaterials to displays and catalysis.

Abstract Arrays of gold discs are investigated as substrates for luminescence and Raman enhancement. These nanoantenna arrays exhibit relatively sharp grating resonances leading to increased field concentration and light-matter interaction in their vicinity. This is harnessed for enhanced luminescence of colloidal nanoparticles in the IR-telecom range and surface enhanced Raman scattering in the near IR.

Plasmonic resonances from nanoscopic metal spheres, discs or rods are used frequently to concentrate light in the near field due to their strong localized surface Plasmon resonances. However the large losses due to absorption and scattering of the (mostly) dipole resonances results in rather broad single particle resonances with low Q-factors. This limits the efficient interaction of the light field with matter and impedes the detection of clear peak shifts for e.g. sensing applications. However plasmonic nanoantenna arrays have attracted considerable attention recently, since in addition to the broad single particle plasmonic resonances they offer relatively sharp surface grating resonances [1]. Even lasing at these resonances was observed when semiconductor nanocrystals surrounded the nanoantennas [2].

Here we report on the use of gold nanodisc arrays for luminescence enhancement in the IR telecom range. Au-discs with diameters in the range 150-250nm are arranged in square and rectangular arrays with periods around 900nm. Transmission measurements using a collimated beam clearly show the sharp grating resonances at a wavelength of 1400nm, which appear at the long wavelength tail of the broad single particle resonances [Fig 1].

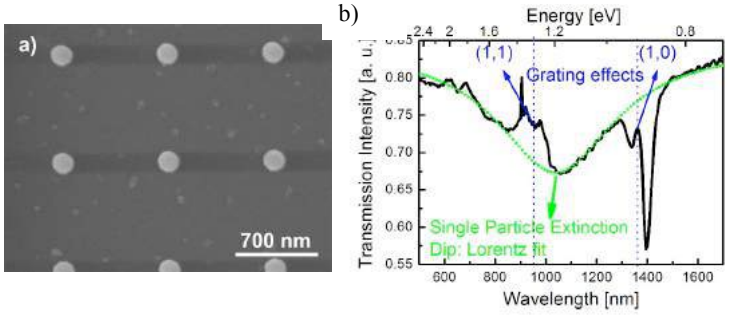

Fig.1: a) SEM-image of Au-Nanodisc array on glass. b) Transmission spectrum of disc array with disc diameter of 250 nm. The experimental curve is shown in black. A Lorentzian fit (green) reveals the underlying single particle surface plasmon resonance. At λ=1400nm the sharp (1 0) grating resonance appears.

Subsequently colloidal PbS-nanoparticles, which emit in the range between 1200-1500nm, were immersed in a PMMA-solution and spread at the nanoantenna array. Photoluminescence (PL) measurements revealed an up to four times enhancement of the emission at the grating resonance [3]. The spectral coincidence of transmission dip and PL-peak, which could be traced for differently sized discs, is a clear indication of their common origin [Fig. 2]. Furthermore the formation of the grating resonances in an asymmetric refractive index environment is studied to

evaluate the applicability of nanoantenna arrays in combination with silicon photonic devices.

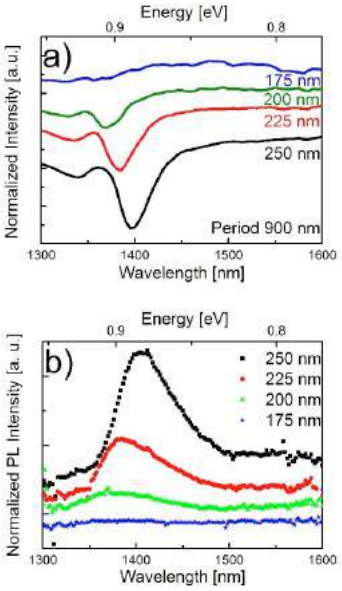

Fig.2: a) Shift of grating resonances with disc diameter observed in transmission. b) Luminescence enhancement of PbS-nanoparticles surrounding the antennas due to the grating resonances.

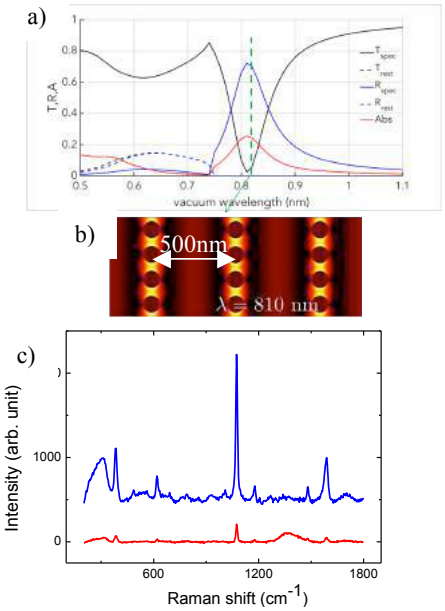

Fig. 3: Periodic Au-disc chains for the combination of near-field hot-spots with the grating resonance a) Simulation of Reflection, Transmission and Absorption for Au-disc chains. b) Field concentration within the chains. c) SERS-measurement showing the importance of polarisation along the chains to observe maximum enhancement: E-field along (blue) or perpendicular (red) to the chain.

To determine the potential of nanoantenna arrays as substrates for surface enhanced Raman scattering, Au-nano-discs were arranged in chains. Near-field hot-spots form in the small spaces between neighbouring discs of the same chain, while the different chains are arranged in a 1D-grating leading to a far-field coupling between the chains. Disc diameters of 100nm and a chain period of 500nm simulations yield a grating resonance at λ=810nm and a clear field concentration between neigbouring discs within the chains is predicted [Fig. 3a,b]. Moreover the experimental investigation of the Raman-effect of 4-methylbenzenethiol (4-MBT) molecules covering the Au-discs showed the remarkable impact of the Laser-polarisation [Fig. 3c]. This can be intuitively understood considering the near- and far-field coupling between Hertzian dipoles. The potentially strong enhancement of the SERS-signals due to the simultaneous combination of the near-field and far-field coupling of particle plasmons might contribute to the development of new large area SERS-substrates operating at non- or lowly focused excitation.

Abstract- This work provides a study the shape dependent resonant properties of the graphene oxide-on FR4, FR4-Cu structures using the GO metamaterials (MMs) patterns. Such different structures are explored for low cost applications in household Wifi antennas.

Recently, metamaterials (MMs) have attracted the attention of many scientists due to their unusual electromagnetic (EM) properties which cannot be found in nature such as negative permittivity and negative permeability [1, 2]. Many researchers have studied the EM response of MMs to use in many applications such as antennas, sensors, lenses, absorbers. Moreover, they can be designed in microwave, millimeter-wave, and optical frequency bands [3]. Furthermore, as an alternative to graphene technology which is expensive and prone to oxidative environments is the use of low cost graphene oxide [4]. It is reasonably easy to produce a large-area of low cost manufacturing grade graphene oxide, having many lucrative nonlinear optical properties [5] for applications in ultrafast photonics and optoelectronics, especially for Kerr effect in optical switching, and fast optical communications [6].

In this work we aim to produce low cost GO and study different shape dependent response GO MM antennas in X, C and S band. The S parameters such as the reflection coefficient (S11) and the transmission coefficient (S 21) were obtained from the simulation and experimental analysis using a VNA. Transmission peaks around 6-8GHz on FR4. From the self-resonance, overlap, and the larger overall current responses with respect to existing SRRs designs, it is clear that the proposed metamaterial's response is the main advantage.

Coupling of magnetic and electric dipoles to magneto-electric resonancesâ€

Surface-enhanced second harmonic generation and fluorescence using effectively lossless GaP nanoantennas in the visible regime

Abstract- Here we show the fabrication of all-dielectric gallium phosphide (GaP) nanostructures with negligible losses in the visible. Second harmonic (SH) generation and surface-enhanced fluorescence and are studied with these platforms. Employing single GaP nanodisks, we observe an increase of more than 3 orders of magnitude in the SH signal with comparison to bulk. We report to the best of our knowledge, the highest yet achieved SH efficiency in the optical region produced by a single nano-object. Furthermore, we show that GaP dimers with 35 nm gap can enhance up to 4000 times the fluorescence emission of dyes located in the gap of the nanoantenna. This is accomplished by a fluorescence lifetime reduction of, at least, 30 times and a high intensity field confinement in the gap region. These results open new venues for low-loss nanophotonics in the optical regime.

The initial motivation on plasmonic nanostructures for the development of nanophotonic devices operating in the optical regime was later partially eclipsed with the observation that losses could, in some cases, overtake actual radiative properties [1, 2]. In this scenario, dielectric nanoantennas have recently emerged as promising alternative candidates to plasmonic systems in the visible range [3, 4]. High-refractive-index dielectric nanostructures can highly concentrate electric and magnetic fields within subwavelength volumes, while presenting ultra-low absorption, compared to metals, when excited above their bandgap energies [5]. In particular, dielectric nanoantennas are expected to boost both nonlinear phenomena and surface-enhanced spectroscopies, without producing significant heating, since locally enhancing the incident light intensity can significantly amplify these processes, as their efficiencies increase with the excitation density.

GaP, in particular, is a dielectric with an associated bandgap wavelength as small as <550 nm and a relatively high refractive index of 3.5, opening interesting opportunities for the development of ultra-low-loss nanophotonic antennas in the optical range. In this presentation, efficient generation of second harmonic light is demonstrated throughout the visible regime by suitably tuning the size of single GaP nanodisks, enhancing their nonlinear response by more than three orders of magnitude with respect to the bulk, via surface effects [6]. Furthermore, by analysing the radiative properties of fluorescent molecules located in the hot-spot of a GaP dimer nanoantenna with 35 nm gap, a fluorescence enhancement factor as high as 2640 is attained when comparing with the bare emitter [6]. Both, high-field confinement effects, and a fluorescence lifetime reduction of more than one order of magnitude, give rise to the measured enhancement factor. The results of this work [6] open new avenues for low-loss nanophotonics in the optical range.

Abstract-*We consider light trapping by bound states in the continuum (BSCs) in linear periodic arrays of optically coupled high-index dielectric nanospheres. Using a Mie multi-scattering approach we numerically demonstrate that the BSC-related resonances in arrays of silicon nanospheres can be employed for both light guiding and light enhancement in he visible-to-near infrared range. Asymptotic behavior of the resonance Q-factor against the number of spheres is elaborated.*

We consider light trapping in linear periodic arrays of optically coupled high-index dielectric nanospheres. The optical properties of the arrays are examined by a Mie multiscattering approach taking into account electric and magnetic multipoles of all orders [1]. When the array is infinite it is known to support bound states in the radiation continuum (BSCs) [2], i.e. structural resonances with infinite life-time embedded into the continuous spectrum of scattering states. Two classes of the BSCs can be identified, namely, topologically and symmetry protected states. In particular, we demonstrate that there is a Bloch guided BSC mode which is stabilized by a topological singularity in space of the resonance coupling constant. We show numerically that this Bloch BSC can be employed for guiding light pulses above the line of light [3]. If the infinite array is terminated at both ends to form a finite chain of dielectric spheres the BSCs become high-Q resonances. We evaluate the asymptotic behavior of the Q-factor of such resonances against the number of spheres in the array. We demonstrate numerically that under illumination by a plane wave finite arrays of 10-15 silicon nanospheres can be used to enhance the amplitude of the impinging light at least by order of magnitude in the visible-to-near infrared range when the material and geometrical parameters of the systems are tuned to the structural resonance associated with a BSC [4].

Abstract-Here, we intend to show a review of our recent investigations in light scattering by nanostructured High Refractive Index Dielectric (HRID) materials and their possible applications for controlling the direction of the scattered light, for switching purposes and, as an alternative to metals, as low-loss near-field enhancers for sensing applications.

Nanostructured high refractive index dielectric (HRID) materials in the VIS and NIR (like Si, Ge, and other semiconductor compounds) have shown to be excellent candidates for building units of more complex optical devices and also, as an alternative to metals for plasmonics and surface enhanced effects (SERS and related techniques)[1,2]. This is because of both their inherent low ohmic losses and the magnetodielectric effects they present in those spectral ranges. These effects are due to the excitation of non-negligible magnetic resonances whose coherent interaction with the electric ones leads to interesting directionality effects which can be the base for constructing nano-antenna elements in the optical range and consequently, leading to advances in the fabrication of more complex optical devices. In this research, for single particles, directionality effects[3-7] and sensing to both particle purity[8] and surrounding medium refractive index[9] will be analyzed. The latter will be also studied for dimer configurations by means of the near field enhancement in the gap[10,11]. Also, for dimer geometries, a novel switching effect will be presented[12].

Abstract-Enhanced light-matter interaction near nanostructures have been widely investigated. Chiroptical signal can also be enhanced for a chiral molecule located at the field with enhanced optical chirality. This work investigates globally enhanced optical chirality near achiral nanostructures with simultaneous electric and magnetic resonances.

Chirality, or the absence of symmetry mirror, enables different chemical interaction between enantiomers and a chiral molecule and different optical interaction between circularly-polarized-lights (CPLs) and a chiral molecule. Therefore, chiral sensing has been actively researched in many fields, such as chemistry, biology, and pharmaceutics. The chiroptical properties of chiral molecules can be characterized through circular dichroism (CD), optical rotatory dispersion (ORD), and Raman optical activity (ROA). However, due to large size mismatch between light and molecules, only weak chiroptical signals could be measured, restricting practical measurement. Tang and Cohen discovered the relationship between absorption rate of chiral molecules and local optical chirality [1] and enabled prediction of CD enhancement before actually fabricating a device and measuring a sample. Intense local chirality enhancement near chiral plasmonic nanostructures has been reported [2]. However, the chiroptical signal from the chiral nanostructure was enormous and exceeded the signal from molecules, so their chirality characterization came from its chiroptical peak shift, not from molecular chiroptical signal itself. In addition, simultaneously existing different signs of chirality in volume result decreased overall chirality enhancement and effectiveness of solution-based chirality sensing. Global, not local, enhancement of chirality requires simultaneous electric and magnetic resonance, and high index materials, such as silicon nanoparticles, have been known to exhibit both electric and magnetic resonances [3]. This study investigates optical chirality enhancement near achiral nanostructures with simultaneous electric and magnetic resonances through full-wave numerical simulation. Such structures with high optical chirality enhancement but no chiral signal from themselves can be applied to chiroptical sensors.

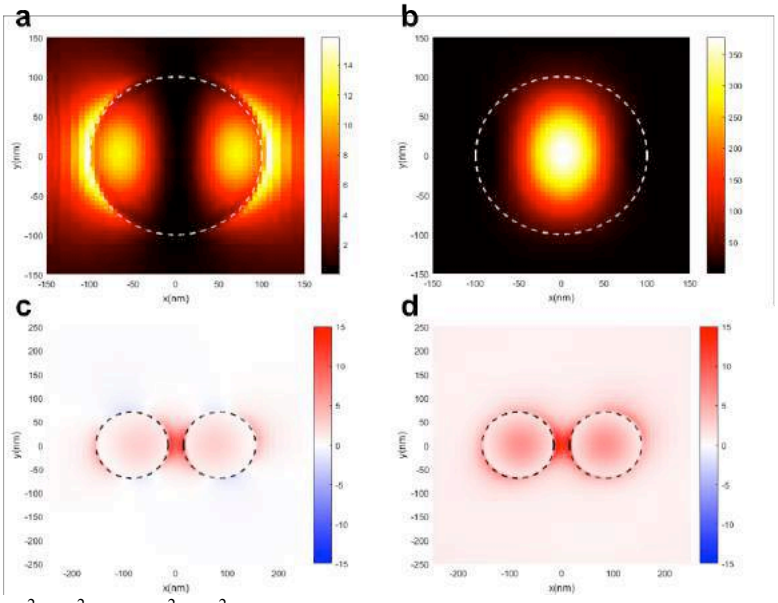

Figure 1. (a,b) $|E|^2/|E_0|^2$ and $|B|^2/|B_0|^2$ near a silicon sphere of radius 100 nm at x polarized light incidence. Electric dipole in x direction and magnetic dipole in y direction are formed. (c,d) Optical chirality enhancement near a spherical silicon dimer aligned in x direction. Electric hotspot formed at x polarized light and magnetic hotspot formed at y polarized light as ref [4] are superposed at the center of the dimer resulting optical chirality enhancement hotspot.

Abstract – Silicon Mie resonators and metasurfaces were nanofabricated using electron beam lithography followed by wet chemical alkaline etching or reactive ion etching. The fabrication process was adapted for both amorphous and monocrystalline silicon in order to obtain efficient resonant light scattering by individual silicon particles. A large palette of colors was created by tuning the size, shape and aspect ratio of the particles.

Nanoparticles of high-refractive index dielectric materials like silicon are known to efficiently scatter incident electromagnetic waves. The extinction spectra show several well pronounced peaks corresponding to electric and magnetic dipole and quadrupole moments resonantly induced in the particles by the incident light. The spectral positions of these peaks are determined by the shape and the size of the individual particles as well as by coupling between the particles if they are situated close enough from each other. For the visible and near-infrared spectral regions, the typical sizes of individual resonant silicon particles are situated in the range from 70 to 250 nm [1,2].

The nanoparticles can be organized in order to form metasurfaces which allows to control collective effects and to optimize the interaction between the particles. For the metasurfaces constituted by the individual particles, the distances between them should be large enough in order to avoid possible near-field coupling. For example, recently we have fabricated the metasurfaces composed of silicon particles situated at distances larger than 1 μm providing vivid structural colors [2]. On the other hand, a metasurface composed of closely packed resonators has shown to be a very efficient antireflective coating in a large spectral range from the visible to the near infrared and it was fabricated by nanostructuring of monocrystalline silicon [3].

All the fabrication processes need to be carefully adapted to the active material and to the substrate in order to control the size and the shape of the individual nanoparticles and their organization in metasurfaces. We used amorphous and crystalline silicon to fabricate all-dielectric colored metasurfaces, absorbers and antireflective coatings. Amorphous silicon thin films were deposited onto transparent silica glass substrates. Then, the films were patterned by electron beam lithography followed by wet chemical etching in alkaline solutions [1] or by dry reactive ion etching [2]. Different materials such as gold and nickel were used to create hard masks adapted to the etching processes. We will also discuss an original maskless fabrication process using focused ion beam

exposure.

We used wet chemical etching in two different types of alkaline solutions (based on potassium hydroxide and tetramethylammonium hydroxide) and we will discuss their influences on the shapes of the silicon resonators. The fabrication method was applied on both monocrystalline and amorphous silicon. In the case of crystalline silicon, the etching rates strongly depend on the orientation of the silicon crystalline planes, on the temperature and on the composition of the alkaline solution. The etching of monocrystalline silicon patterned with the same mask but in different alkaline solutions can give rise to the formation of nanofeatures with very different shapes [1]. In this case, very careful numerical simulations were needed to control the shape of the obtained features. Contrarily to the case of crystalline silicon, the etching rate of amorphous silicon is isotropic because of the isotropic atomic density. In that case, the final shape depends only on the shape of the mask. Dry reactive ion etching was also applied to both amorphous [2-5] and monocrystalline [3] silicon. This process allows obtaining a very good etching anisotropy and nearly vertical walls of the structures.

The shapes and the sizes of the obtained nanofeatures were controlled by scanning electron microscopy, and then the fabricated arrays of nanoparticles were characterized by optical spectroscopy in reflection mode with a dark-field microscope. The different scattering modes were identified as magnetic and electric dipole and quadrupole Mie resonances by comparing experimental and numerically simulated spectra. We also fabricated silicon monomers [4] and dimers [5] that were used to tailor the spontaneous emission of organic molecules.

In conclusion, we fabricated all-dielectric silicon metasurfaces by electron beam lithography followed by alkaline and reactive ion etching and we observed vivid colors provided by the resonant light scattering by individual silicon particles. The relative strength of the electric and magnetic resonances can be easily tuned with the aspect ratio of the particle. This allowed us to create a large palette of colors when considering the same particle height and simply tuning the aspect ratio of the particle by varying the diameter.

Novel photonic and plasmonic structures: theory and applications

Extreme absorption enhancement in ZnTe:O/ZnO intermediate band core-shell nanowires by interplay of dielectric resonance and plasmonic bowtie nanoantennas

Kui-Ying Nie, Fang-Fang Ren, Jiandong Ye*
School of Electronic Science and Engineering, Nanjing University, Nanjing 210093, China

Abstract- we explore a rational design of a hybrid structure composed of ZnTe:O/ZnO core/shell NWs with Al bowtie nanoantennas, which exhibits strong ability in tuning and enhancing broadband light response due to the interplay of NW dielectric resonance and plasmonic coupling of metallic nanoantennas.

Intermediate band solar cells (IBSCs) are conceptual and promising for next generation high efficiency photovoltaic devices, whereas, IB impact on the cell performance is still marginal due to the weak absorption of IB states. The demand for IBSCs with higher conversion efficiency and lower cost is driving academic and industrial research efforts in the search for desirable intermediate band materials. Thanks to the strong interaction with light, one dimensional semiconductor nanowires (NWs) have provided an extraordinary platform in applications of photonics and solar energy harvesting [1-2]. To this end, we explore a rational design of a hybrid structure composed of ZnTe:O/ZnO core/shell NWs with Al bowtie nanoantennas, which exhibits strong ability in tuning and enhancing broadband light response due to the interplay of NW dielectric resonance and plasmonic coupling of metallic nanoantennas. The nanowire dimensions are primarily optimized to offer highly confined energy density by engineering leaky-mode dielectric resonances in the visible spectrum region, which maximizes the overlap of the absorption spectrum and the optical transitions in ZnTe:O intermediate-band (IB) photovoltaic materials. By coupling with bowtie antennas composed of low-cost and CMOS-compatible Al metal, the absorption efficiency of ZnTe:O/ZnO core-shell single NW is further enhanced owing to the increase in the radiative loss induced by the excitation of local surface plasmons. The interplay of dielectric and metallic resonance effects in subwavelength-scale nanowires opens up new avenues for overcoming the poor absorption of sub-gap photons by IB states in ZnTe:O to achieve high-efficiency IBSCs.

Nonlinear polarization rotation of polarization-structured beams through isotropic Kerr nonlinearities

Bing Gu*, Bo Wen, Guanghao Rui, and Yiping Cui
Advanced Photonics Center, Southeast University, Nanjing 210096, China
*corresponding author: gubing@seu.edu.cn

Abstract: Structured intense laser interacting with matter will result in a variety of novel nonlinear optical effects, modulate the light propagation behavior, and change the structural property of a material. In this work, we report a theoretical investigation of the spatial self-phase modulation (SSPM) effect and nonlinear ellipse rotation of both hybridly polarized vector beams and elliptically polarized vector beams through isotropic Kerr nonlinearities. Based on the vectorial Rayleigh-Sommerfeld formulas under the paraxial condition, we obtained the analytical expressions of the focal fields of both the hybridly polarized vector beam and the elliptically polarized vector beam. We determine the isotropic third-order nonlinear refractive indexes of a medium excited by the vector field with arbitrary ellipticity. Then we numerically simulate the far-field vectorial self-diffraction behaviors and nonlinear ellipse rotations of two types of vector beams through isotropic Kerr nonlinearities. We systematically study the dependence of the self-diffraction behaviors on both the physical origin of the optical nonlinearity and the nonlinear phase shift. It is demonstrated that the SSPM intensity pattern, the distribution of state of polarization, and the spin angular momentum (SAM) flux of a hybridly polarized vector beam could be manipulated by tuning the magnitude of the isotropic optical nonlinearity. Interestingly, we observed the radial-variant nonlinear ellipse rotation of elliptically polarized vector beams through isotropic Kerr nonlinearities. Our results may find interesting applications in nonlinear mechanism analysis, nonlinear characterization technique, and SAM manipulation.

Negative refraction in vertically multilayered hyperbolic metamaterials.

Abstract- Negative refraction has attracted significant interest of researchers due to its various applications including super-resolution imaging, slow light devices, and cloaking. Although it can be realized in hyperbolic metamaterial, conventional hyperbolic metamaterial has been suffered from high resistive loss and narrow working frequency. In this work, new design of hyperbolic metamaterials of vertically stacked metal-dielectric multilayer is proposed. Comprehensive comparison between two types of vertical and horizontal multilayer hyperbolic metamaterial is followed based on numerical calculation of negative refraction.

Metamaterials have been transforming a number of fields with unprecedented optical phenomena. In particular, hyperbolic metamaterials are highly anisotropic metamatarials, which have opposite signs of permittivity depending on the direction [1,2]. They have shown extraordinary properties such as negative refraction, diverging photonic density of states, and super resolution effect. Conventional hyperbolic metamaterials can be realized by horizontally stacked metal-dielectric multilayer [3,4]. However, according to the Maxwell-Garnet's effective medium theory, the optical resonance is inevitably accompanied in conventional horizontal multilayer structures, restricting their performance with high resistive loss and narrow working frequency.

Here, we suggest new design of hyperbolic metamaterials of vertical metal-dielectric multilayer, which does not require any resonance. Therefore, it shows low loss and broad working frequency, suggesting practical applications of hyperbolic metamaterials. In this study, we compare the two types of vertical/horizontal multilayer hyperbolic metamaterials. Based on the calculated effective permittivity, we report that vertical multilayer broadens the working frequency of hyperbolic metamaterials, compared to conventional horizontal multilayer. Furthermore, the numerical simulation of negative refraction in two types of hyperbolic metamaterials is also conducted, in which vertical multilayer structure suffers much less loss and therefore transmits most of the light. Although the proposed design of new hyperbolic metamaterials has not been experimentally realized yet, it will open the new world, providing the possibility of the realization of various applications of hyperbolic metamaterials.

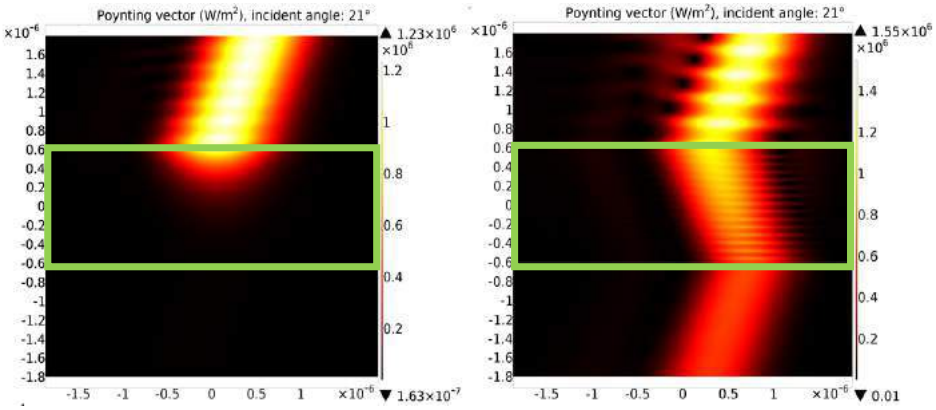

Figure 1. Numerical simulations of negative refraction in two metal-dielectric multilayered hyperbolic metamateirals, which is composed of Ag and Al2O3. The green boxes indicate hyperbolic metamaterials; left and right ones are for horizontal multilayer at 365 nm wavelength and vertical multilayer at 480nm, respectively. Most of light is absorbed and cannot propagate through horizontal multilayer (left) due to high restive loss, whereas most of light propagate through vertical multilayer (right).

Resonance splitting in 3D Bi-flake Metamaterial

Z. Liu[1], W. J. Sheng[1], S. Du[1], J. J. Li[1*], and C. Z. Gu[1,2*]

Abstract-A 3D metamaterial composed of two metal flakes with supplementary angles were fabricated by ion beam induced folding technique. Due to its asymmetry configuration, trapped mode can be excited by the destructive coupling between two flakes, and the evanescent wave of surface plasmon plays a leading role. The resonance peak can be split into two peaks, and these steep resonance peaks have great potential for sensing and detecting applications.

In recent years, great interests have been devoted to 3D plasmonic structures with the development of 3D micro/nano fabrication techniques and high demand of spatial optical interconnections. Varieties of 3D fabrication techniques have been developed such as layer-by-layer stacking[1], shadow evaporation[2], and ion-beam folding[3]. Among them, ion-beam folding is a most flexible method to make 3D structures with designable shapes and orientations. The 3D structures have far more ways of inter- or intra-coupling, and can be modulated by external signals such as mechanical, heat or pressure, indicating potentials on active devices.

It has been proved that symmetry-broken structures will lead to trapped-mode with high Q-factor[4]. In this work, we studied a special 3D metamaterial, the building block of which is composed of two metal flakes with supplementary angles. From the simulation and optical measurement data, it can be found that when the inclined angles of both flakes are 90°, there's only one peak in the spectrum. As the inclined angle changes, the peak splits into two peaks, and they gradually shift opposite to each other. These two peaks come from coupling of the LC modes on the edge of the structures, corresponding to normal and trapped modes respectively. The steep peak is a good candidate for sensing devices.

Application of Surface Plasmon Antenna To CMOS Terahertz Detectors

X.Ji, J.Peng, Y.Liao, Z. Shen, R.Wu, and F.Yan
School of Electronic Science and Engineering, Nanjing University, Nanjing 210093, China

Abstract- On-chip surface plasmon antenna used for CMOS Terahertz detectors is demonstrated. Unlike the traditional metal antenna, it is designed with heavy-doped polycyrstalline silicon material, backed with an silica layer to prevent radiation from going inside the lossy silicon substrate. By optimizing the antenna pattern using a frequency-domain solver, HFSS, surface plasmon polaritons (SPP) are excited in the antenna and can propagate THz signals to receievers. A CMOS terahertz detector integrated with the proposed antenna at 0.65THz is fabricated in 0.18μm standard CMOS technology. The measurement results show the detector can boost the voltage response by 200% due to the increased local electrical field. The transmission-mode image of the metal blade using the detector is further exhibited. The results demostrate that the designed surface plasmon antenna has a high performance to THz radaition comparable with the conventional radio-wave one.

For using FETs to detect sub-THz waves, FETs are usually integrated with the antennas for collecting THz signals [1-4]. In order to obtain high-performance detection, matching of the input impedance of the antenna and FETs should be carefully considered. However, there remain the challenges to realize antenna with ideal power matching for CMOS devices in THz region [1-2]. New surface plasmon antenna designs [5-8] provide a strategy overcoming this trade-off by converting the input light into the localized surface plasmon polaritons resonances.

Under the normal incidence of electromagnetic waves, the propagation of SPPs (K_{spp}) in the metal-like material can be expressed as

$$K_{SPP} = \frac{2\pi}{\lambda}\sqrt{\frac{\varepsilon_1\varepsilon_2}{\varepsilon_1+\varepsilon_2}}$$

where ε_1 is the dielectric constant of the medium while $\varepsilon_2 = \varepsilon_{r2} + j\varepsilon_{i2}$ is the dielectric constant of the metal-like material. The denotations ε_{r2} and ε_{i2} represent the real and imaginary part of ε_2 respectively. It has been pointed out that the effect of SPP enhanced transmission will increase with a higher value of the ratio between the dielectric constant's real and imaginary part $\varepsilon_{r2}/\varepsilon_{i2}$. From the well-known Drude-type calculation, we calculate the real and imaginary of heavy-doped silicon. The typical ratio is $\varepsilon_{r2}/\varepsilon_{i2} = 0.37$ at 1THz, which suggests a good capacity to support the excitation of SPPs in the terahertz wavelength.

We design on-chip silicon antenna with the modified bowtie structure which combines the advantages of both rod and bowtie to achieve the high localized field enhancement for Thz radiation. As the antenna geometrical parameters have influence on the SPP excitation, the High Frequency Structure Simulator (HFSS) calculation is performed. By monitoring the SPP modes observed as the maximum in electrical field, the most proper structural parameters of the antenna are achieved.

On the basis of the above simulation results, Si surface plasmon antenna coupled NMOS detector at 0.65THz is fabricated using 0.18μm CMOS process on an 8 inch Si wafer with a thickness of 300 μm.

The NMOS channel length and width are 0.18μm and 0.32 μm, respectively. According to the earlier FETs device described in [2], when THz signals coupled to the source terminals of MOSFETs, the transistors under the gate voltage rectify the signals and generate a detectable DC source–drain voltage .

The fabricated detector is then characterized using a Thz source around 0.65 THz with an illumination power of 1 mW. We compare the voltage response–gate bias characteristic of detectors at 0.65THz with and without the surface plasmon antenna. The response from the detector with antenna exhibts about 200 times larger than one without the antenna. Such enhancement of voltage response is a direct experimental evidence of plasmonic effect from Si antenna in Thz region. Furhtermore, the scanned transmission-mode image of a cutter blade embedded in polystyrene foam using the pixel is carried out. These results show that the detector has a high performance to THz radaition comparable with that of conventional radio-wave one. The demonstrated on-chip surface plasmon antenna provides a technology platform for the ease of design and fabrication of CMOS THz detectors without the need of strict matching of the antenna and Si FETs receiever.

Abstract-An analytical method to design optical coatings for giant field enhancement under total internal reflection will be presented. Enhancements of several decades can now be localized at arbitrary altitudes within a multi-dielectric component and for different wavelengths.

Volume confinement and field enhancement in optical devices still promote key applications in the field of sensors and micro-sources. Different techniques have been studied and we proposed here an optimized method based on optical interference coatings (OIC). To fit more and more severe requirements, modern design techniques allow producing multidielectric devices with nearly 1000 layers. They are mainly used in free space to control specular properties and less commonly for field enhancement. Narrow-band filters may provide such property, but the enhancement is confined within their spacer, which excludes sensitivity to the surrounding medium.

For this reason several works were devoted to resonances of all-dielectric multilayers in total internal reflection, to build a huge over-intensity at the substrate interface. However, design optimization was not fully achieved, due to a lack of analytic formulation; indeed numerical data are used to identify the reflection poles of the structure, without any additional control. Here, we introduce the concept of zero-admittance layers (ZAL) so as to increase the degrees of freedom and extend the design technique to enhancement optimization. The ZAL are standard dielectric materials whose optical thicknesses are adjusted wrt the total multilayer. Several ZAL are then introduced for a multi-wavelength or multi-angle optimization. We first show how these layers allow reversing the depth field distribution within a stack, and provide giant enhancement. Then the procedure is extended for depth localization. Finally the design technique is generalized to provide huge resonances at a given set of illumination angles and wavelengths that are beforehand chosen.

Simulation and Design of CMOS Terahertz Detector With Surface Plasmon Antenna

[*]xji@nju.edu.cn

Abstract- In this paper, CMOS terahertz detector integrated with surface plasmon antenna is proposed. The antenna is constructed by the doped silicon material and the simulation results show its capacity to realize strong light concentration at 650GHz. In addition, the effects of the different parameters on the antenna performance are studied and we find that gap spacing of the bow-tie structure is an important factor to determine the antenna's resonant frequency along with its detected field strength. Besides, CMOS terahertz detector integrated with the proposed bowtie antenna is fabricated by the standard CMOS technology. The measured results from the device are well agreed with the simulated ones.

It has been revealed in previous studies that semiconductor based antennas are capable of supporting SPP resonance and achieving strong field confinement[1-2]. Nevertheless, these reported SPP antennas are not fabricated by the standard CMOS technology, such a drawback will become an obstacle for their future utilization. Here, we propose the design of the bowtie antenna which is constructed from the doped silicon material. The antenna model is established in electromagnetic simulation software CST Microwave Studio whose schematic is illustrated in Fig. 1 (a). Open boundary and plane wave excitations are set up to simulate normal incidence of uniform plane wave on the antenna. The antenna lies on the xoy plane of the coordinate system while the plane propagates along the z axis and polarized along the y axis. As is pointed out that the gap spacing between the two arms of the bow tie antenna plays a significant role to influence antenna's behavior, we here also study the effect of the gap spacing on the proposed surface plasmon antenna.

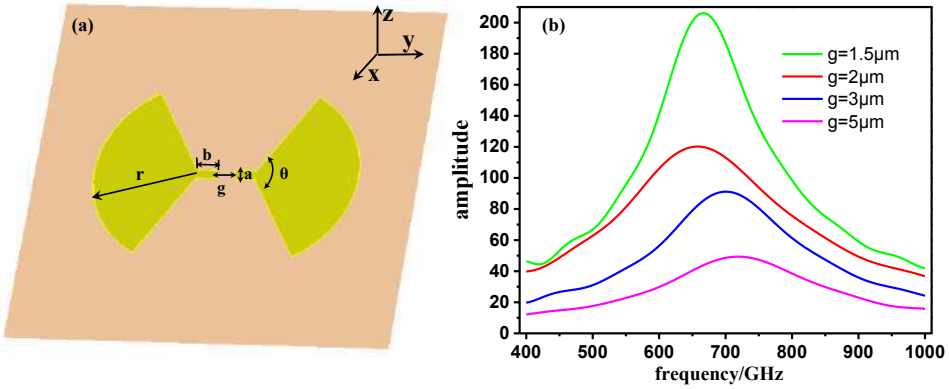

Fig. 1 (a) Schematic of the proposed bow-tie antenna; (b) The detected E-field amplitude versus frequency with respect of different gap spacing values

In the simulation, the gap spacing (g) ranges from 1.5 to 5μm while all the other antenna parameters remain constant as b=14μm, a=1μm, r=54μm and θ =120°.As is shown in Fig. 1 (b), the detected E-field amplitude reaches its maximum value when the gap spacing is 1.5μm. As the value of gap spacing rises, the resonance will occur at a higher frequency end while the detected field amplitude decreases, which conforms to the findings of the bow tie antenna in the optical wavelength[3-6].

Besides, we can insert the excitation port between the two arms of the bow-tie antennas to see their impedance features. The simulated results indicate that SPP resonances occur when the imaginary part of the antenna input impedance changes from inductive (above zero) to capacitive (below zero) at the resonant frequency. In the interested frequency range of 600 to 700GHz, it can be seen that as the gap spacing increases, resonance moves to the higher frequency end. Such results are also agreed with that of the optical bow-tie antenna, for which the extended length of the gap spacing will lead to a decreased capacitance value and a longer resonant wavelength[4].

On the basis of the simulation results above, the bowtie SPP coupled NMOS detector is fabricated using 0.18μm CMOS process on an 8 inch Si wafer with a thickness of 300 μm. The fabricated detector is then characterized using a THz source around 0.65 THz with an illumination power of 1 mW. The measurement results show that the detector has a high performance to THz radiation.

Recent Progress in Novel Functionalities of Plasmonic and Metamaterial Structures

Enhanced Magneto-chiral Effects at Microwave Frequencies by a Single Metamolecule

Satoshi Tomita

Nara Institute of Science and Technology, Japan
tomita@ms.naist.jp

Abstract— We have experimentally and numerically studied the directional birefringence of X-band microwaves by magneto-chiral (MCh) effects of a single metamolecule at room temperature. By applying a dc magnetic field, we observe an emergence of the MCh effects with simultaneous space-inversion and time-reversal symmetry breaking. The MCh effect is enhanced by using the magnetic resonance of the magnetic meta-atom. Numerical calculation predicts a giant MCh effect by interacting magnetic resonance with a specific resonant structural optical activity.

Symmetry breaking is a fundamental interest in physics. In condensed matter, symmetry breaking causes intriguing electromagnetic properties. The break in space-inversion symmetry in chiral structures like sugars causes reciprocal structural (natural) optical activity. Broken time-reversal symmetry in magnetized materials leads to non-reciprocal magneto-optical (MO) activity; that is to say, MO effects. These optical activities look similar, but have different physical origins. The MO activity is caused by the Lorentz force on electrons, whereas the structural optical activity is due to electromagnetic induction in the chiral structures.

It is natural and interesting to ask what electromagnetic waves will experience when time-reversal and space-inversion symmetries are simultaneously broken. Combination between MO and structural optical activities, gives rise to the directional birefringence independent of polarizations; that is, *magneto-chiral (MCh) effects* [1, 2, 3, 4]. The MCh effect is promising for new functional optics such as a polarization-independent non-reciprocal "one-way mirror". Moreover, the quest for large MCh effects paves a way toward the realization of a synthesized gauge field; for example, an effective magnetic field for electromagnetic waves [5, 6]. The system with the symmetries broken simultaneously is of interest also in terms of topological spin textures like Skyrmion [7]. The MCh effect at room temperature is, however, much weaker than MO and structural optical activities in natural materials.

In a previous study [8], we reported the direct observation of MCh effects in the X-band microwave region by a single metamolecule consisting of a metallic chiral structure and a ferrite rod at room temperature. A weak dc magnetic field of 1 mT was found to induce the MCh effects at frequencies of resonant structural optical activities, referred to as chiral resonances. The MCh effects were increased as the dc magnetic field was increased up to $\pm$200 mT. The difference in non-reciprocal refractive index due to the MCh effect was in the order of 10^{-3}, which was much larger than that observed in natural materials at the visible frequencies [9]. The large MCh effect is associated with the chiral resonance in the metallic chiral structure. However, interaction of the chiral resonance with the magnetic resonance by the ferrite rod remained to be addressed. By applying strong magnetic fields, magnetic resonance of the ferrite rod approaches the chiral resonance frequencies. This motivates a further enhancement of MCh effects.

In this invited talk, we report a comprehensive study of enhanced MCh effects at microwave frequencies by a single metamolecule [10]. Microwave transmission coefficients, S-parameters of S_{21} and S_{12}, are measured through the single metamolecule under magnetic fields up to $\pm$400 mT. We observe the difference between S_{21} and S_{12} in amplitude and phase, which is reproduced by numerical calculation based on a finite element method. The difference is caused by the MCh effect with simultaneous space-inversion and time-reversal symmetry breaking. We demonstrate that the MCh effect can be enhanced by using the ferrite meta-atom magnetic resonance. Moreover, numerical calculation reveals an enormous enhancement of the MCh effect by interacting the magnetic resonance with an exclusive chiral resonance, leading to the giant MCh effect. Non-reciprocal Fano-resonance between the magnetic resonance and exclusive chiral resonance in the meta-atoms is a key in the giant MCh effects. As a consequence, one-way transparency is realized in the MCh metamolecule at room temperature and convenient magnetic field strength. These conditions are quite preferable for practical applications such as a one-way mirror. The present study thus paves

a way toward the realization of a synthetic gauge field for electromagnetic wave [5, 6], and is one further step for *meta-condensed-matter physics* using metamaterials.

Optical Cloaking with Existing Materials

K. Kajikawa

School of Engineering, Tokyo Institute of Technology
kajikawa@ee.e.titech.ac.jp

Abstract— We report macroscopic scattering cancellation caused by difference of local-electric polarization field between core and shell materials. We employ this phenomena to find parameters for the optical cloaking of metallic nanowires.

Optical cloaking is the method to make an object to be transparent. There are a few methods to bring about this phenomenon. One is based on the transformation optics, by covering an object a metamaterial film with appropriate spatial distribution of refractive indices, as the light make a detour around the object [1,2]. Since the realization of the required refractive indices are tough at optical frequency, this method is unrealistic. The other method is to reduce the scattering efficiency to be zero by covering a film of dielectrics or semiconductors [3,4,5]. This method can be realized using the existing materials such as AlAs or Si semiconductors with high refractive index [5]. In this method, macroscopic scattering cancellation is caused by difference of local-electric polarization field between core and shell materials. We employ this to perform realistic optical cloaking for metallic nanowires and found some parameters.

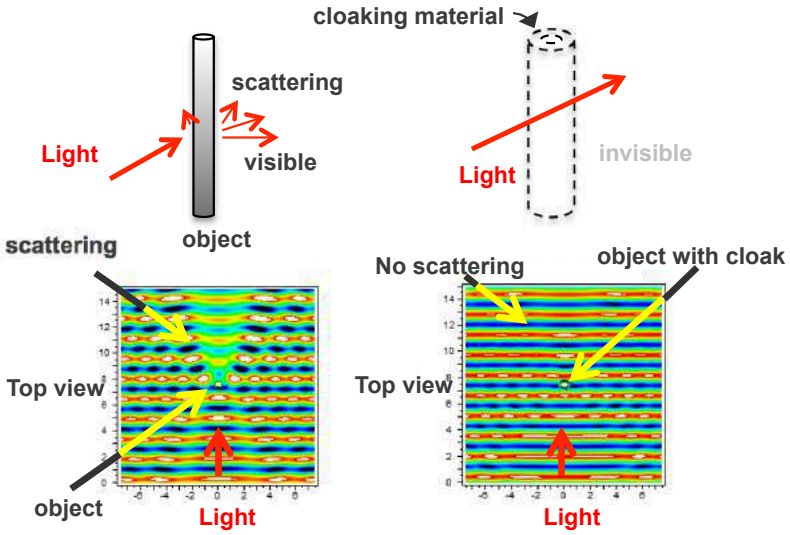

Figure 1: FDTD simulation results of optical cloaking.

To discover the most suitable structure for the cloaking at visible wavelengths with dielectric multilayered structure, we performed analysis of the electromagnetic field by solving classical Maxwell equation. After the determination of the parameters of refractive index and the thickness of the shell, we performed the 2D FDTD simulation to make sure the cloaking. As shown in Figure 1, the strong light scattering was observed from the cylinder core without cloaking, the light front is stable and invisible when the core was covered with a cloak. We found a number of pairs of the core and shell of existing materials: core/shell = dielectrics/dielectrics, dielectrics/metals, metals/dielectrics and even metals/metals.

These cloaking technique can be used for transparent electrodes and electrical-ciruit wires.

Fine Tuning of Plasmonic Properties for Au Nano-Structures by Electrochemical Metal Dissolution/Deposition

Hiro Minamimoto*, Shunpei Oikawa, and Kei Murakoshi

Abstract-The control method for plasmonic properties of the metal nanodimer structures has been established via electrochemical metal dissolution reactions. The reaction rate can be precisely tuned by changing the electrochemical conditions. With the progress of the electrochemical reactions, the maximum plasmon resonance wavelength shifted to the shorter wavelength region corresponding to the decrease volume of metal nano-structures. Thorough various attempts, unique optical properties emerged by the structural control in an atomic scale was revealed by *in-situ* electrochemical optical measurements.

Localized surface plasmon resonance (LSPR) which is the collective oscillation of free electrons in the metals is excited in the vicinity of the mental nano-structures under the illumination of the visible or near infrared light. The strong optical field is generated by the excitation of LSPR.[1] Especially for the dimer structures, the intensity of the strong optical field becomes relatively strong compared to the case of the single structures. In order to use the generated optical field efficiently, it is necessary to tune the photo response properties of metal nano-structures by the control of the metal size, shape, composition, and environments. Recently, it has been reported that the nano-dimer structures with the gap distance of less than 1 nm can concentrate the light into the molecules scale before the formation of the tunneling plasmon (charge transfer plasmon) at the center of the gap.[2] At the present stage, fine tuning of the metal nano-structures with the resolution less than 5 nm is quite difficult to be achieved by the ordinary techniques, such as the electron beam lithography method. In this study, we have tried to establish the new method for the control of the plasmon active metal nano-structures with the aim of the arbitrary tuning of plasmon resonance properties. The optical property change was evaluated through *in-situ* electrochemical spectroscopic measurements.

The Au nano-dimer structures on the conductive glass substrate using nano-sphere lithography method (Au-NSL). In addition to this, the well-defined Au structures were also prepared by electron beam lithography technique. Electrochemical dissolution of Au nano-dimer structures were performed with the three-electrode system. Pt plate and Ag/AgCl (sat. KCl) electrode were used as the counter and reference electrodes, respectively. During electrochemical measurements, extinction spectra for the substrate were obtained.

As the first attempts, the tuning of the plasmonic properties for Au-NSL were performed with the system as indicated in Fig. 1. SEM images of Au-NSL structures which were obtained before applying electrode potential were shown in Fig. 1. The *in-situ* electrochemical extinction spectra were obtained under the illumination of polarized light parallel to the long axis. The polarized electrode potentials were 0.89 and 0.87 V corresponding to Fig. 2a and b. As can be seen in extinction spectra, the drastic optical property change was confirmed in the case of 0.89 V. After 600 s, the plasmon resonance peak were disappeared with the resonance wavelength shift.

This phenomenon can be explained by the diminish of the structures due to the fast reaction rate. On the contrary, with the slow dissolution rate at the case for 0.87 V, the scattering cross-sections which reflect volume change of nano-dimer were almost maintained but the maximum plasmon resonance wavelength were slightly shift around 100 nm. It can be considered that this wavelength shift is mainly derived from the gap distance change of dimer structures. Taking into above results, we have succeeded in obtaining appropriate condition for the fine tuning of plasmonic properties for Au nano-structures. Based on the spectroscopic measurement results, we have tried to estimate the gap distance change. From the calculations, the change in the gap distance can be estimated as less than 5 nm, which is difficult to be controlled by the ordinary nano-control methods.

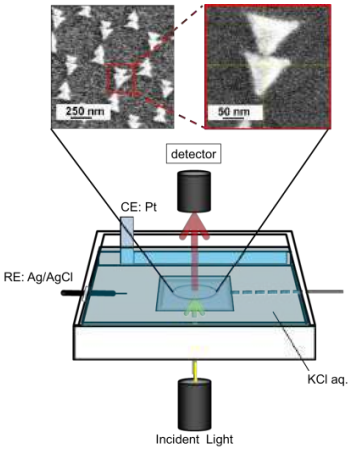

Fig.1 Schematic illustration of electrochemical extinction spectrum measurements cell. SEM images indicate prepared Au-NSL structures.

For further investigations, we have attempted to control of the optical properties using well-defined Au-nanostructures prepared by electron beam lithography technique. By introduction of well defined-structures to the present system, more detail discussion would be realized. As the results for the single Au-nano dimer disk structures obtained with the scattering spectra, we have succeeded in the observation of the drastic optical property change corresponding to each property change of the charge transfer and tunneling plasmon mode. We can say that our results indicate the atomic scale resolution for the present electrochemical method. From all results in our attempts, as conclusions, the present electrochemical method can be considered as the promising technique for the control of the optical properties of the Au nano-structures in an atomic scale.

Abstract— Plasma is suitable for a component and/or an alternative of metamaterial. By installation of plasma into solid metamaterial structure, metamaterial becomes tunable, energetic and nonlinear since the part of the plasma change permittivity even to values in the negative sign with frequency dispersion, and store kinetic energy in electron motions in the level of eV which is sufficient for nonlinear photonics for harmonic wave generation. Plasma also provides spatial gradient of refractive index due to the inherent spatial profile of electron density, and it controls propagation paths of electromagnetic waves, similar to the cloaking devices composed of solid metamaterial. These findings extends roles of metamaterial further to scientific areas that have not been covered by metamaterial.

Metamaterial science opens functions of media for electromagnetic waves, which has not been covered, like negative values of refractive index and cloaking layers [1, 2]. Its motivation is now expanding to potential functionalities that enable us to make it tunable and nonlinear [3]. We have reported plasma-metamaterial composites as examples in the expanded category of metamaterial media [4, 5], and the experimental results suggest nonlinear and cloaking phenomena as well as tunable characteristics.

Plasma has dispersive permittivity ε_{p} which is in the Drude type. ε_{p} becomes negative when the given wave frequency ω is lower than the electron plasma frequency ω_{pe}, and it varies from zero to +1 as ω gets higher than ω_{pe}. The synthesized refractive index in negative-permeability metamaterial takes negative, positive and imaginary values. Furthermore, due to its energetic properties coming from high-energy electrons and rectified current flows in plasma, we observed harmonic wave generation, which makes the frequency dispersive property more rich.

In addition, since plasma has a spatial profile of electron density, ε_{p} changes its value in the balance between ionization and boundary regions, including both positive and negative values. Consequently, such a property leads to a similar spatial profile to that in cloaking layers designed in transformation optics [6]. ε_{p} exhibits a variety of profiles, and the plasma can become an alternative of metamaterial in a cloaking layer and other devices which control a propagation path of electromagnetic waves. We observed wave scattering in plasma layer, and the profiles of the detected signals coincides with numerical results of the finite-difference time-domain method.

Such experimental observations convince us that plasma plays roles that cannot be achieved by conventional solid-state metamaterial, and their functions will increase as concepts and technologies introduced to regulations of plasma generation.

A generic way for creating topological electromagnetic states

Xiao Hu
International Center for Materials Nanoarchitectonics (WPI-MANA)

Abstract-Topological photonic phenomena are attracting significant interests from viewpoints of both basic science and potential applications. We have proposed a new way to realize two-dimensional (2D) topological photonic crystals based on honeycomb lattice of dielectric cylinders [1]. The idea can be applied for various systems.

Similar to graphene, Dirac-like linear frequency dispersions exist at K and K' points for the neat honeycomb lattice. We show that deforming the honeycomb lattice in the designed way which preserves the C_{6V} symmetry will open a frequency gap, accompanying with a band inversion between p-orbit- and d-orbit-like electromagnetic modes at Γ point. The system exhibits counter-propagating edge photonic modes with topological protection. Our theoretical prediction has been confirmed by recent experiments [2]. Because only dielectric material is used in the present approach, one can achieve topological photonic properties with working frequency of radio through visible lights by varying merely the lattice constant of photonic crystal. The idea has been extended to 2D waveguides, 3D photonic crystals, phononic and electronic systems [3-7], and is expected to be applicable to other quantum and classic systems, including surface plasmon polariton, BEC, and LC circuits.

Bi-anisotropic response in three-dimensional split ring resonators fabricated by a self-folding method

Yuto Moritake[1*] **and Takuo Tanaka**[1,2,3]

Abstract-We experimentally demonstrated infrared metamaterials composed of three-dimensional split ring resonators (3D-SRRs) fabricated by a metal-stress-driven self-folding method we developed so far. The self-folding method enables to mass and easy fabrication of 3D SRRs operating in the infrared region due to self-organized nature of the process. By using this method, bi-anisotropic response in 3D-SRRs was controlled, which realizes 3D magnetic materials in the infrared region.

Artificial magnetism in metamaterials has opened a new paradigm to realize intriguing phenomena including negative refractive index, optical cloaking, s-polarization Brewster effects. Especially, negative refractive index materials have attracted significant attention due to exciting functionalities such as negative refraction, sub-wavelength focusing and so on. Split ring resonators (SRRs) are representative metamaterial structures for realizing artificial magnetism. Magnetic component of light can couple to a magnetic resonant mode with induced magnetic dipole and effective permeability at the magnetic resonance in SRRs changes from unity.

To demonstrate artificial magnetism in the optical region using SRRs experimentally, planar type SRRs are generally used due to restriction of sample preparation. However, in planar metamaterials, a magnetic component of light cannot directly couple to the magnetic resonant mode since the excited magnetic dipole in planar SRRs is normal to a substrate at normal incidence. On the other hand, three-dimensional (3D) SRRs allows direct coupling between a magnetic component of light and the magnetic mode in SRRs. However, fabrication of 3D structures for optical metamaterials is still difficult although it can be performed by using some special techniques and state-of-art equipment at the laboratory level [1].

To overcome this issue, we developed a metal-stress-driven self-folding method to fabricate 3D-SRRs [2-4]. Firstly, two-dimensional (2D) gold ribbons are formed on a Si substrate by using electron beam lithography and a conventional lift-off method. The 2D ribbons have two arms connected by a patch. The Si substrate with 2D patterns is isotropically etched using ICP-RIE. When Si under the arms is completely etched and the gold arms are released, intrinsic stress in deposited gold films spontaneously induces folding of the arms as shown in Fig. 1. The role of the center patch is an anchor for the arms not to be peeled off from the substrate after release. Owing to self-organized nature of the process, this method allows mass and easy fabrication of 3D structures.

By using the method, we investigated bi-anisotropic response in infrared metamaterials. General 3D metamaterials show bi-anisotropic response due to luck of inversion symmetry along a propagation axis. In bi-anisotropic materials, electric (magnetic) dipole can be excited by not only electric (magnetic) fields but also magnetic (electric) fields of light, which results in unwanted complex electro-magnetic coupling preventing

purely magnetic resonance in SRRs. Appropriate adjustment of the patch position in gold ribbons enables to control of inversion symmetry along the propagation axis as shown in Fig. 2. Analysis using simulations and effective parameter retrieving revealed elimination of the bi-anisotropic response in 3D-SRRs, which indicates 3D magnetic metamaterials is realized in the infrared region. In the presentation, we will discuss the results in detail.

Abstract-We demonstrate active tuning of the resonant response of metamaterials utilizing organic π-conjugated materials in terahertz (THz) frequency ranges. Electrochemically grown heavily-doped polypyrrole (PPy) film was used as a linear actuator to slightly shifting relative position of stacked two layers of split-ring resonator (SRR) array. We also show that a stacked closed-ring resonator (CRR) array is also effective to obtain relatively large spectral shift with a small lateral shift.

In recent years, numerous studies have been carried out to develop novel types of metamaterials and metadevices [1]. In metamaterials, artificially designed subwavelength resonant structures, or meta-atoms, such as split-ring resonator (SRR) play crucial roles in obtaining rich variety of unique responses to electromagnetic fields [2]. However, resonant characteristics of such SRRs usually restrict their working frequency only in a narrow range, therefore numerous attempts have been made to add tunability to metamaterials to develop active devices [1]. Based on the fact that resonant condition of meta-molecules or layered metamaterial arrays can be controlled by relative position and/or orientation via near-field interaction between meta-atoms [3, 4], tunable metamaterials and metadevices have been developed [5-8]. Here we demonstrate our recent results on the electro-active metadevices in terahertz (THz) frequency ranges utilizing organic π-conjugated polymers [8].

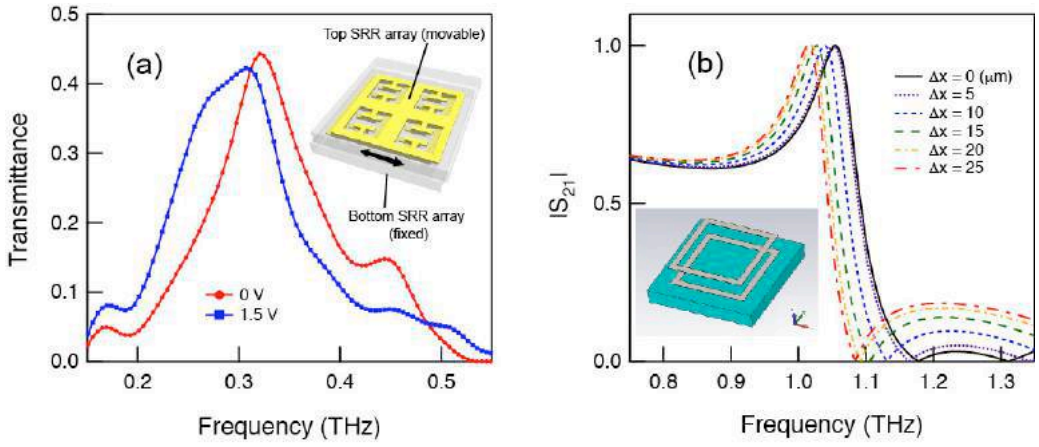

Figure 1 (a) Measured THz transmission spectra of tunable THz device based on PPy(PF6) linear actuator under applied voltage. (inset) Schematics of the double-layered resonator arrays with fixed bottom layer and movable top layer. (b) Simulated THz transmission spectra of stacked CRR array THz metamaterial. (inset) Schematic of stacked CRR array THz metamaterial.

Among rich variety of π-conjugated polymers, doped polypyrrole (PPy) film is unique since its volume can be controlled even in ambient air by applying low voltage of only a few Volts, and thus can be utilized as electro-active polymer actuators [9]. We have synthesized thin films of PPy doped with PF6 ions, PPy(PF6), by electrochemical polymerization and utilized them as linear actuators to laterally shift relative position of stacked SRR arrays (inset of Fig. 1 (a)). By applying voltage to the polymer actuators, a contraction of the polymer film can be induced and this shifts one of the stacked SRR layer. Therefore, a frequency shift of resonant THz transmission can be obtained (Fig. 1 (a)). We also show that the stacked closed-ring resonator (CRR) arrays [10] (inset of Fig. 1 (b)) can be effective to obtain relatively large spectral shift with a small lateral shift. In the numerical simulation, we have obtained spectral shift of the narrow-band transmission by assuming a similar lateral shift of the stacked CRR arrays (Fig. 1 (b)). Our findings might be utilized to develop novel types of electro-active THz metadevices. We also found that resonant frequency can be shifted by changing dielectric constant of dielectrics between CRR arrays, which may be utilized for sensing devices.

Symmetry Classification of Topological Photonic Crystals

Max Lein[1] & **Giuseppe De Nittis**[2]

[1]Advanced Institute of Materials Research, Tohoku University, Japan
[2]Pontificia Universidad Católica de Chile, Chile
maximilian.lein.d2@tohoku.ac.jp

Abstract— As a first step to understand topological effects in photonic crystals via *photonic bulk-boundary correspondences*, we have adapted the Altland-Zirnbauer classification scheme and obtained a classification of topological photonic crystals. Our classification justifies the name "Quantum Hall Effect for light", and suggests that *the Chern number quantifies the net number of edge modes traveling from left to right*. Furthermore, we identify *dual symmetric materials* as a second candidate for exhibiting novel topological effects.

Inspired by ideas from solid state physics, one recent success was the prediction [RH08] and experimental realization [WCJS08, RZP$^+$13] of an analog to the Quantum Hall Effect with electromagnetic waves. The idea here is to exploit periodic patterning to create a photonic bulk *band gap* and choose materials which *break a certain symmetry*. A first principles explanation, starting from Maxwell's equations and culminating in the proof of *photonic bulk-boundary correspondences*, is still missing, and the first step is to adapt the Cartan-Altland-Zirnbauer classification scheme and classify topological photonic crystals according to certain discrete symmetries. After a first attempt [DL14] where we had not taken the real-valuedness of electromagnetic fields correctly into account, we have now obtained a classification of electromagnetic media [DL16] according to discrete symmetries. It turns out only very few symmetries of the form $T_j = (\sigma_j \otimes \mathbb{1})C$ or $U_j = \sigma_j \otimes \mathbb{1}$ are admissible, $(C\Psi)(x) = \overline{\Psi(x)}$ being complex conjugation and σ_j the Pauli matrices in the $(\mathbf{E}, \mathbf{H})$ splitting. That leads to the following classification:

Theorem (Symmetry classification of media) *Suppose the material described by* $W(x) = \left(\begin{smallmatrix} \varepsilon(x) & \chi(x) \\ \chi^*(x) & \mu(x) \end{smallmatrix}\right)$ *is* lossless *and* not negative index. *Then the materials given below possess the following symmetries (*T_j *are time-reversal-type symmetries,* U_2 *a unitary, commuting symmetry):*

Material	Topological Effects	Conditions on W	Symmetries	CAZ Class
Non-gyrotropic materials	*No*	$\varepsilon = \mathrm{Re}\,\varepsilon$, $\mu = \mathrm{Re}\,\mu$, $\chi = 0$	$T_3 : (\mathbf{E}, \mathbf{H}) \mapsto \big(\overline{\mathbf{E}}, -\overline{\mathbf{H}}\big)$	*AI*
Gyrotropic materials	*QHE for light*	$\mathrm{Im}\,\varepsilon \neq 0$ *or* $\mathrm{Im}\,\mu \neq 0$	*None*	*A*
Dual symmetric materials & vacuum	***Unknown***	$\varepsilon = \mathrm{Re}\,\varepsilon = \mu$, $\chi = -\chi^*$	$T_1 : (\mathbf{E}, \mathbf{H}) \mapsto \big(\overline{\mathbf{H}}, \overline{\mathbf{E}}\big)$ $T_3 : (\mathbf{E}, \mathbf{H}) \mapsto \big(\overline{\mathbf{E}}, -\overline{\mathbf{H}}\big)$ $U_2 : (\mathbf{E}, \mathbf{H}) \mapsto \big(-\mathrm{i}\,\mathbf{H}, +\mathrm{i}\,\mathbf{E}\big)$	—

Our classification justifies calling the experiment suggested by Haldane the "Quantum Hall Effect for light", and suggests that in a two-dimensional topological photonic crystal *the Chern number quantifies the net number of edge modes traveling from left to right*. Furthermore, we identify *dual symmetric materials* as a second candidate for exhibiting novel topological effects due to the *presence* of a *second* time-reversal symmetry.

Abstract— Embedding chiral metasurfaces or photonic crystal slabs into semiconductor nanostructures and/or microcavities allows to create compact sources of circularly polarized light including lasers. The mechanisms to control the circular polarization of light emission by chiral structuring are discussed.

The goal to create compact circularly polarized light sources including lasers without need in bulky wave plates or external magnetic field has drawn a considerable attention in recent years. A monolithic electrically pumped quantum cascade laser with circularly polarized THz emission was demonstrated in [1], using "fishbone" gratings in the surface metallization. Recently, a close to circularly polarized lasing at $\hbar\omega \approx 1.5$ eV was achieved [2] from an AlAs/AlGaAs Bragg microcavity with GaAs quantum wells in the active region and chiral-etched upper distributed Bragg refractor under optical pump at room temperature.

The fabrication of chiral nanostructures from achiral semiconductor materials appeared to be a very effective method to produce a circularly polarized light emission from quantum emitters in the absence of magnetic field [3-6]. They may work as chiral metasurfaces or photonic crystals, depending on the relation between the light wavelength and period of the structure.

The advantage of using chiral semiconductor/air structures with a large contrast of dielectric permittivities is their giant optical activity. This allows one to fabricate a very thin "wave plate", with a thickness of the order of the emitted light wavelength. Unlike the traditional wave plates, chiral nanostructures may have in-plane rotational isotropy due to the C_4 symmetry. Thus, they do not require linearly polarized emission of the active material at some precise polarization direction, which is an important advantage of the demonstrated approach over conventional quarter-wave plates.

Polarization dependence of transverse photo-voltage in porous thin metal films

Teruya Ishihara and Marjan Akbari

Tohoku University, Sendai, Japan
*corresponding author: t-ishihara@m.tohoku.ac.jp

Abstract- Photo-induced voltage is generated in a metallic thin film when the light beam is obliquely incident. The voltage perpendicular to the incident plane (transverse photo-induced voltage: TPIV) is dependent on azimuth angle and ellipticity of the light polarization. By rotating the relative configuration of the film and the electromagnetic field of light, it is possible to deduce its polarization state, which can be utilized to develop a broadband ellipticity meter.

Porous thin metal film can have different optical response from the pristine metal film [1]. When the pore size is smaller than the light wavelength, the film can be considered as a metamaterial. Due to the local DC charge on the metal surface generated by photo-rectification, which is one of the second-order optical nonlinearity, the film may exhibit net DC voltage depending on the symmetry of the applied light field [2-4].

In order to prepare nano porous metallic films we employed two methods. One is to start from an alloy film. By applying nitric acid to a 100 nm-thick white gold leaf (Au : Ag = 50 : 50 wt %) , a bicontinuous porous Au film can be formed [5]. Another method is to use polystyrene spheres as a mask for sputtering. This method is more flexible and various kind of porous metal (including Au, Ag and Al) film can be prepared.

Nanosecond light pulses from an optical parametric oscillator were used as the light source. Polarization states were controlled by achromatic wave plates. Generated voltage was measured with a digital oscilloscope as a function of the incident wavelength or the incident angle. When the transverse voltage is measured as a function of a half-wave plate angle, various patterns are obtained depending on the ellipticity of the incident light. Inversely we can utilize this dependence to deduce ellipticity of unknown polarization [6].

Near-Field Visualization of Plasmons in Single Gold Nanotriangles

K. Imaeda[1], S. Hasegawa[1] and K. Imura[1*]
[1]Graduate School of Science and Engineering, Waseda Univ., Japan
[*]corresponding author: imura@waseda.jp

Abstract-We studied static and dynamic characteristics of plasmons excited in single gold nanotriangles by scanning near-field optical microscope. Near-field transmission images observed near plasmon resonances showed oscillating patterns depending on the observation wavelengths. The observed spatial characteristics are well reproduced by spatial features of eigen functions of a particle confined in a triangular potential well. The dephasing time of the plasmon was visualized by time-resolved near-field imaging, and found that the spatial distribution of the dephasing time varied depending on the excitation positions in the triangle.

Plasmon resonances excited in gold nanoparticles confine light fields spatially and temporally, and consequently induce intense optical fields.[1] To better understand the plasmons, visualization of plasmons is essential. In this study, we performed static and dynamic near-field microscopic measurements on single gold nanotriangles, and revealed the spatio-temporal characteristics of the plasmons excited.[2-4]

Gold nanotriangles were chemically synthesized and dispersed on a coverslip. An aperture-type scanning near-field optical microscope was utilized for optical characterization of the sample. A halogen lamp and a mode-locked Ti:sapphire laser were used for the static transmission and two-photon induced photoluminescence (TPL) measurements, respectively. We also performed time-resolved TPL autocorrelation measurements of the sample to examine the dephasing time of the plasmon.

Near-field transmission spectrum of a single gold nanotriangle shows multiple plasmon resonances from visible to near-infrared spectral region. Figure 1(a) shows a scanning electron micrograph of a gold nanotriangle. Figure 1(b) shows near-field transmission image of the nanotriangle taken at 590 nm. The image shows unique spatial features, which are different from the geometrical shape. The observed spatial features are well reproduced by spatial character of an eigen function calculated for a particle confined in a triangular potential well, as shown in Fig. 1(c). Near-field two-photon excitation image also shows the unique oscillating pattern attributable to plasmon modes excited in the triangle, as is similar to those of the transmission images. We

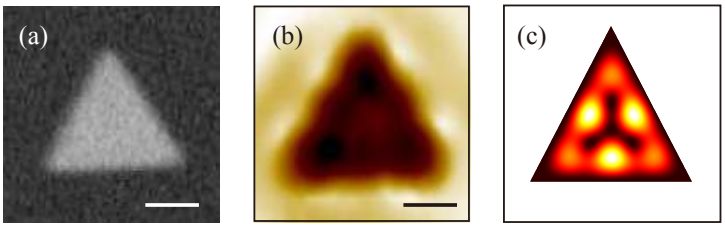

Figure 1(a) A scanning electron micrograph of a single gold nanotriangle. (b) Near-field transmission image of a single gold nanotriangle observed at 590 nm. Scale bars : 200 nm. (c) Calculated eigen function for a particle confined in a triangular potential well.

visualized the spatial distribution of the plasmon dephasing time in a single nanotriangle by time-resolved near-field imaging. We found from the spatial distribution of the dephasing time that the dephasing times varies depending on the internal position on the triangle. The result indicates that the simultaneous excitations of the multiple plasmons are involved in the observation.

Abstract Optical non-thermal excitation of magnetostatic spin waves (MSWs) is performed in magnetophotonic crystals (MPCs) and plasmonic structures. It is demonstrated that when excited at the resonance of the MPC the magnetization precession amplitude is enhanced by a factor of 2.5, while the local inverse Faraday effect can be increased up to 5.6 times compared to a stand-alone magnetic film. The origin of the enhancement is the concentration of the electromagnetic energy within the magnetic layer due to the optical confinement.

Ultra-short laser pulses is one of the promising ways for local optical excitation of magnetization dynamics [1], which is highly in demand for various applications. The local spin manipulation is performed only at the light excited area that can be within submicron range and at time scale of femtoseconds. Complex light-matter interaction depends on the type of material studied and light energies used. In iron-garnets, prominent materials for magnonics that demonstrate small damping, non-thermal optical excitation can be performed by photoinduced magnetocrystalline anisotropy, implying the absorption of photons, or via inverse Faraday effect (IFE). Both of the non-thermal excitation types are characterized by the dependence on pump pulses polarization. It has been shown that optical confinement provides a significant enhancement of the direct magnetooptical effects [2] (Faraday rotation, circular and linear birefringence, non-reciprocity).

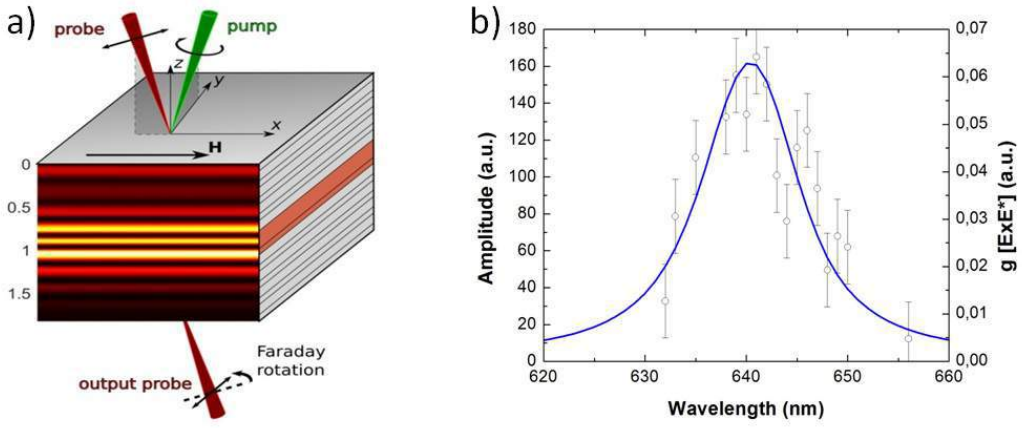

Figure 1 a) Schematic representation of the experiment. Generation of spin waves in magnetophotonic crystal, formed by Bragg mirrors and a transparent magnetic dielectric sandwiched between them. **b)** Amplitude of the magnetization precession and effective field of the inverse Faraday effect versus wavelength of the pump beam.

Micro-structured materials with periodically modulated dielectric constant the so-called magnetophotonic crystals (MPC) have demonstrated the increase of the Faraday effect. Magnetoplasmonic crystals enhance Faraday effect, transversal magneto optic Kerr effect and others up to the orders of a magnitude [3]. It is consistent to expect the possibility of the inverse effects increase in specially tailored periodic structures.

In this work, magnetostatic spin waves (MSWs) have been excited in micro-structured materials (Figure 1). It has been shown that when excited at the resonance of the MPC the magnetization precession amplitude can be enhanced by a factor of 2.5, while the local IFE can be increased up to 5.6 times compared to a stand-alone magnetic film of the same thickness and composition. Alternatively IFE can be enhanced in plasmonic nano-antennas, structures formed by slits or holes in gold-layer or Au-nanoparticles deposited on a magnetic dielectric. Optimal structure parameters that provide effective MSW excitation are found using rigorous coupled-wave approximation. The energy of electromagnetic radiation localized under a nanoparticle is transferred to magnons, which leads to an increase of the effective magnetic field. In both cases optical confinement provides the local impact on the magnetization at spatial scale of several tens of nanometer, which is very promising for holographic memory and quantum information.

New features of photonic Dirac cones on the Γ point

Kazuaki Sakoda
National Institute for Materials Science
sakoda.kazuaki@nims.go.jp

Abstract- We derive a necessary and sufficient condition for the photonic Dirac cone on the Γ point of periodic metamaterials and photonic crystals. We formulate a Green tensor to show that the propagation direction of the Dirac-cone modes can be controlled by the polarization of the incident wave. We analyze lossy slab modes to show that their group velocity exceeds the light velocity, which apparently contradicts special relativity. This problem of superluminal propagation is resolved by considering the energy velocity.

The Dirac cone is originally an idea to describe the energy spectrum of massless particles. It is characterized by the isotropic linear dependence of their energy on their momentum. A similar energy spectrum was discovered in the dispersion relation of periodic metamaterials in the Brillouin-zone center in the microwave region.[1-4] Such device structures were named CRLH (composite right-/left-handed) transmission lines. To materialize the linear dispersion, it was necessary to make two dispersion curves of the CRLH transmission line degenerate in the zone center, or the Γ point of the Brillouin zone, by the fine tuning of the device structure.

Later the materialization condition of the Dirac cone in the dispersion relation of periodic metamaterials and photonic crystals was clarified for general cases by tight-binding approximation[5-7] and the k-p perturbation theory.[8,9] Mei et al.[8] discussed the formation of the Dirac cone, the Berry phase, and mapping into the Dirac Hamiltonian for phononic and photonic crystals, while the present author derived the sufficient condition for the Dirac-cone formation.[9] Because the effective refractive index is equal to zero at the vertex of the Dirac cone,[10] which is called the Dirac point, quite curious phenomena and their applications are expected. We can also expect novel phenomena like the control of the propagation direction by the polarization of the incident wave.[11]

For the photonic Dirac cone to be materialized, two electromagnetic eigenmodes with particular symmetry combinations should have the same frequency in the Brillouin-zone center by fine-tuning the structure and/or the material parameters. Examples of the photonic Dirac-cone dispersion relation are shown in Fig. 1 where ω_r denotes the Dirac-point frequency. The Dirac cone with an auxiliary quadratic dispersion surface is realized, for example, in metamaterials of the C_{4v} symmetry, while the double Dirac cone is realized in the triangular-lattice metamaterials of the C_{6v} symmetry. The dispersion relation was derived by the first-order perturbation based on the k-p perturbation theory and the group theory.[9] For example, in the case of the degeneracy of an E mode and an A_1 mode in the two-dimensional square lattice of the C4v symmetry, the eigen frequency around ω_r is obtained by diagonalizing the following perturbation matrix, where *b* is a sample parameter.

$$\mathrm{C}_{\mathbf{k}}^{(EA_1)} = \begin{pmatrix} 0 & 0 & bk_x \\ 0 & 0 & bk_y \\ b^*k_x & b^*k_y & 0 \end{pmatrix}$$

By solving the eigen problem, we obtain three solutions, two of which give the isotropic linear dispersion.

We apply our theory to photonic crystal slabs (Fig. 2) to show that the propagation direction of the Dirac-cone mode in the slab can be controlled by the polarization of the incident wave. For this purpose, we

derive the retarded Green tensor to describe the optical response of the Dirac-cone modes.[11] We analyze the dispersion and the propagation speed of the slab Dirac-cone modes with diffraction loss to show that their apparent group velocity can be larger than the light velocity in free space, *c*, which contradicts special relativity. This problem of superluminal propagation is resolved by considering the energy velocity, which remains smaller than *c*.[12]

Radiative heat-transfer between metallic gratings using adaptive spatial resolution

R. Messina, A. Noto, B. Guizal, and M. Antezza (Invited speaker)
Laboratoire Charles Coulomb - UMR 5221 CNRS, University of Montpellier, Montpellier, France

Contact address: mauro.antezza@umontpellier.fr

Abstract- We calculate the radiative heat transfer between two identical metallic one-dimensional lamellar gratings [1]. To this aim we present and exploit a modification to the widely-used Fourier modal method [2], known as adaptive spatial resolution [3], based on a stretch of the coordinate associated to the periodicity of the grating. We first show that this technique dramatically improves the rate of convergence when calculating the heat flux, allowing to explore smaller separations. We then present a study of heat flux as a function of the grating height, highlighting a remarkable amplification of the exchanged energy, ascribed to the appearance of spoof-plasmon modes, whose behavior is also spectrally investigated. Differently from previous works, our method allows us to explore a range of grating heights extending over several orders of magnitude. By comparing our results to recent studies we find a consistent quantitative disagreement with some previously obtained results going up to 50%. In some cases, this disagreement is explained in terms of an incorrect connection between the reflection operators of the two gratings.

The Fourier Modal Method with Adaptive Spatial Resolution under conical mounting

B. Guizal
Laboratoire Charles Coulomb - UMR 5221 CNRS, University of Montpellier, Montpellier, France

corresponding author: bguizal@montp2.fr

Abstract- The Fourier Modal Method [1] equipped with the concept of Adaptive Spatial Resolution [2] (FMMASR) is derived and presented, in details, in the case of lamellar diffraction gratings under conical mounting. In the present work, we focus on efficiency and reduction of the numerical load. Therefore, special care is given to homogeneous media where we exploit two properties: (i) in such media the Eigen-problem can be simplified and reduced to its half size and (ii) once the solution is obtained for a given homogeneous medium, the solution for any other homogeneous medium can be readily deduced and with extremely low computational cost.

Abstract- The Fourier Modal Method (FMM) [1] is used to obtain the band structure of a 1D graphene based photonic crystal. The approach is valid for the first bands where the conductivity of graphene can be described by a Drude model. The structure consists of graphene layers periodically inlayed in a homogeneous lossless dielectric host medium. In the model, the graphene sheet is considered as layer with atomic thickness and its dielectric permittivity is deduced from its surface conductivity. Under these conditions, we show that it is possible to use the FMM in order to obtain a polynomial eigenvalue problem allowing the computation of the band structure. Furthermore, we explore the spatial field-structure of certain modes.

Analytical T-matrix solution to the 1D grating diffraction problem.

A. A. Shcherbakov

Moscow Institute of Physics and Technology, Russia
alex.shcherbakov@phystech.edu

Abstract— The combination of two rigorous methods, namely, the C-method and the true modal method for 1D grating diffraction problem allows one, first, to analytically prove the validity of the Rayleigh expansion in the grating region, and, second, to obtain a general analytical solution to the diffraction problem in form of the T-matrix, which elements are written as quadratures involving grating profile function.

The Rayleigh hypothesis (RH) was a subject of intensive debates for quite a long time. Even after establishment of theoretical limits on the validity of the RH [**?**, **?**, **?**, **?**, **?**, **?**] in a series of works, there was evidence calling into question these limits [**?**, **?**]. Moreover, article [**?**] demonstrated that the RH can be successfully used to analyse diffraction by deep sinusoidal gratings, and even for the correct near field calculations. In [**?**] there were formulated a concept and basic steps for an analytical proof of the RH. This work implements these ideas and demonstrates that the association of a basic Chandezon method [**?**] idea, namely, the coordinate transformation, which does not depend on any hypothesis, and the True Modal Method technique [**?**] - a construction of the modal basis of the true permittivity and permeability profile - leads to the required proof, and yields an analytical solution to the grating diffraction problem.

Consider a 1D grating of period Λ which profile is defined by piecewise twice differentiable function $f(x)$. Suppose that this profile defines the interface between upper and lower homogeneous isotropic media with dielectric permittivity and magnetic permeability ε_a, μ_a, and ε_b, μ_b respectively. Then, it is derived that components of the T-matrix of this grating relating upward (sign "+") and downward (sign "−") propagating harmonics of indices p and q at both sides of the interface are given by

$$\begin{aligned}
T_{pq}^{++} &= \zeta_{pq}^{+}\frac{1}{\Lambda}\int_0^{\Lambda}\exp\left[j(q-p)Kx + j(\beta_q^a - \beta_p^b)f(x)\right]dx,\\
T_{pq}^{+-} &= \zeta_{pq}^{-}\frac{1}{\Lambda}\int_0^{\Lambda}\exp\left[j(q-p)Kx - j(\beta_q^a + \beta_p^b)f(x)\right]dx,\\
T_{pq}^{-+} &= \zeta_{pq}^{-}\frac{1}{\Lambda}\int_0^{\Lambda}\exp\left[j(q-p)Kx + j(\beta_q^a + \beta_p^b)f(x)\right]dx,\\
T_{pq}^{--} &= \zeta_{pq}^{+}\frac{1}{\Lambda}\int_0^{\Lambda}\exp\left[j(q-p)Kx - j(\beta_q^a - \beta_p^b)f(x)\right]dx.
\end{aligned} \tag{1}$$

Here $K = 2\pi/\Lambda$, $\beta_q^{a,b} = \sqrt{\omega^2\varepsilon_{a,b}\mu_{a,b} - k_{x,q}^2}$ with $k_{x,q} = k_x^{inc} + Kq$, and factors $\zeta_{pq}^{\pm}$ are rational functions of $\varepsilon_{a,b}$, $\mu_{a,b}$, $\beta_{p,q}^{a,b}$, and $k_{x;p,q}$, different for the TE and the TM polarization. The Rayleigh decomposition

$$F_y = \begin{cases} \displaystyle\sum_{p=-\infty}^{\infty} b_p^{+}\exp\left(jk_{1p}x + j\beta_p^b z\right) + b_p^{-}\exp\left(jk_{1p}x - j\beta_p^b z\right), z \le f(x), \\ \displaystyle\sum_{p=-\infty}^{\infty} a_p^{+}\exp\left(jk_{1p}x + j\beta_p^a z\right) + a_p^{-}\exp\left(jk_{1p}x - j\beta_p^a z\right), z > f(x), \end{cases} \tag{2}$$

is also proven to be valid (here F_y stands for transverse field).

Despite one often searches for a solution to the diffraction problem in S-matrix form, the obtained result presents certain advantages. First, it opens an opportunity to transform the T-matrix analytically. Second, it displays the structure of the T-matrix assisting in its smart transformation. Third, in some cases (like the inverse problem, for example) the solution in the form of a T-matrix can be sufficient.

Abstract-Biochemical detection applications and on-chip optical interconnects are examples of the useful applications considered for integrated photonic platforms dedicated to the UV and visible spectral range. This achievement requires the realization of efficient and compact microlaser sources that can be coupled to optical waveguides and are compatible with photonic circuitry. We develop a cost-effective practical approach relying on the controlled growth of thin AlN buffer layers on silicon substrates, followed by the growth of multiple quantum wells (MQW) GaN/AlN (for UV operation), or InGaN/GaN MQWs (for violet and blue operation) with a high radiative efficiency up to T=300K. This unique Nitride-on-Silicon platform could be released into a membrane by the selective under-etching of the silicon substrate.

We present a series of microdisk lasers operating at room temperature under pulsed optical excitation over a broad spectral range extending from 275nm to 470nm. All microdisks present a Q factor above 1000 and reach 4000 in the best resonators. We are able to investigate the gain threshold of the different active layers. The microlasers operate under pulsed optical excitation, and the lasing threshold is reduced by a factor 10 from deep-UV GaN/AlN microdisks to the violet InGaN/GaN ones. This work allows us to expect a variety of integrated photonics applications, including for example multi-color integrated laser sources: we demonstrate here the versatility of this nitride-on-silicon platform, and the first realization on this platform of efficient active layers for a tunable lasing action over a 200nm broad UV to visible spectral range. Far and near field optical properties of large scale spherical microparticle arrays

A. A. Shcherbakov[1], **T. Kaempfe**[2], **and Y. Jourlin**[2]

[1]Moscow Institute of Physics and Technology, Laboratory of Nanooptics and Plasmonics, Dolgoprudnyi, Russia

alex.shcherbakov@phystech.edu

Abstract— The work is devoted to experimental and theoretical study of the far and the near field optical properties of 2D monolayer arrays of silica microspheres. In the far field results of measurements of angular dependent diffraction are compared with simulation of realistic monolayers performed by the Generalized Source Method. In the near field simulation results are used to predict geometric parameters of microscale arrays obtained by the colloidal lithography.

Ordered monolayer arrays of silica microspheres attract high interest due to promising applications in photovoltaics, mainly for light trapping functionality. They were demonstrated to increase outcoupling efficiency in organic light-emitting diodes and to possess attractive antireflection properties useful for solar cells. Layers of silica microspheres often represent highly ordered structures thus making diffracted light to be strongly angular dependent. For applications it is then important to be able to carefully predict and optimize both spectral and angular optical characteristics of arranged silica particles.

For preparation of experimental samples we used the Langmuir-Blodgett technique. It is one of the most efficient methods for preparing regular monolayers of microspheres over large areas with homogeneous deposition of the particles. First, 1 μm diameter spherical silica particles were suspended in butanol (concentration was 35 mg/ml). After ultrasonic dispersion during 30 min, the particles were injected into a carrier fluid and brought to liquid surface to form a monolayer array with the aid of surface tension forces. The quality of the self-assembly of particles within the transfer zone was controlled by a camera with a custom image processing software [**?**].

In this work we first present experimental measurements of diffraction efficiency angular dependency for plane wave diffraction on high-quality ordered monolayer of silica microspheres, which supplement data previously published by other authors. Simulation of experimental results was performed by a highly efficient rigorous diffraction calculation method [**?**] taking into account realistic microsphere arrangement and particle size dispersion. This allowed us to obtain reasonably good correspondence between experiment and theory, and to qualitatively explain the shapes of the experimental curves, as well as the observed differences between experimental and theoretical results. Comparison of simulations of freely suspended monolayers and monolayers on a substrate revealed a grating anomaly nature of peculiarities of the obtained curves. Furthermore, simulation of substrate interference effects allowed us to carefully predict the microscopic structure of micropillar arrays obtained with the colloidal lithography technique.

Treatment of the nonconvergence of the Fourier modal method and the C method arising from field hypersingularities

Haitao Liu[1*], Yanpeng Mei[1], Junda Zhu[1], and Ying Zhong[2]

[1]Key Laboratory of Optical Information Science and Technology, Ministry of Education, Institute of Modern Optics, Nankai University, Tianjin 300350, China

Abstract-Perturbative approaches are reported to overcome the recently observed nonconvergence of the Fourier modal method (FMM) and the coordinate transformation method (C method) arising from field hypersingularities at lossless metal-dielectric edges. Perturbations of profile or refractive index are applied for representative examples of triangular or parallelogram (or rectangular) gratings, respectively. However, for vanishing perturbations, the converged values of the diffraction efficiency can approach a fixed value for some numerical examples but cannot for other examples.

For modeling diffraction gratings the FMM is perhaps the most widely used method due to its simplicity and versatility. Thanks to previous revolutionary works such as the correct Fourier factorization rules and the scattering-matrix propagation algorithm, the convergence and stability of the FMM have been dramatically improved. Despite of this, the FMM still shows nonconvergence for binary gratings with certain sets of grating parameters [1]. This nonconvergence of the FMM is then attributed to the existence of irregular field singularities [2] (or called hypersingularities [3]) at lossless metal-dielectric right-angle edges, for which the transverse electric field components approach infinity as ρ^{-1} near the edge (ρ being the distance to the edge). The nonconvergence of the FMM and the C method for gratings with lossless metal-dielectric arbitrary-angle edges is further proposed and attributed to the field hypersingularities [3].

Here we propose perturbative treatment to overcome the nonconvergence of the FMM and the C method arising from the field hypersingularities [4,5]. Triangular gratings and parallelogram (or rectangular) gratings are taken as representative numerical examples. For triangular gratings with hypersingularities, we replace the sharp edge with a rounded edge to remove the hypersingularities at the edge, and then observe the convergence of diffraction efficiency with the C method. However, by gradually decreasing the radius of the rounded edge, the converged values of the diffraction efficiency do not approach a fixed value (the expected value for the sharp edge) [Figs. 1(c)-(d)]. For the example of parallelogram (or rectangular) gratings with hypersingularities, we smooth the grating boundaries with a medium of gradually varied refractive index to remove the hypersingularities. With the decrease of the width of the perturbative medium, the converged values of the diffraction efficiency can approach a fixed value for some numerical examples [Figs. 1(a)-(b)] but cannot for other examples of parallelogram gratings. While for rectangular gratings the converged diffraction efficiency can always approach a fixed value [4]. We also find that for deep sub-wavelength parallelogram or rectangular gratings, the FMM tends to converge even with the existence of hypersingularities, and the converged value of diffraction efficiency consists well with the theoretical value predicted by the effective medium theory.

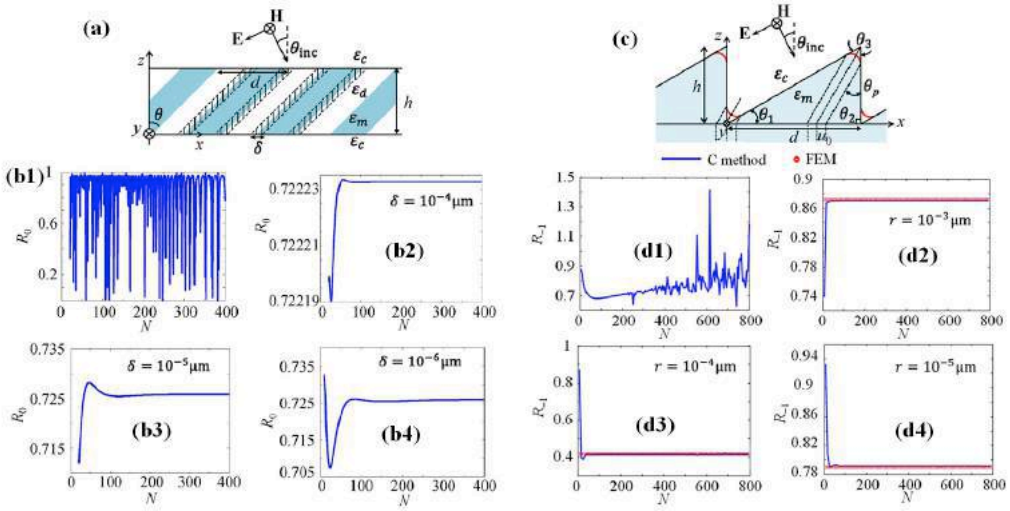

Figure 1 (a) Treatment to overcome the nonconvergence of the FMM for parallelogram or rectangular gratings by smoothing the sharp lamellar boundaries with a gradually-varied medium (with a width δ). (b) Convergence test of the 0th-order reflection efficiency R_0 for the parallelogram grating with different δ. The grating parameters are the same as those in Fig. 6(b) of [3], and (b1) shows the reproduced nonconvergence results. (c) Treatment to overcome the nonconvergence of the C method for triangular gratings by replacing the sharp edge with a rounded edge (with a radius r). (d) Convergence test of the -1st-order reflection efficiency R_{-1} for asymmetric triangular gratings with different r. The grating parameters are the same as those in Fig. 7(b) of [3], and (d1) shows the reproduced nonconvergence results.

Numerical modeling of biperiodic structures by a vertical mode expansion method

Hualiang Shi[1,*], **Ya Yan Lu**[2]

Abstract— The vertical mode expansion method (VMEM) is a special numerical method tailor-made for analyzing the scattering of light by structures with multiple finite-height cylindrical objects. In this paper, a VMEM with 2D boundary integral equations is implemented for biperiodic structures consisting of cylindrical objects with arbitrary cross sections.

Due to the existing nanofabrication techniques, many photonic structures can be considered as combinations of numerous cylindrical inclusions. Mathematically, in a Cartesian coordinate system $\{x, y, z\}$ where the z-axis is perpendicular to the substrate surface, a typical cylindrical region is $S_l = \{(x, y, z) : (x, y) \in \Omega_l, -\infty < z < \infty\}$, where Ω_l is the cross section of the l^{th} cylindrical object, and the material parameters depend only on z in S_l. Taking advantage of the periodicity of the entire structure, the problem can be considered only in a unit cell. In the simplest case, a unit cell consists of two regions S_0 and S_1, and we assume S_0 encloses S_1. Examples of a biperiodic structure and its unit cell are shown in Fig. 1. In the vertical mode expansion method

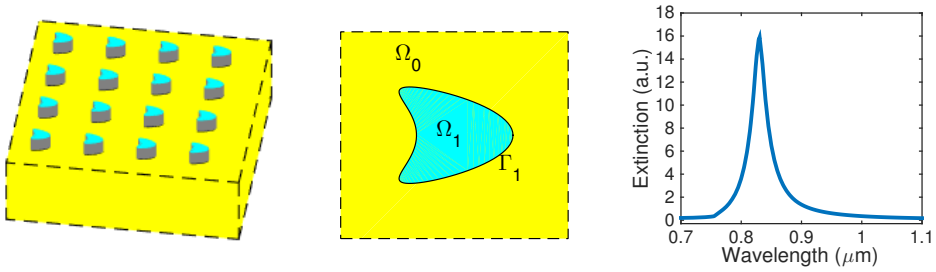

Figure 1: Left: a periodic array of particles on a substrate. Middle: cross section of a unit cell. Right: extinction spectra of the left periodic array of gold elliptic cylinders for a normal incident plane wave.

(VMEM) [1, 2], the field in S_l is expanded in the vertical modes $\phi_j^{(l,p)}(z)$ (where $p = e$ or $p = h$ for two different polarizations) with corresponding expansion "coefficients" $V_j^{(l,p)}(x, y)$. The unknown $V_j^{(l,p)}$ satisfies a 2D Helmholtz equation in Ω_l. An important step in the VMEM is to solve a linear system for all $V_j^{(l,p)}$ or $\partial_\nu V_j^{(l,p)}$ on Γ_l, where Γ_l is the boundary of Ω_l and ν is a unit normal vector to it. In a unit cell, the linear system only need to be set up on Γ_1. To achieve this, we calculate the Neumann-to-Dirichlet operator $\mathcal{N}_j^{(l,p)}$ which maps $\partial_\nu V_j^{(l,p)}$ to $V_j^{(l,p)}$ on Γ_1 for $l = 0, 1$. The operators can be obtained by the boundary integral equation (BIE) method [2]. Particularly, for the domain Ω_0, we need to incorporate the quasi-periodic boundary conditions in the BIEs. To illustrate the method, a numerical example is shown in Fig. 1.

The VMEM gives 2D formulations for 3D problems, and it is relatively simple to implement and highly competitive in terms of efficiency and accuracy.

Abstract-We identified two different scattering processes characteristic of the low- and high wavelength ranges of optical reflection spectra of butterfly wing scales. Our computer simulations based on the solution of 3D Maxwell equations helps to understand the connection between the wing scale nanoarchitecture and the measured optical spectrum.

The color of various butterflies may originate not only from pigments, but from photonic nanoarchitectures [1], too, found in the scales covering their wings. Most important tools to analyze the structure of wing scales are top-view Scanning Electron Microscopy (SEM) and cross sectional Transmission Electron Microscopy (TEM) imaging. Both methods give only two dimensional (2D) information and it is a non trivial task to decompose the real three dimensional (3D) structure of the scale based on these 2D images. We performed extensive full 3D Maxwell equation calculations to reveal the connection between the 3D structure and the optical spectrum, utilizing many different scale structure models, for the so called "pepper-pot" scale structure, typical of Lycaenid butterflies [2,3]. Our simulations showed that different scattering processes determine the spectrum in different wavelength ranges. For large wavelengths (>350 nm) the optical reflection can be well described by a corresponding effective multilayer model and the peak positions are well represented by a simple first order scattering approximation [4]. One has to include second order scattering processes inside the layers, however, in order to correctly reproduce the small wavelength side of the spectrum (<350 nm). Hence, to calculate the large wavelength part of the spectrum one needs the parameters of the layer structure, which is provided by TEM images. Detailed information on the layer structure, which is provided by the SEM images, is only necessary for calculating the small wavelength part of the spectrum.

Abstract— Metasurfaces are planar metamaterials that consist of a single or a few stack of subwavelength thickness metal-dielectric layers. They could be periodically structured or not with subwavelength scale patterns according to the transverse directions. The strong interaction between an electromagnetic field components and these surfaces, exhibits some properties that could not be found in nature. These artificial properties strongly depend on the shape and arrangement of the elementary patterns and they are often linked to a plasmon resonance phenomenon. Metasurfaces working in the visible range generally consist in periodical arrangments of plasmonic resonators. These resonators are inherently muti-scale, as their responses relie on the excitation of resonances in very small gaps, like in the case of gap-plasmon resonators or for bow-tire antennas. The simulation of their electromagnetic response can be very challenging and may be successfully treated thanks to a modal method holding the complexity of the patterns shape. Here we present a polynomial modal method [1, 2, 3, 4] that is particularly suited for the simulation of metallic structures. Advanced coordinates transformation such as matched coordinates and tilted coordinates are included in order to hold efficiently the complexity of the geometry without any approximation. Such a tool even offers the possibility to control the way the resonators are periodically arranged.

Tailoring fluctuation-induced interactions with nanostructures.

F. Intravaia

Max-Born-Institut, 12489 Berlin, Germany
francesco.intravaia@mbi-berlin.de

Abstract— We investigate how the strength and the functional dependence of fluctuation-induced interactions are altered by acting on the geometry and the material properties of the system's constituents.

In the constant race towards miniaturization driven by modern technologies, phenomena which are irrelevant at the macroscopic level become more and more important for systems with micro- and nano-scopic size. A large class of these effects are fluctuation-induced interactions which find their origin in the classical and quantum fluctuations of the system. Paradigmatic examples are van der Waals forces and the Casimir effect [1]. The understanding and control of these interactions is essential for opening new avenues for fundamental investigations and for designing new and better performing nanodevices.

Recent investigations have shown that tailoring the geometry and leveraging on the material properties of the system can lead to profound modifications of these phenomena, offering an additional knob to study and to harness these interactions [2]. Along these lines, in this contribution we review some recent results addressing equilibrium and nonequilibrium fluctuation-induced interactions with atomic and mesoscopic systems (e.g. MEMS) [3, 4, 5].

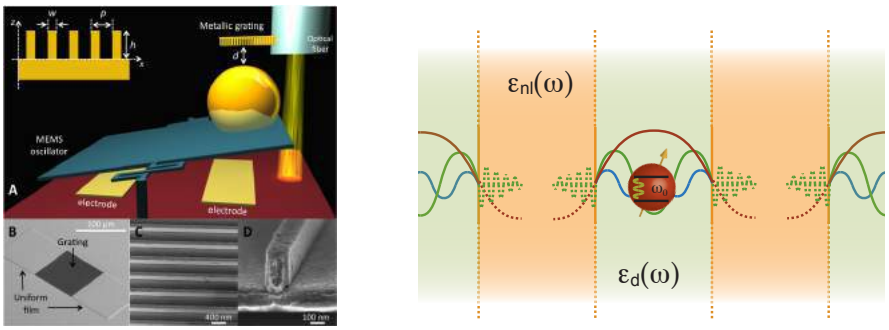

Figure 1: Two examples of nanostructured systems which were used to tailor fluctuation-induced interactions. (Left) Schematic drawing of an experimental configuration used to measure the Casimir force between a gold-coated sphere and a gold 1D grating [3]. (Right) Scheme of an atomic system embedded in the metal/dielectric layered material. This system was analyzed in a framework capable of including local-field corrections in (weakly absorbing) dielectric systems and the nonlocal optical properties of metals [5].

Abstract-Through nonlinear crystals, second and third harmonic signals are obtained. However, such signals are limited to low efficiency as an output. Metamaterials can be used to generate harmonic signals corresponding to nonlinear behaviors. Here, we introduce a new strategy how to amplify the second and third harmonic signals via magnetic metamaterials. We theoretically and numerically show that the higher induced polarization currents with harmonic signals can be achieved by the grating structure and an actual model is suggested and performed.

Metamaterials which consists of artificial structures under sub-wavelength scale have been well studied and gave rise to unusual properties such as negative refractive index [1], invisibility cloak [2], super-resolution imaging [3] and metasurfaces [4]. In addition, nonlinear behaviors based on metamaterials have been researched. Here, we focus on second and third harmonic generation caused by nonlinear behaviors. Conventional second and third harmonic signals are so weak and limited to low efficiency. To overcome such disadvantages, we introduce a new strategy how to amplify the second and third harmonic signals via magnetic metamaterials. First of all, magnetic metamaterials show their nonlinear behaviors at the magnetic resonance, indicating a higher absorption coefficient and higher induced polarization currents [5, 6]. So, the enhanced second and third harmonic signals can be created by the current loop composed of nanostrip metamaterials shown in Fig 1(a). The nanostrip has inversion symmetry in x-direction and no inversion symmetry in y-direction, resulting in third and second harmonic signals, respectively [6]. It is well shown in Fig 1(c) that the x component of polarized current generates the third harmonic signals and the y component of that current generates the second harmonic signals. Moreover, we recognized that the presence of a grating in the metamaterial structure are absolutely related to the good performance of the second and third harmonic signals. The grating has the same width with a unit cell of magnetic metamaterials and is embedded under the glass substrate, which is depicted in Fig. 1(b). We can readily compare the transmission between no grating structure and grating-based structure in Fig. 1 (c) and (d). The amplitude of the second and third harmonic signals in grating-based structure is almost doubled and quadrupled, respectively, compared to the case of no grating structure. We show that enhanced second and third harmonic signals as nonlinear behaviors are indeed achieved by the grating structure from magnetic metamaterials. Finally, we fabricate and measure the model suggested in Fig 1(b) in practice and show whether the amplified second and third harmonic signals are present or not.

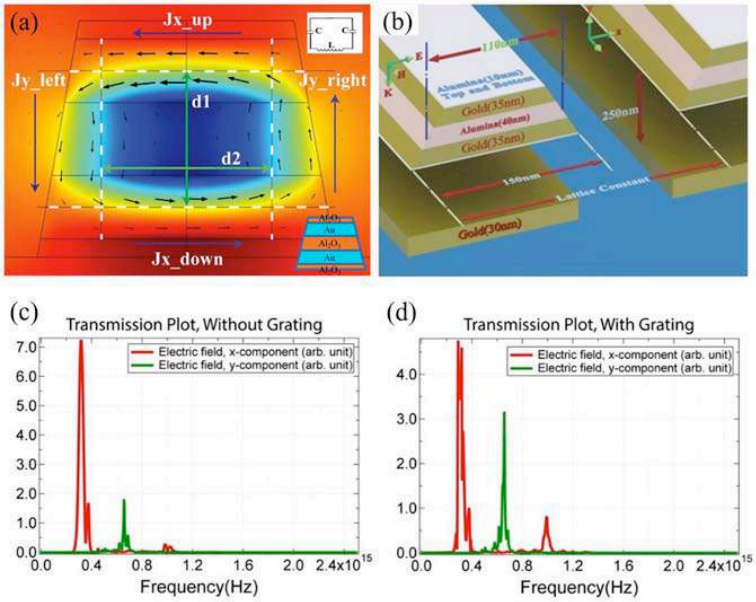

Figure 1. (a) Magnetic field distribution and electric field displacement (black arrows) in magnetic frequency. The external magnetic field induces a current loop which can be divided into two orthogonal groups. (b) Scheme of the actual model. The model is a 5-layer trapezoid placed on a glass substrate upon a grating. The grating is embedded under the glass substrate. (c) and (d) indicate the second and third harmonic signals in the transmitted waves with no grating structure and grating-based structure, respectively.

Experimental realization of ITO based mode-multiplexed nanophotonic modulators

H. Jeong[1], I. Kim[1], and J. Rho[1,2,3*]

Abstract-Photonic and optical devices have been improved using the state of the art nanofabrication techniques. Also, photonic modulators have been affected by the nanotechnology, so we has already theoretically designed mode-multiplexed modulator using indium-tin-oxide (ITO) pattern which can distinguish one modes from waveguide modes. Thus this research is to verify that the device can modulate two wave modes by fabricating and experiment the designed structure. The results improve waveguide system multiplying functionality-per-area.

Recently, as nanofabrication enables to create metamaterials and meta-devices, photonic devices have developed with the progress of nanotechnology. Similarly, wave mode modulators have advanced to increasing efficiency and improving performance using transparent conducting oxides (TCOs) [1]. TCOs, such as ITO and aluminum zinc oxide (AZO), are transparent conductive materials which have the both metal and optical properties in near infrared range (NIR). Also, the TCOs' optical properties can be changed by controlling carrier concentration [2]. We used this controllable optical transmission of ITO to create modal dichroism for designing the mode-multiplexed modulator [3]. The modal dichroism obtained by the modulator increase the bandwidth of modulation and functionality-per-area. This research is to fabricate the designed device and prove that it can modulate two wave modes. The schematics of the modulator is shown in Fig. 1(a), and the structure is fabricated following method. After the silicon etching of silicon on insulator (SOI), three patterns are deposited in order of ITO, silicon dioxide and gold using E-beam evaporator as Fig. 1(b), (c). Before deposition, the specimen should be aligned using overlay process. The alignment error is less than 20nm and reproducibility is more than 75% [4], so three alignments are possible to deposit three materials in accurate location on Si layer. Therefore three panels of ITO respond separately to the signal from gold panels insulated with 20nm silicon dioxide layer. The charge density of the ITO panels along vertical axis should be same with the theoretical results in constant doping concentration and voltage of two panels. Thus, annealing is required to stabilize the state of the ITO panel, and defining annealing condition is important to this step. Waveguide input and output section is created by engraving gratings using focused ion beam (FIB) milling or electron beam lithography (EBL). The section should be fabricated to transmit waves maintaining enough propagation efficiency, so the section has already been prepared before the main manufacturing process. Total device image is shown in Fig. 1(d). If the device is fabricated following this method, the device can modulate two modes independently. This means that modal dichroism can be realized and functionality-per-area is multiplied twice. Therefore, when it is required to select

one mode from two or more modes, the designed device is more efficient than other devices. Also, the method of three times overlay process help fabricate other structure design requiring several overlay process.

Abstract- Hyperlens is an optical imaging method for super-resolution imaging. Due to the unique hyperbolic dispersion relation of hyperlens, sub-diffraction information of objects can be propagated to far-field. Here, we propose a new design consisting of multiple hyperlenses arranged in hexagonal arrays in large scale for high-throughput imaging. With proposed design, we report the experimental demonstration of sub-diffraction imaging on hyperlenses. Biomolecular samples are imaged by visible light through the hyperlens array with resolution down to diffraction limit.

Super-resolution imaging technology has brought interest as a useful tool for observation in biology and nanotechnology [1]. This technology helps to overcome the diffraction limit of conventional imaging system, wherein two objects located closer cannot be resolved clearly in the far field. Recent progress in metamaterials, which are artificial structure never existing in nature, are able to image beyond the diffraction limit. Hyperlens is the kind of special artificial metamaterials with hyperbolic dispersion that can resolve small objects in the optical far field [2-5]. Previous hyperlens research results have been achieved to resolve features down to sub-diffraction limit in visible range [6], still have difficulty to the use of hyperlenses in practical applications. Here, we propose a new design consisting of multiple hyperlenses arranged in arrays in wafer scale for high-throughput imaging and robust to sample positioning. With proposed hyperlens array, we show the experimental result of super-resolution imaging on hyperlenses by combining to conventional microscopy system for imaging biomolecules. Hippocampal neuron cells are imaged by visible light through the hyperlens array with resolution down to 150 nm, beyond the diffraction limit. High resolution imaging result of neuron at sub-diffraction size shows that hyperlens can be used as a useful imaging tools in biology, pathology, medical science and nanotechnology.

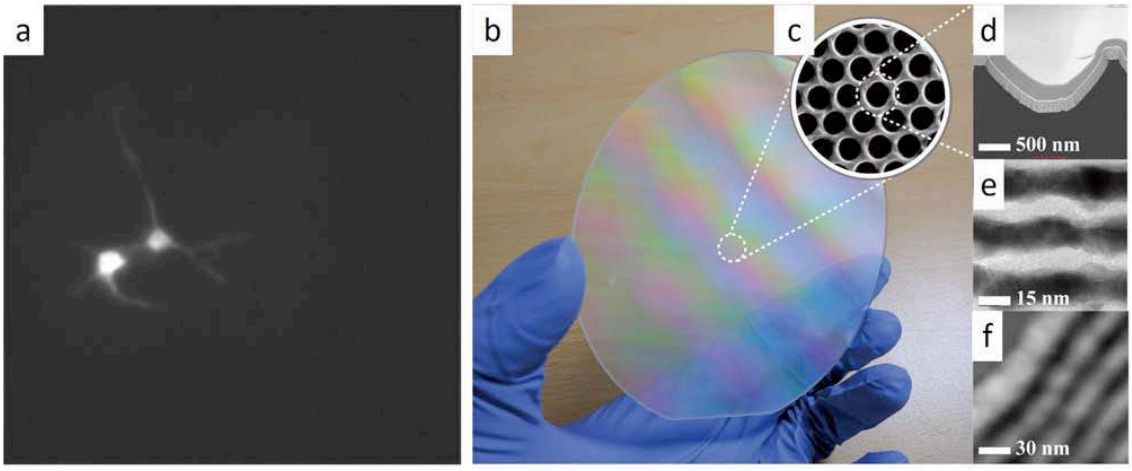

Figure 1. (a) Neuron image captured by hyperlens. (b-f) Fabricated wafer-scale hyperlens array. SEM top-view image(c), cross-sectioned TEM image (d) and magnified image of bottom and side wall region (e-f), respectively [7, 8].

Gate set tomography on electron spin qubits in diamond

Ji-Won Yun[1], Donghyuck Lee[1], and Dohun Kim[1]

[1]Department of Physics and Astronomy, Seoul National University, Seoul 08826, Korea
[*]corresponding author: dohunkim@snu.ac.kr

Abstract-Nitrogen-vacancy (NV) centers in diamond are excellent candidates for investigating quantum phenomena and constructing quantum two level system due to long coherence time even at room temperature environment [1]. To realize reliable quantum processor, it is essential to confirm performances of single and multiple qubit gates, and traditionally quantum state and process tomography are used to fully reconstruct input and output quantum states under the quantum operator in question [2,3,4]. These methods, however, are prone to state preparation and measurement (SPAM) errors, and number of measurement to complete the characterization grows exponentially with number of qubits. Gate set tomography (GST) is a newly developed method which is self-consistent and overcomes this limit [5]. In this study, we used GST to characterize the gate fidelity of electron spin qubit formed by a nitrogen-vacancy center in diamond. We briefly introduce photo physics of NV centers and GST, and we discuss the accuracy of the single qubit gates we apply to nitrogen-vacancy centers that was obtained using GST. We further discuss the characteristics of main noise source due to nuclear spin bath in diamond, which is deduced from analyzing quantum processes using GST.

Abstract-The confocal microscopy has high resolution and high efficiency, and is used as a major workhorse throughout the entire optical imaging field, and its applications range from cell imaging to quantum information experiment using single molecules. For long-term fluorescence characterization of single molecules or manipulation of single-cell as well as image acquisition, a technique capable of correcting errors caused by external temperature change, sample drift, etc. is required, and previously, a method of periodically locating the local maxima of the intensity spatial distribution such as simulated annealing was used. However, in the quantum information experiment to measure weak atomic light intensity, it is difficult to use the existing motion tracking method because the power is at the femto-watt level and the photon statistical shot noise limit. In this study, we introduce the development of a single-photon-counting three-dimensional position tracking confocal microscope, which mainly aims at quantum information optical experiment of Diamond NV center. Combined with single photon counting and software lock-in modulation, motion tracking in a single molecule level can be performed in real time. As performance verification we show an example of measuring magnetic resonance of single NV center in bulk diamond over several days at a signal to noise ratio of 20:1

Abstract- We present a low-cost multi-contrast microscope operating on a smartphone platform. Our method is based on our recently developed color-coded LED microscopy (cLEDscope). In cLEDscope, LED lights of red, blue and green color illuminate a specimen with different angle, and computation of the acquired images in each color enables bright-field, dark-field and differential phase contrast imaging in a single shot. As cLEDscope can be readily built with inexpensive LED array and CMOS camera, we noted that simple modification of a smartphone, which is already equipped with a color CMOS camera, would transform it into multi-contrast microscope. We designed and fabricated a smartphone adapter composed of micro-LED arrays and specimen stage, so that its installment on a smartphone enables multi-contrast biological imaging. Android-based App was also implemented to acquire images and perform the computation. Details of our cLEDscope adapter and experimental demonstration with biological specimens are presented.

We demonstrated cLEDscope on a smartphone platform. Integration of microLED array as an illuminator and smartphone lens as an objective transformed a smartphone into multi-contrast microscope capable of BF, DF and DPC imaging in a single shot. Its multi-contrast imaging capability was demonstrated by visualizing structures of transparent biological specimens. This method may be utilized for educational purposes as well as diagnostic imaging tool of biological specimens in resource-limited settings.

Abstract- We present in situ imaging and analysis of the penetration and dissolution characteristics of hyaluronic acid based MNs (HA-MN) with various needle heights in human skin in vivo. In contrast to other studies, we measured the actual penetration depths of the HA-MNs by considering the experimentally measured refractive index of HA in the solid state. For the dissolution dynamics of the HA-MNs, structural alteration of the MNs could be clearly visualized, and the volumetric changes of the MNs were measured.

Transdermal drug delivery (TDD) has been recently highlighted as an alternative to oral delivery and hypodermic injections. Among many methods, drug delivery using a microneedle (MN) is one of the promising administration strategies due to its high skin permeability, minimal invasiveness, and ease of injection. Many researchers have investigated applicability of MN technology to oligonucleotide delivery, insulin delivery, protein vaccine delivery, and DNA vaccine delivry. In addition, microneedle-based TDD is explored for cosmetic and therapeutic purposes, rapidly developing market of microneedle industry for general population.

To date, visualization of microneedles inserted into human skin has primarily been performed *ex-vivo*. MRI, CT and ultrasound imaging do not provide sufficient spatial resolution, and optical microscopy is not suitable because of their limited imaging depth; structure of microneedles located in 0.1~1mm into the skin cannot be visualized.

Optical coherence tomography (OCT) is a non-invasive, cross-sectional optical imaging modality for biological tissue with high spatial resolution and acquisition speed. Compared with ultrasound imaging, it exhibits superior spatial resolution (1~10 um) and high sensitivity, while providing an imaging depth of biological tissue down to 1~2 mm. Here, we present in situ imaging and analysis of the penetration and dissolution characteristics of hyaluronic acid based MNs (HA-MN) with various needle heights in human skin in vivo. In contrast to other studies, we measured the actual penetration depths of the HA-MNs by considering the experimentally measured refractive index of HA in the solid state. For the dissolution dynamics of the HA-MNs, structural alteration of the MNs could be clearly visualized, and the volumetric changes of the MNs were measured with an image analysis algorithm.

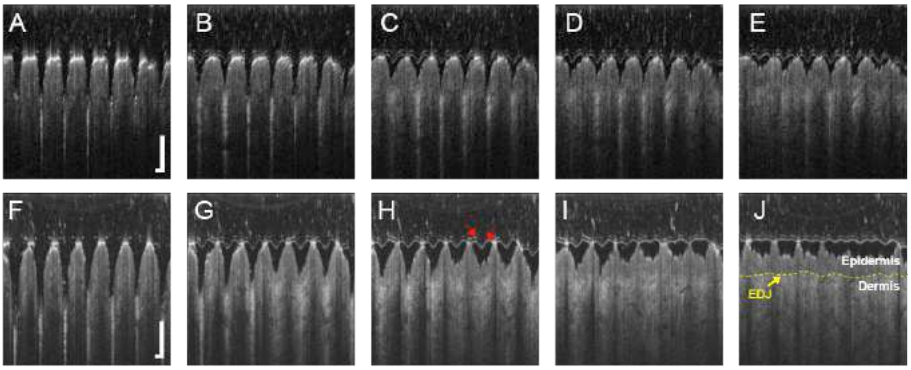

Figure. 1 Time-series image of XZ cross-sectional OCT tomography of human skin tissue from 0 to xx hour after (A-E) 350μm and (F-J) 600μm insertion. Yellow arrow pointed dashed line is epidermal dermal junction (EDJ). the upper layer is epidermis and lower layer is dermis. White line pointed by red arrows is boundary of PU. Scale bar is 500μm.

Abstract- Here, we demonstrate a strategy for single-shot quantitative phase imaging in color-coded LED microscopy. We employ a circular LED illumination pattern that is trisected into subregions with equal area, assigned to red, green and blue colors, respectively. We also describe computational model and single-shot quantitative phase imaging capability of our method by presenting phase images of calibrated phase sample and dynamics of cells.

we demonstrate single-exposure QPI in the platform of cLEDscope. The LED source pattern is configured as a circle that is trisected in equal angles with red, blue, and green colors. Image acquisition with a color image sensor and computation based on weak object transfer functions allow for the measurement of the phase distribution of transparent biological specimens. We describe a computational model and our phase estimation algorithm for such configuration. Phase measurement accuracy is validated with imaging of precalibrated silica microspheres, and the single-shot phase imaging capability is demonstrated with the static and time-lapse imaging of unlabeled cells.

In cLEDscope, a color LED array replaces the light source of a conventional microscope. Patterned LED illumination and computation with the images in red (R), green (G), and blue (B) colors realize multi-contrast and QPI. The circular LED pattern was trisected into subregions with equal area, and each region was assigned red (R), green (G), and blue (B) colors (Fig. 1). The size of the illumination pattern was set to be larger than the pupil size of the optical microscope.

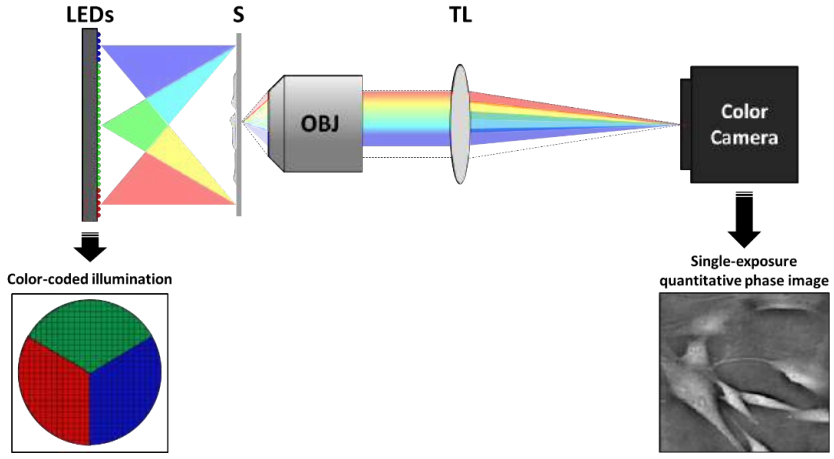

Figure. 1 Schematic of cLEDscope for single-exposure QPI. A color LED array is placed ~100 mm away from the

specimen plane (S). The LED illumination pattern is trisected into subregions with equal area. Each region is assigned red, green, and blue colors. Light passing through a transparent specimen is collected by an objective lens (OBJ), and subsequently detected by a color image sensor. Computation with R, G, and B images in combination with weak object transfer functions results in quantitative phase images. S: specimen plane, TL: tube lens.

Long-term stability enhancement of dynamic spectro-ellipsometry

D. Kim[1*], V. Dembele[1], and I. Choi[1]

[1]Division of Mechanical System Engineering, Chonbuk National University, 567 Baekje-daero, Deokjin-gu, Jeonju 54896, Korea

[*]corresponding author: dashi.kim@jbnu.ac.kr

Abstract: This paper describes a long-term stability enhancement of dynamic spectro-ellipsometry by which we can measure spectral phase difference between p- and s-polarization of the reflected wave from a periodic nano pattern or a thin film with extreme high stability. Long-term stability enhancement scheme is provided for a thin film object by analyzing the spectral ellipsometric parameter $\Delta(\lambda)$ stability.

Typical spectroscopic ellipsometric (SE) system employs mechanical rotating mechanisms or electrical modulation devices to extract the ellipsometric spectral parameters $\Psi(k)$ and $\Delta(k)$. Such time-consuming polarization modulation scheme limits the measurement speed of conventional spectro-ellipsometry. The proposed scheme is highly robust to the external noises and it enables us to extract the ellipsometric spectral parameters of large scale nano-pattern object in real time with high accuracy. [1-2] The newly proposed snapshot spectro-ellipsometry based on an interferometric spectro-polarization modulation technique has no moving parts, and it is extremely robust to external vibration due to its unique optical design. This paper describes how long-term stability of the proposed dynamic spectro-ellipsometry can be improved.

Graphene quantum dot based nanohybrid material for photoluminescence with surface plasmonic

Byeongho Park[1], Seung Won Cho[1], and Seong Chan Jun[1*]
[1]School of Mechanical Engineering, Yonsei University, Seoul, Republic of Korea
[*]corresponding author: scj@yonsei.ac.kr

Abstract- We made graphene quantum dot (GQD) and Au nanocompound as an innovative fluorescent material. Such sample showed high photoluminescence characteristics and new emission peak in the visible range, since the strong light confinement obtained from the Au nanoparticles as an antenna remarkably enhance the light absorption. Our material with nanosphere structure provided bluish-green emission after the hybridization of GQD and Au (GQD/Au). It exhibited a photoluminescence quantum yield of up to 26.9%, which is better than twice of GQD's (~11%).

We developed a novel nanosphere including GQDs and Au. The UV light was employed to assembly of GQDs and Au with photo-excited electrons and reducing capability of Au^{3+}. The size of the GQD/Au nanospheres was 150–170 nm, which is larger than that of the intrinsic GQDs (4–7 nm). The photoluminescence was improved with two emission peak for blue and green at 468 and 529 nm of wavelength. Our material, GQD/Au nanospheres showed high emission efficiency with 26.9 % of quantum yield over double of typical GQD's. Such fluorescent material can be perceived as exceptional candidates for applications such as light emitting source, optoelectronic devices, and bio-imaging with intriguing emission wavelength and intensity.

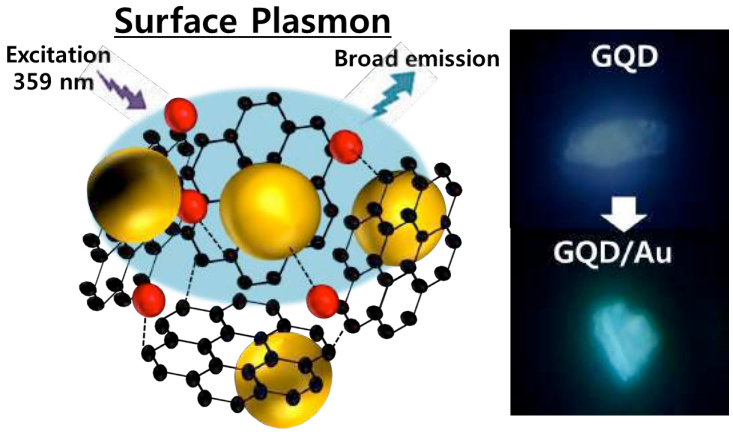

Figure 1. schematic of GQD/Au sample with enhanced photoluminescence of surface plasmon and fluorescence image of GQD and GQD/Au

Effects of micro patterns on negative refractive index of planar surface

Abstract- The metasurfaces which don't appear properties in nature have many interesting properties. Among many properties of metasurfaces, the enhancement of optical signals become more important for optical and electromagnetic field. In this paper, we changed the optical signal by using micro patterned planar surface which can control the permittivity and permeability.

Metasurfaces have many properties which don't appear in nature include anti-refractivity, anti-doppler effect, independence of wavelength and frequency, anti-phase of phase velocity and group delay, and surface plasmon. [1-3] The metasurface's characteristics were appeared by negative permittivity and negative permeability which made negative refractive index.

For negative refractive index equations,

$$n = -\sqrt{\mu \cdot \varepsilon} \tag{1}$$

where n is refractive index, μ is permeability, ε is permittivity. For negative permeability and permittivity,

$$\varepsilon_\gamma(\omega) = 1 - \frac{\omega_{pe}^2}{\omega^2 - j\omega\zeta} = 1 - \frac{\omega_{pe}^2}{\omega^2 + \zeta^2} + j\frac{\zeta\omega_{pe}^2}{\omega(\omega^2 + \zeta^2)} \tag{2}$$

$$\mu_\gamma(\omega) = 1 - \frac{F\omega^2}{\omega^2 - \omega_{0m}^2 + j\omega\zeta} + j\frac{F\omega^2\zeta}{(\omega^2 - \omega_{0m}^2)^2 + (\omega\zeta)^2} \tag{3}$$

Above (2), (3) equation, we can control permeability and permittivity by changing the wavelength or frequency and can make a negative permeability and permittivity.

Photonics techniques in biological and medical have been developed rapidly for new optical bio imaging system and control biological cells. [4,5] The enhancement of optical signal by using metasurfaces can be embedded in certain part of bio imaging system.

Characteristics of diffusive transport with use of metasurfaces for Spatial resolution of fNIRS

Z. Shoaib[1], J. H. Kim[1], HChoi[1,2], and M. Y. Jeong[1,2*]

[1]Department of Cogno-Mechatronics Engineering, Pusan National University, Busan, Korea

[2]Nano-Integrated Cogno-Mechatronics Engineering, BK21 Plus group, Pusan National University, Busan, Korea

[*]corresponding author: myjeong@pusan.ac.kr

Abstract-Functional near-infrared spectroscopy (fNIRS) is an emerging brain imaging technique. We proposed to use metasurfaces and optical antennas to control the absorption and scattering of light which are the major factors of attenuation of light in the current fNIRS system. Furthermore, with the use of metasurface, we can not only detect the ballistic component but also the diffusive and snake components which in result will enhance the receiving signal intensity of the light.

fNIRS is an optical brain imaging technique which uses near-infrared light of wavelength (690 nm to 820 nm) to detect the hemoglobin (Hb) changes in the brain [1]. Photons introduced at the scalp pass through the most of the tissue, and are either absorbed, scattered, or reflected back from oxy-Hb and deoxy-Hb. Because relatively predictable quantities of photons follow a banana-shaped path back to the surface of the skin, these can be measured using photo detectors. The drawback of current fNIRS system is that it can detect a small amount of light intensity (ballistic component only) of total transmitted intensity of light [2] as shown in Fig. 1. In this study, we will propose to use metasurfaces and optical antennas to enhance the overall performance of the optical brain imaging system by detecting ballistic, snake and diffusive components.

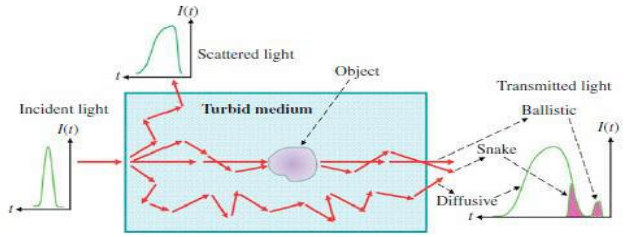

Fig. 1. Schematic diagram of light pulse propagating in a turbid medium showing the ballistic, snake and diffusive photons. Adapted from reference [8].

The two major factors for the attenuation of light in current fNIRS system are absorption and scattering [3]. Changes in the chromophore concentrations cause changes in the reflected light intensity, and are quantified using a modified Beer-Lambert law [1] to detect the ballistic component only [2] given as

$$I = I_0 \exp\{-(\mu_a + \mu_s)L\} \quad (1)$$

Where I is the detected and I_0 is the incident intensity, μ_a is the absorption coefficient, μ_s is the scattering coefficient and L is the differential path length factor.

Photonic techniques in biological and medical research depends on the development of new optically active materials that can measure, control and process biological cells and molecules at an unprecedented level [4]. For example optical nano antennas hold promise for enhancing the efficiency of photon detection, light emission, sensing and spectroscopy [5]. The optical nano antennas are introduced to enhance the transmission efficiency from the transmitter to the receiver [4]. Furthermore, with the use of optical responses of anisotropic plasmonic antennas and a new class of metasurfaces based on arrays of these antennas, we can control the constant interfacial phase gradient that can deflect light into desired direction [6]. With the use of nano structured metasurfaces we can get minimal reflectance (<0.02%) and maximal transmittance (>99.8%) for a wavelength

range, covering visible and near infrared [7]. So that by combining high transmission, low reflectivity and low absorption we can detect a high amount of transmitted intensity.

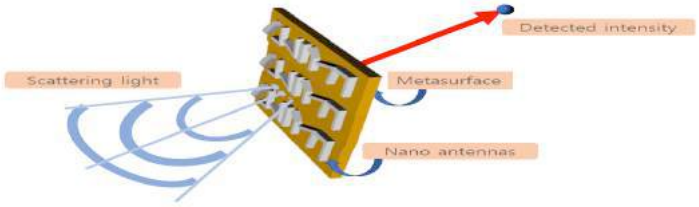

Fig. 2. Schematic of metasurface with optical nanoantennas for fNIRS signal enhancement.

Metasurfaces can be a useful tool to control these parameters which in result will enhance the intensity of the detected light. Moreover, we will use optical antennas [5] in metasurfaces to further enhance the efficiency of the light emission and detection. As discussed above, the major part of the intensity of light is consisted of diffusive component whereas the modified Beer-Lambert law only uses the ballistic component. Therefore, with the use of metasurfaces we can detect the diffusive component which will enhance the intensity of detected light given as [2]

$$I = I_0\left[\exp\{-(\mu_a + \mu_s)L\} + \frac{\Omega}{4\pi}\exp(-\mu_{eff}L)\right] \tag{2}$$

Where $\mu_{eff} = \sqrt{3\mu_a(\mu_s' + \mu_a)}$ and μ_s' is the reduced scattering coefficient. Figure 2 shows the schematic of proposed metasurface with optical antennas.

In our future work, we will use the proposed metasurfaces to develop an efficient optical brain imaging system which can be used as a better brain imaging tool as compared to the current fNIRS system. The enhancement in the detection of intensity of light will give more useful information about the functionality of the brain and this could be useful in diagnosis of many brain diseases and disorders. Furthermore, the use of metasurfaces will improve the spatial resolution of the optical brain imaging system which could be very beneficial for deep brain imaging.

Enhanced mechanical reliability of anti-reflective nanostructured polymer films prepared by sequential heat treatment process

D.-I Kim[1], N. E. Yeo[2], and M. Y. Jeong[3,*]

[1]BK21+ Nano-integrated Cogno-mechatronics Engineering, Pusan National University, Busan 46241, Korea

[2]Department of Opto-mechatronics Engineering, Pusan National University, Busan 46241, Korea

[3]Department of Cogno-mechatronics Engineering, Pusan National University, Busan 46241, Korea

[*]corresponding author: myjeong@pusan.ac.kr

Abstract-Anti-reflection characteristics and mechanical reliability of nanostructured polymer films prepared by nanoimprint process were evaluated to understand effect of the critical imprint parameters on the performance. The nanoscale cone array in hexagonal pattern was fabricated on PET and PMMA films by the thermal imprint process. Characterization of anti-reflection (AR) performance showed that the reflectance and transmittance of the prepared nanopatterned polymeric films were excellent 0.3% and 99%, respectively. However, a pencil hardness test unveiled that the nanostuructred AR film were significantly damaged by the scratch and has poor anti-scratch performance. In this study, the various thermal imprint process with heat treatment process were proposed and the effect of process on the anti-scratch performance were evaluated. It was found that the flat pressing under an elevated temperature higher than a glass transition temperature followed by an immediate cooling improves anti-scratch performance.

The anti-reflection surface treatment technology is highly required for the practical applications such as optical system, large-area display, solar cell panel and handheld devices. In typical optical system, anti-reflective (AR) surface improves the efficiency by minimizing reflection of incident light. One of conventional methods is applying multi-layer AR coating that have different refractive index and induce destructive interference of light [1]. However, it requires expensive and complicated deposition process which hinder fabrication of large-area AR surface. Thus, as an alternative solution, AR film employing nanostructure inspired by AR structures in moth eye was intensely investigated [2], [3]. Nanoimprint lithography technique allows us to fabricate large-area AR nanostructured film with high fidelity. However, nanoimprinted polymer film exposed to harsh condition showed poor mechanical reliability owing to the intrinsic mechanical property of polymer substrate. Therefore, anti-scratch performance of AR nanostructure polymer film is one of main issues should be resolved for the practical applications.

In this work, anti-reflection characteristics and mechanical reliability of nanostructured polymer films prepared by nanoimprint process with heat treatment were evaluated to improve mechanical reliability of AR film. The nanoscale cone array in hexagonal pattern was fabricated on PET and PMMA films by the thermal imprint process as shown in Figure 1(a). Figure 1(b) shows the fabricated nanoscale cone array on PMMA film. It was found that the fabricated Characterization of AR performance showed that the reflectance and transmittance of the prepared nanopatterned polymeric films were excellent 0.3% and 99%, respectively. However, a pencil hardness test unveiled that the nanostructured AR film were significantly damaged by the scratch and has poor anti-scratch performance. The continuous measurements of reflectance across the scratch

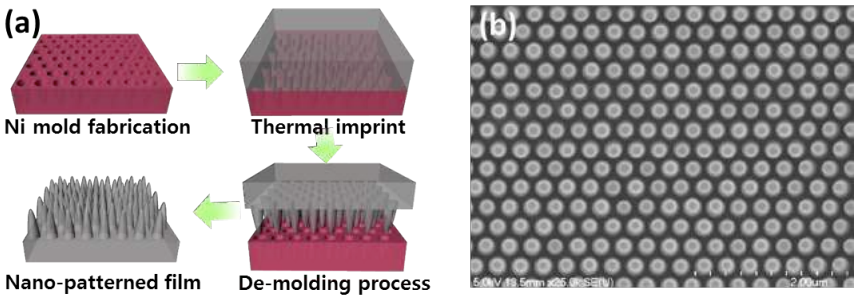

Figure 1: Schematic diagram of Thermal imprint process for AR nanostructure film (a) and the imprinted PMMA film with nanoscale cone array in hexagonal pattern (b)

showed that high reflectance is resulted by the mechanical damage of the nanostructure and the substrate.

To improve anti-scratch performance of AR film, the various thermal imprint process with addtitional heat treatment were proposed and the effect of heat treatment on the anti-scratch performance were evaluated. Figure 2 shows that the maximum reflectance measured form the scratch generated during pencil hardness test on AR films prepared with various heat treatment process. It can be seen that additional flat pressing followed by immediate cooling process is effective in comparison with sample 1, imprinted without suggested heat treatment process. It was found that the flat compression with elevated temperature higher than glass transition temperature followed by an immediate cooling improves anti-scratch performance. It can be concluded that the improved mechanical reliability of the film

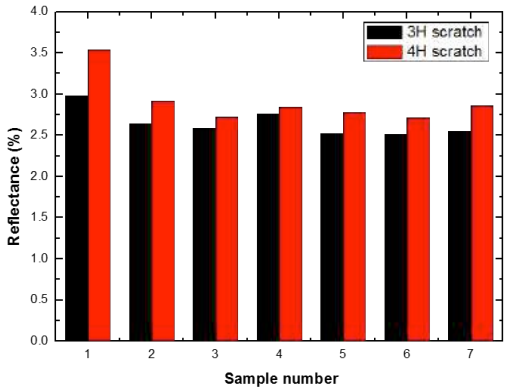

Figure 1: Reflectance measured from the scratches of the nanopatterned films after pencil hardness test.

A Study of Band Gap Effect of Seismic Metamaterials using Leaf Springs

J. Y. Yoon[1], S. J. Lee[1], and N-C. Park[1*]
[1]Yonsei University, Korea
[*]corresponding author: pnch@yonsei.ac.kr

Abstract-Elastic metamaterials that have negative effective properties have been investigated to prevent acoustic or seismic waves. In this study, seismic metamaterials were developed using leaf springs to achieve negative effective properties. We fabricated reduction model of seismic metamaterials and investigated effect of shock absorption using vibration exicter. Finite element model about reduction model was constructed and was verified validity of simulation results. Using similarity analysis, effect of shock absorption of real-size seismic metamaterials was investigated about seismic waves.

Elastic metamaterials can prevent external shock such as acoustic or seismic waves because of negative effective properties in specific frequency range. Seismic metamaterials of various shapes have been investigated and designed. S. Brûlé constructed regular mesh of cylindrical and empty boreholes and implemented seismic test [1]. Y. Yan constructed rubber coated steel of cubic shape [2] and M. Miniaci constructed rubber coated steel of cylinder shape [3]. These seismic metamaterials use tension-compression stiffness of pure material such as rubber or soil. Seismic metamaterials require low stiffness because the seismic wave has low frequency domain (1~10 Hz). However, tension-compression stiffness of pure material has large size to low stiffness, and therefore unit cell sizes of these seismic metamaterials are larger than 3 m. In this study, seismic metamaterials using leaf springs was constructed to reduce unit cell size. The leaf springs can be designed to have low stiffness and small size compared to tension-compression stiffness of pure material. Therefore, seismic metamaterials using leaf springs are more realistic and effective design than other metamaterials.

The unit cell of seismic metamaterials using leaf springs consists of three components: inner mass, outer mass, and leaf springs, as schematically shown in Fig. 1. The inner mass and outer mass are cubic and have length L_i and L_o, respectively. The inner mass is high density material and the outer mass is low density material to widen frequency range when the effective mass is negative. Figure 1 shows one dimensional case of seismic metamaterials. Leaf springs are supplemented in two or three dimensional cases at each axis.

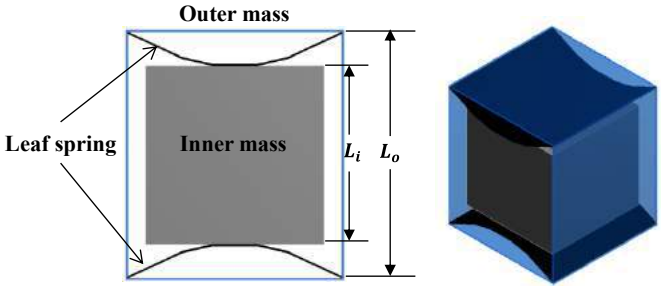

Fig. 1 Schematic diagram of the unit cell of the one dimensional seismic metamaterials using leaf springs

The seismic metamaterials using leaf springs that serialize seven unit cells was investigated using finite element analysis and experiment of reduction model. Input shock is El Centro seismic wave and was applied on side using exicter. Measurement point is the opposite side and experiment results was measured using accelerometer. The shock response of seismic metamaterials had band gap to 5 Hz from 10 Hz. This frequency domain is closed to frequency domain of seismic wave. Therefore, the seismic metamaterials using leaf springs that has 8.4 m total length can absorb shock of earthquake. This simulation and experiment results will be presented in the conference.

Variable stiffness using electromagnetic force in acoustic metamaterials.

Dongwook Kim[1], **Junsun Yoo**[2], **and No-Cheol Park**[1*]
[1]Department of Mechanical Engineering, Yonsei University, Koera
[2]Center for Information Storage Devices , Yonsei University, Korea
[*]corresponding author: pnch@yonsei.ac.kr

Abstract- The narrow band gaps of elastic materials is an obstruction for practical applications. In this paper, we proposed a method of changing band gaps through variable stiffness of the proposed lattice structure. We used attractive force between ferromagnetic materials and electromagnets that works like a spring. Electromagnetic circuit was designed to make variable stiffness of the structure. The dispersion equation and attenuation factor of this system was derived.

Elastic materials do not have negative mass density and stiffness in naturally. Recently, some researchers demonstrated that elastic metamaterials with double negativity can be achieved by combining structures.[1-3] However, most of the metamaterials that is aforementioned have negative effective mass and stiffness in narrow frequency region. The band gap of combining structures can be defined by lattice model as shown in Fig.1. The dispersion equation can be derived as below

$$\mathrm{m}_1 m_2 \omega^4 - [(m_1 + m_2)k_2 + 2m_2 k_1(1 - \cos(qL))]\omega^2 + 2k_1 k_2(1 - \cos(qL)) = 0 \quad (1)$$

where, ω is forcing frequency and q is a wave number.

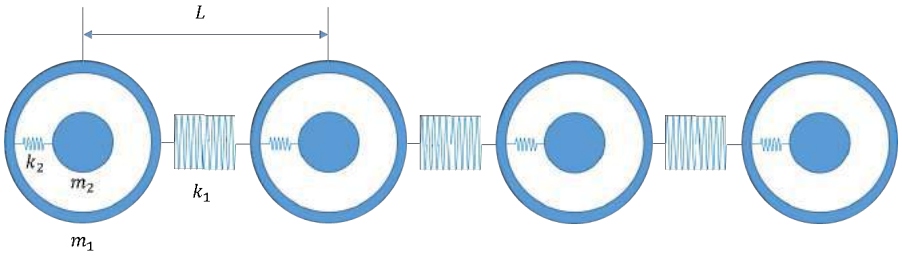

Fig. 1 Lattice model of metamaterials with combining structures

Conventional model has the fixed stiffness k_2 in a unit cell. In this study, the stiffness k_2 could be changed by an electromagnet. Moving mass m_2 is an electromagnet and attracted by another electromagnet. The attractive force can be controlled by flowed current in the coil. An electromagnetic circuit is proposed to have linear force between two electromagnets acting as a stiffness as shown in Fig. 2. Therefore, the band gap can be changed by the changeable stiffness k_2.

Quantum manipulation and characterization of electron spin qubits in diamond

Dohun Kim[1]

Department of Physics and Astronomy, Seoul National University, Seoul 08826, Korea
dohunkim@snu.ac.kr

Abstract-Nitrogen-vacancy (NV) centers in diamond are excellent candidates for investigating quantum phenomena, constructing quantum two level system, and realizing quantum limited sensors due to long coherence time even at room temperature environment. In this talk, I briefly introduce optical quantum manipulation and measurements realized using spins in diamond, including electron spins and nuclear spins. For characterizing quantum processes, gate set tomography (GST) is a newly developed method which is self-consistent and overcomes limit of traditional state and process tomography. We apply GST method to electron spins and discuss accuracy of the single qubit gates obtained by analyzing gate sequence data using GST. We further discuss the way toward using GST method to multiple spins and qubits.

Abstract-A metal enhanced fluorescence DNA microarray analysis has been demonstrated using glancing angle deposited (GLAD) Ag nanorods substrate for diagnosis of atopic dermatitis. To maximize the fluorescence enhancement factor, the effects of nanorod length on the fluorescence signal were examined. To examine the feasibility of the proposed highly sensitive DNA microarray for real application, a DNA screening chip for diagnosis of Atopic dermatitis was prepared using the fabricated GLAD substrate and the performance of the chip was tested using the real blood sample from the patient.

Metal-enhanced fluorescence (MEF) shows a significant potential to enhance the sensitivity of fluorescence detection by allowing fluorophores to interact with enhanced electromagnetic fields generated by the localized surface plasmon resonance effects of metallic nanostructures. We used a glancing angle deposition (GLAD) process to fabricate Ag nanorods on the whole area of slide glass substrate to serve as an inexpensive and large-area metal-enhanced fluorescence substrate for DNA microarray [1]. To maximize the signal enhancement, the effects of length of Ag nanorods (Ag-NRs) on the signal enhancement were examined. To measure the enhancement factor of GLAD-MEF substrates, a Cy5 conjugated Kallikrein-related peptidase 7 (KLK-7-Cy5) DNA probes, which is one of the DNA marker for atopic dermatitis, were spotted on each substrate and the fluorescence signal was measured after the blocking and washing process. The maximum enhancement factor of ~108x comparing with glass substrate was obtained from Ag-vertical nanorods with 500 nm length. To examine the reliability of GLAD-MEF substrate, we compared the performance of GLAD-MEF substrates with the commercial Amine slide (Amine 2®, Array-it, USA). From the fluorescence measurement experiments, the maximum signal enhancement of ~26x was obtained from the GLAD-MEF substrates compared to commercial amine slides. To examine the feasibility of the proposed MEF substrate for real application, we prepared the atopic dermatitis DNA microarray chip using the optimized Ag-NRs MEF substrate and examine the fluorescence signals repeatability and accuracy by using the blood samples from asthma patient.

Fabrication of Glass micromixer with High chemical resistance

M. R. Haq, Y. K. Kim, and S. M. Kim*
School of Mechanical Engineering, Chung-Ang University, Seoul, 06974, Korea
*corresponding author: smkim@cau.ac.kr

Abstract- A glass micromixer with high chemical resistance was fabricated by glass molding process with vitreous carbon (VC) mold. A VC mold was fabricated by carbonization of replicated furan precursor. The effects of molding temperature and pressure on the replication quality were examined to optimize the glass molding process. The channel shape changes of glass chip during the mixing process with organic solvent as a working fluid were measured and compared with the conventional PDMS chip.

Although the polymer replicated microfluidic chips are generally used in various research fields due to its cost-effectiveness, a glass microfluidic chip offers more advantageous than polymer chips when a high thermal, mechanical and chemical durability are required. In this study, a low-cost glass micromixer fabrication has been realized using glass molding process (GMP) and thermal fusion bonding process (TFB). In the GMP, a mold having durability at high temperature is essentially required. A low cost and high surface quality vitreous carbon (VC) mold was fabricated by carbonization of replicated furan precursor. A photoresist master pattern was fabricated by photolithography technique and the master pattern was transferred to a polydimethyl-siloxane (PDMS) mold by soft lithography. A mixture of 89.9 wt% furan resin, 0.2 wt% p-Tolenesulfunic acid and 10 wt% ethanol were poured into the PDMS mold and a furan precursor having microchannel structure was obtained by curing process. To obtain VC mold with microchannel cavitiy, a carbonization process was carried out with a maximum temperature of 1000˚C in a temperature history programmed furnace [1]. A GMP process was conducted to fabricate glass microchannel structure on a soda line glass substrate at a molding temperature of 720˚C and a pressure of 10 kPa. To test the feasibility of glass micro mixer, the inlets and outlet were drilled of the molded glass micro structure and another soda-lime glass was bonded by thermal fusion bonding process with a temperature of 620˚C, pressure of 16.2 kPa, and holding time of 3 hrs. To examine the advantage of the fabricated glass micromixer, a mixing experiment using toluene with different colors were injected using syringe pump in fabricated glass micromixer and PDMS micromixer which was replicated using the fabricated VC mold. The channel width was decreased in the PDMS chip due to the swelling effects. However, glass chip shows high chemical resistance as expected.

Abstract-A micro/nano hierarchy structure was fabricated by UV-nano imprinting process and glancing angle deposition (GLAD) technique to improve the signal noise ratio of GLAD metal-enhanced fluorescence (MEF) substrate. Since the metallic nanorod structure formed only on the top of micropillar structure (Spotting area), the non-spot region shows lower background signal than the full metallic nanorod structure substrate, which improve the signal to noise ratio of enhanced fluorescence substrate.

Metal-enhanced fluorescence (MEF) is a powerful technology to improve the sensitivity of fluorescence analysis by allowing fluorophores to interact with enhanced electromagnetic fields generated by the localized surface Plasmon resonance effects of metallic nanostructures [1]. As a low cost and large area MEF substrate fabrication process, a glancing angle deposition (GLAD) has been proposed [2]. GLAD is a physical vapor deposition process in which deposition flux is incident onto the substrate at a large oblique angle to the surface normal (>75°). Although the fluorescence signal from the biomolecules spotted on the GLAD nanostructures increased significantly, the background signal also increased. In this study, a micro/nano hierarchy structure was proposed to improve the signal to noise (S/N) ratio of GLAD MEF substrate. The proposed high S/N ratio MEF substrate was composed of micropillar structures which corresponding to the spotting area and GLAD nanostructures. The micropillar structures were fabricated by UV-nanoimprinting process on a slide glass substrate, and a GLAD process was carried out with a rotation speed of 5 rpm and glancing angle of 85° on the fabricated micropillar structure. During the GLAD process, the nanorod structures formed only on the top of micropillar structure due to the shadowing effect of micropillar. To examine the proposed hierarchy structure, the S/N ratio of Straptavidin-Cy5 spots on the proposed substrate were measured and compared with that on a conventional GLAD substrate. The measured S/N ratio of the proposed substrate was 223.4 and that of the conventional GLAD was 148.6.

Solar Energy Harvesting based on Photosynthesis

WonHyoung Ryu[1*]
[1]Department of Mechanical Engineering, Yonsei University, Seoul 03722, Republic of Korea
[*]corresponding author: whryu@yonsei.ac.kr

Abstract-In photosynthesis of plant cells, algae, or cyanobacteria, high energy electrons are generated and transferred in a photosynthetic electron transfer chain. The photosynthetic electrons (PEs) are either used to maintain the life of the plants or stored in a form of carbohydrates. There are multiple approaches to harvest the PEs and utilize them as a clean energy source. In this presentation, recent development of bio-solar cells based on PE harvesting will be introduced and discussed.

Plant cells produce photosynthetic electrons (PEs) by splitting water during photosynthesis. In the beginning of photosynthesis, antenna complex embedded in thylakoid membrane absorbs photon energy and converts them into excited electrons with high quantum efficiency. These excited electrons, known as PEs, are transferred through electron acceptors in order to grow cell or store surplus energy as a form of carbonhydrates. However, since the energy state of the PEs is lowered once they are stored as organic matter, many researchers have tried to extract PEs from photosynthetic electron transfer chain before their conversion into organic matter. Such previous works include collection of PEs by electrochemical oxidizing through mediator as an electron interceptor and use of electrical linker materials such as CNTs, electrically-conducting polymer matrix, or conducting linker to working electrodes between photosynthetic components and the surface of electrodes. Although these works demonstrated the feasibility of harvesting PEs in large scale, there are still issues including efficiency decrease from mediator use and limited stability or requirement of additional electron donors of isolated photosynthetic extracts. In this work, we present nanoelectrode systems to directly extract PEs without mediator. Fabrication of vertically-aligned patterned nanoelectrode systems is explained. Furthermore, we will discuss how the nanoelectrode geometry and illumination conditions affect the longevity of algal cells inserted by the nanoelectrodes during PE extraction. PE extraction for up to 7 days was achieved from nanoelectrode inserted into living algal cells.

Spectral Beam Combining (SBC) of multiple fiber lasers is a simple and straightforward method to obtain high power laser beam. The SBC system is typically composed of three parts, fiber laser arrays, transmission optical system, and diffraction grating parts. Performance of the SBC system is mainly determined by the diffraction grating parts where diffraction efficiency and damage threshold problems are dealing with. Thus, many SBC related researches have been focused on a highly efficient and robust diffraction gratings. Metallic gratings exhibit high diffraction efficiency with thin layers, but they have very small laser damage thresholds due to high light absorption in a metal. On the other hand, dielectric gratings can have relatively high-damage thresholds and also by stacking low refractive index and high refractive index medium alternatively, high reflectance mirror can be realized and reflectance become higher as number of layers increases. Moreover, exquisite grating patterns on the uppermost layer can engineer diffracted beam efficiency, but unfortunately most of geometrical parameters, such as number of multilayers, thickness and grating height, in the dielectric gratings are in a trade-off relationship. For instance, increasing number of multilayers is favorable for reflectance, but unfavorable for laser damage threshold. Therefore, all the geometrical parameters in the multilayer dielectric gratings (MLDG) should be optimized [1, 2]. In this abstract, I will discuss our efforts in design and experimental demonstration of MLDG, which is composed of HfO_2 and SiO_2 multilayers. First, I will present two design methodologies, rigorous coupled-wave analysis (RCWA) [3] and finite-difference time-domain (FDTD) method. RCWA is used to optimize different parameters and FDTD is used to calculate near/far-field characteristics. Second, I will present a laser interference lithography (LIL) set-up used in the device manufacturing. Through LIL set up, large-scale MLDG device (35mm x 35mm) is fabricated on a thick fused silica substrate (20mm). Finally, I will introduce optical characterizations for reflectance, diffraction efficiency and laser induced damage threshold. I believe our efforts for design optimization and large-scale fabrication will result in high efficient and robust MLDG for high power SBC.

Design of a flexible metamaterial superlens system for large-area nano patterning below the diffraction limit

Jinhyung Lee[1,2], Changsu Park[1,2] and Shinill Kang[1,2*]
[1]School of Mechanical Engineering, Yonsei University, Seoul, 03722, South Korea

Abstract- We propose a method to design a flexible superlens system for large area nano patterning below the diffraction limit. The superlens structure including silver layer, silicon oxide layer and chrome nano mask was designed through FDTD simulation. To fabricate flexible superlens structure, silicon oxide layer(spacing layer, protective layer), silver layer and chrome grating mask were formed on a silicon substrate as a sacrificial wafer. PDMS was spin coated onto the chrome grating in order to achieve a flexible superlens substrate. After silicon etching, the flexible superlens structure was fabricated. Using the flexible superlens structure, we demonstrated that large-area nano patterns with a 60nm half-pitch below the diffraction limit were achieved at 365 nm illumination wavelength.

Superlens has received much attention for its ability to overcome the diffraction limit by amplifying the exponentially decreasing evanescent wave via surface plasmon resonance of thin metal slab. Since superlens lithography can be integrated with conventional photolithography systems, it is possible to fabricate nanopatterns below the diffraction limit at low cost and high throughput.[1] However, most of the previously reported superlens are fabricated on a rigid substrate(quartz substrate), which makes it difficult to fabricate large-area nanopatterns due to the issue of conformal contact between superlens and photoresist in photolithography process.[2,3]

This study proposes a method to design a flexible superlens system for large area nano patterning below the diffraction limit. By using a flexible superlens, conformal contact between superlens and photoresist can be achieved. First, the superlens structure was designed to amplify the evanescent wave via surface plasmon resonance of silver layer through finite difference time domain(FDTD) analysis. Simulation results show that the intensity of the evanescent wave can be maximized when superlens structure is designed as follows; a 60 nm half-pitch chrome grating mask with a thickness of 35 nm, a silicon oxide layer with a thickness of 30 nm, and a silver layer with a thickness of 30 nm. The light of 365 nm wavelength was illuminated to a superlens in normal incidence.

Based on the FDTD simulation results, the superlens structure was fabricated. A 5nm thick silicon oxide layer(protective layer) was first deposited on a silicon substrate as a sacrificial wafer by electron beam evaporator, and then silver (superlens) with a thickness of 30nm and silicon oxide(spacing layer) with a thickness of 30nm were deposited on a silicon oxide protective layer. A 60nm half-pitch chrome grating with 35nm thick was patterned on top of the spacing layer by using UV nanoimprint lithography. Subsequently,

PDMS was spin coated onto the chrome grating in order to achieve a flexible superlens substrate. After an etching process of silicon in potassium hydroxide(KOH) solution, a flexible superlens structure was fabricated. Superlens lithography was performed using a conventional photolithography system at 365 nm. A nano-pattern with a half-pitch of 60 nm below the diffraction limit was fabricated. Applications of nano patterns fabricated through superlens lithography is a subject of an ongoing research.

Abstract- This talk will address how nanopatterns can be created at high speed and improved scalability, by utilizing continuous mechanical methods highlighted by roll-to-roll imprinting, nanoscale inscribing, and vibrational nanoindentation. Such continuous and scalable mechanical methodologies are based on simpler and cheaper principles, free from ponderous instruments, and applicable to flexible substrates, thereby enabling a big array of tangible applications particularly requiring large-area fabrication. In particular, we focus on two recent results on the plasmonic biosensors and polymer light-emitting diodes.

Abstract- A more facile nanoarchitecturing methodology for localized surface plasmon resonance (LSPR), particularly securing scalable and cost-effective fabrication procedure, is called for. We develop 3D plasmonic nanoarchitectures comprising the double-bent Au strips (DAS) integrated on transparent nanogratings, which can be continuously fabricated via roll-to-roll nanoimprint lithography along with inclined Au deposition. We also demonstrate the DAS shape can be tuned for optimal LSPR performance simply by controlling the Au deposition angles, towards flexible and transparent plasmonic sensors with high sensitivity.

Localized surface plasmon resonance(LSPR), generating optical absorption peaks at specific wavelengths due to surface plasmon confinement in a nanoscale metallic structure, has been capitalized in many diverse sensing devices. The present methods involving both top-down and bottom-up approaches, such as colloidal nanoparticle synthesis and etching-based nanofabrication, work well but suffer from exacting alignment, high cost, limited processable area, and overall complex procedure. A facile method to create LSPR nanoarchitectures in a scalable and cost-effective fashion is therefore called for.

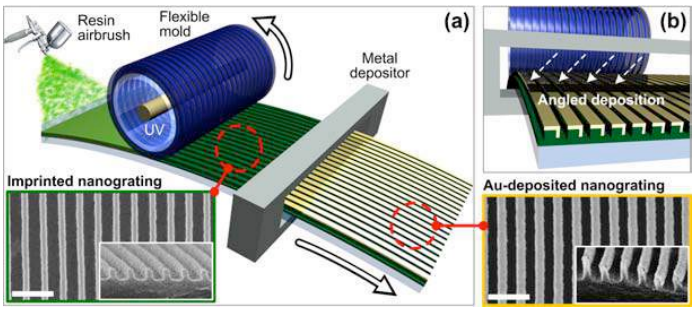

Figure 1. (a) Schematic and conceptual drawing of the overall fabrication procedure based around the continuous R2R NIL. (b) Enlarged conceptual view of the angled Au evaporation over the NIL-ed transparent polymer nanograting structures

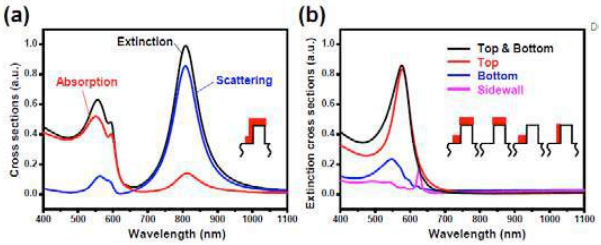

Figure 2. (a) Calculated extinction, absorption and scattering cross-sections of the double-bent Au strips on 1D grating. (b) Calculated extinction cross-sections of the partical segment of the double-bent Au strips.

In this work, we develop a scalable 3D plasmonic nanoarchitecture comprising the double-bent nanoscale Au strip array integrated within the transparent nanograting framework, which can be continuously fabricated on a large-area flexible substrate via roll-to-roll nanoimprint lithography (R2R NIL) and angled Au deposition without resorting to laborious etching or tedious alignment for orderly nanostructures (Figure 1). We first form the polymeric nanograting pattern array by R2R NIL, and then to deposit a metal layer onto the top and/or sidewall of each grating. Here, the long metallic structures can be 'folded' along the nanograting topography in a more compact fashion, compared to the ones simply patterned on a flat surface, thereby yielding the longer oscillation length for surface plasmon polaritons (SPPs) for higher sensitivity in a smaller device footprint. While the nanoscale Au strips can be tuned to unbent, single-bent, or double-bent shapes simply by controlling the Au deposition angle and thickness, (Figure 2b), we investigate that the double-bent Au strips (DAS) shows the best LSPR performance (Figure 2a). Utilizing the DAS formed on a flexible large-area polymer films, we demonstrate one specific example: a plasmonic sensor detecting the biological molecules. The continuous R2R-based manufacturing methodology and straightforward working principle may spur the DAS strip array to further extend the scalability and applicability; it can be conjugated with various antibodies on universal substrates, towards highly-sensitive, reliable, and inexpensive molecular detection platforms.

Abstract- This study reports a cost-effective method of replicating glass microfluidic chips using a vitreous carbon (VC) stamp. A glass replica with the required microfluidic microstructures was synthesized without etching. The replication method uses a VC stamp fabricated by combining thermal replication using a furan-based thermally-curable polymer with carbonization. To test the feasibility of this method, a flow focusing droplet generator with flow-focusing and channel widths of 50 µm and 100 µm, respectively, was successfully fabricated in a soda-lime glass substrate.

The VC mold was fabricated via carbonization of a Furan-based replica, which was itself fabricated via a series of replication steps using PDMS and a furan-based thermal curable polymer. Since the demolding properties of the furan-based resin are extremely poor, it is not feasible to replicate a silicon wafer master pattern directly. The first replication step generates an elastomeric intermediate mold made from PDMS. PDMS has superior mechanical and surface properties, and can transfer a pattern to a Furan-based resin with high fidelity. The intermediate PDMS mold was fabricated via a conventional soft-lithography process using 10 parts of Sylgard 184 (Dow Corning, USA) and 1 part of a curing agent. The master pattern of the microfluidic structure was fabricated on a 4 inch silicon wafer via using a photolithography process that employed SU-8 3050 (Microchem Co., USA) as a photoresist. The height of the master pattern was 40 µm.

The second replication step was performed using a mixture that included a furan resin (Kangnam Chemical Co. LTD.), p-TSA (p-Toluenesulfonic acid), and ethanol. The furan mixture was poured onto the PDMS mold. Before solidification, the mixture was degassed to remove air bubbles created during mixing. In the first curing process, the mixture was allowed to polymerize naturally over 5 d under atmospheric conditions. Next, thermal curing was performed in a conduction oven at up to 100 ˚C for 2 d.

The furan precursor synthesized using the aforementioned method was carbonized in a furnace at 1000 ˚C under N2 for 5 d. During this process, pyrolysis phenomena caused shrinkage of the furan precursor to occur. Fig. 1 (a)~(d) shows a schematic diagram of the proposed VC stamp fabrication method.

A soda-lime glass substrate with a thickness of 3 mm was used as imprinting material. Fig. 1(e)~(f) shows the schematic flow diagram of the glass imprinting process. First, the VC mold was installed in the middle of the imprinting system and the glass substrate was placed to cover the VC mold. To prevent the oxidization of the VC mold during the process, the chamber was maintained in an inert environment via nitrogen purging. Meanwhile, the mold and substrate were heated beyond the glass transition temperature of the soda-lime glass, i.e. to 680 °C. Pressure of up to 163.5 kPa was then applied. After cooling to room temperature, the glass replica was removed from the VC mold.

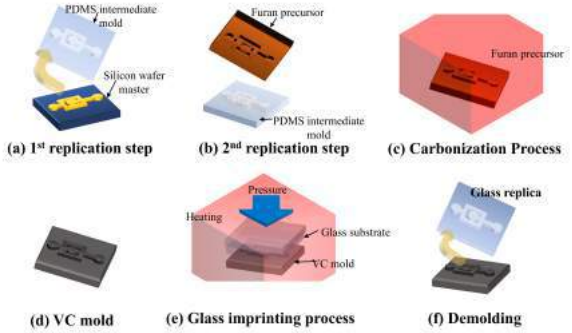

Fig. 1 Proposed fabrication method for the glass microfluidic device

To verify the fidelity of the glass imprinting process, the samples were measured at each step. As shown in Fig. 2, the difference between the surface morphologies of the silicon master (a) and Furan replica (c) is negligible. However, considerable shrinkage occurs during the carbonization process. Based on the measurement results, the sample volume shrinks by approximately 30%.

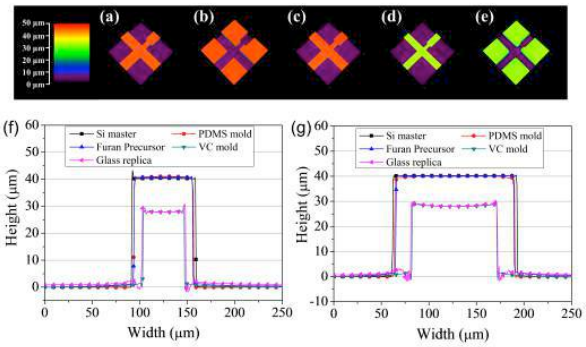

Fig. 2 3D microscope measurement results of (a) the silicon master, (b) the PDMS mold, (c) the furan precursor, (d) the vitreous carbon stamp and (e) the replicated glass microfluidic structure, and comparison of the surface profiles measured in (f) the channel and (g) the orifice.

We demonstrated that our approach can provide cost-effective glass microfluidic chip fabrication. Fabrication of all-glass chips via thermal fusion bonding is the subject of ongoing research.

Abstract- An all-glass bifurcation microfluidic chip for blood plasma separation was fabricated by a cost-effective glass molding process using an amorphous carbon (AC) mold, which in turn was fabricated by the carbonization of a replicated furan precursor. To compensate for the shrinkage during AC mold fabrication, an enlarged photoresist pattern master was designed, and an AC mold with a dimensional error of 2.9% was achieved.

An all-glass bifurcation microfluidic chip for blood plasma separation was fabricated, using the glass molded microchannel plate prepared from an AC mold. To compensate for the shape change during AC mold fabrication, an enlarged silicon master pattern was prepared by conventional photolithography. A furan precursor was obtained by thermal replication using a replicated PDMS mold from the master. After the carbonization of the furan precursor, an AC mold with microchannel cavities was obtained. Finally, the glass bifurcation microfluidic chip was obtained by implementing glass molding for the microchannel plate, micro-drilling for the inlet and outlet connecting holes, and thermal fusion bonding for sealing. To examine the feasibility of the all-glass bifurcation microfluidic chip, the performance of the blood plasma separation was evaluated.

Fig. 1 shows the 3D surface profiles of the fabricated (a) silicon master, (b) PDMS mold, (c) furan precursor, (d) AC mold, and (e) molded glass microfluidic plate, obtained from the confocal microscopy results. It is clearly seen that the positive and negative microfluidic channel structures were uniformly transferred in each fabrication step. The measured widths and heights of microchannels in each sample are summarized in Table 1. Fig. 2 shows the comparisons of the cross-sectional surface profiles of the inlet microchannel (a) between the silicon master, PDMS mold (inverted), furan precursor, and AC mold, and (b) between the AC mold and the glass replica (inverted). Fig. 2(a) shows that a small shape change (shrinkage) occurred during the PDMS and furan precursor replication processes due to polymerization, and a significant shape change took place during the AC mold fabrication because of material decomposition during carbonization. Although an inherent substantial shape change occurred during the AC mold fabrication process, the shape change during the glass molding process is negligible, as shown in Fig. 2(b).

Abstract- Screening for enzymatic activities at the single cell level is of particular importance to find variants with specific desired activities, either in the natural diversity or in synthetic libraries obtained through mutagenesis. Droplet-based microfluidics offers promising platforms for the automation and miniaturization of assays, usable for single cell analysis. We demonstrate here a complex coupled assays for the measurement of the enzymatic activity of the bacterial asparginase.

Droplet-based microfluidics technology has become a powerful tool for the quantitative analysis of compartmentalized reactions which can take place in tremendously small volumes. Water-in-oil emulsions have been successfully used to a variety of biotechnological applications serving as diagnostic platforms, set-ups for sample analysis or combinatorial screening. The latest advances in chip design, construction and formation of monodisperse droplets have allowed the generation of volumes in the fL range. Such small volumes have formed a solid basis for the study of single-molecule enzymatic reactions and there has been an explosive interest towards this direction, as evidenced by the numerous high-impact research reports during the recent years. In addition, there have been reported several studies where microfluidic approaches have been successfully applied for high-throughput screening of libraries resulted from directed evolution experiments. The analysis of such libraries aims at the isolation of variants with the desirable properties while the selection pressure can be tuned by the experimental conditions. Notably in cases where, enzyme variants are to be screened for the identification of catalytically improved species, it is very critical to be able to discriminate distinct catalytic properties. Therefore, the success of such high-throughput screening set-ups solely relies on the availability of a highly sensitive enzymatic assay, which allows the quantitative activity characterization of each variant on the single-cell level.

In this paper, the quantitative characterization of single-cell enzymatic reactions using the most recent state-of-the-art droplet-based microfluidic set-ups. For that purpose, we displayed the therapeutic enzyme L-asparaginase II from E.coli (EcASNaseII, EC 3.5.1.1) in the inner membrane of E.coli cells by capitalizing the ApEx (Anchored Periplasmic Expression) system. Upon compartmentalization of single cells displaying EcASNaseII in water-in-oil emulsions, we measured enzymatic activities and performed steady-state kinetic experiments by applying a highly sensitive Amplex Red-based fluorescent assay. Figure 1 shows the enzymatic kinetics of the L-asparaginase.

Abstract- We perform the designing, constructing, and operating of the high-throughput and scalable micro- and nanopatterning system that utilizes continuous mechanical inscribing of a well-cleaved rigid pattern mold edge over a compliant substrate. By controlling the mold shape, inscribing force and speed, and processing temperature, many diverse small-scale patterns including 1D grating and 2D mesh, can be continuously created on any commercial polymer films at high speed. We also demonstrate the applications of such flexible micro- and nanopattern films.

Small-scale patterns have attracted a considerable amount of research and commercialization effort for the performance innovations of existing systems as well as the novel device developments in many fields involving photonics, sensing, bioengineering, metamaterials, displays, and so forth. However, most of the current micro- and nanopatterning processes based on such as photolithography, e-beam lithography, and laser interferometry, have suffered from complicated processes, long processing times, and difficulty in large area processing. A more straightforward and scalable micro- and nanopatterning methodology, hopefully without resorting to complex optical instruments and post-etching, is therefore highly requested.

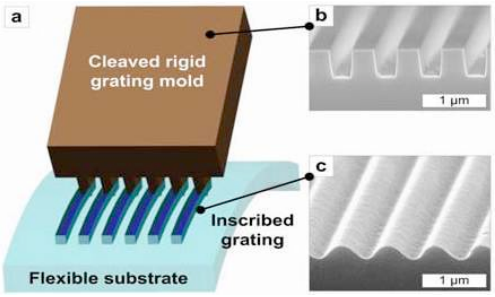

Fig. 1. (a) Schematic overview of continuous micronanopatterning by inscribing a rigid mold edge on a flexible substrate. SEM images of (b) a well-cleaved 700 nm-period SiO2 nanograting mold and (c) a resulting pattern inscribed on a polycarbonate substrate.

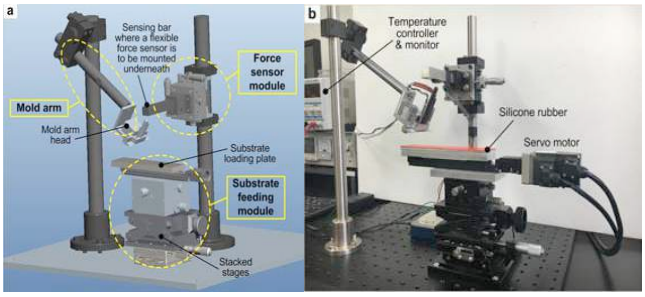

Fig. 2. The high-throughput micronanopatterning system utilizing continuous inscribing principle: (a) a 3D modeling assembly where three main modules are categorized and (b) a completed prototype connected with a servo motor, force sensor, heater, and the controller.

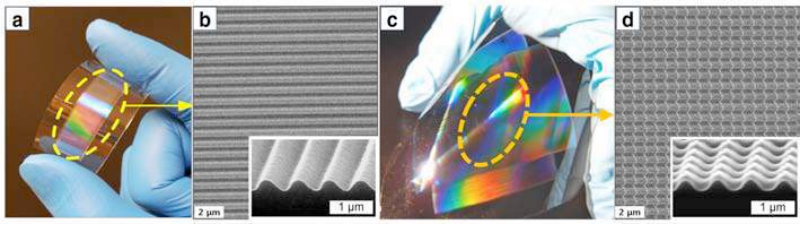

Fig. 3. Fabricated samples applying the continuous inscribing based micronanopatterning system on a flexible PC substrate: (a) 1D and (d) 2D optical view and SEM images of (b) 1D, (e) 2D top and (c) 1D, (f) 2D cross-sectional views.

To this end, we adopt a reliable mechanical machining protocol to small-scale patterning, developing a Dynamic Nano-Inscribing (DNI) process. Figure 1 depicts the overview of DNI; a rigid mold containing desired pattern, typically 1D grating, is cleaved across the grating direction. The edge of a mold then makes conformal contact to the target substrate, usually of compliant polymers. Under proper force and temperature, the mold edge slides over the substrate while continuously inscribing the nanopatterns. DNI enables continuous micro- and nanopatterning at high speed by using a simple and compact system as shown in Figure 2. By controlling the mold shape, inscribing force and direction, many diverse micro- and nanopatterns can be readily created, as demonstrated in Figure 3. Starting from the 1D nanograting structures (Figure 3a-b), we can extend it to multidimensional nanopatterns simply by sequentially performing DNI in multiple directions (Figure 3c-d), which otherwise demand complicated nanofabrication.

Abstract- We developed a compact desktop-sized Roll-to-Roll nanoimprinting system equipped with an airbrushing module for high-speed and uniform resin coating. A diluted resin can be smoothly airbrushed on a continuously moving substrate. The resin-coated substrate then makes a conformal contact with a roll bearing a flexible nanopattern mold, where the nanopattern is continuously stamped on a substrate as the rolling proceeds. The system enables the control of initial resin film thickness as well as the residual layer thickness of imprinted pattern.

While micro- and nanoscale patterns are of great interest for both academia and industry due to their extraordinary characteristics particularly in photonic and metastructure fields, the existing nanopatterning methods based on optical lithography and laser interferometry suffer from their low throughput, high cost, and area limitation. Nanoimprint lithography (NIL) can be an alternative solution to improve the nanopatterning productivity by performing direct mechanical stamping on the target substrate using a nanopattern mold. To further expand its scalability and applicability, NIL can be integrated with a continuous roll-to-roll (R2R) processing principle, where the roll wrapped with a flexible nanopattern mold continuously imprints the pattern on a UV-curable resin-coated substrate as rolling proceeds under conformal contact, finalized by UV curing at the outlet (Figure 1). To better utilize R2R NIL in scalable fabrication of diverse devices at high yield, a parametric study on a set of important parameters including rolling speed, contact force, and UV curing conditions is crucial. In this work, we develop a simple, desktop-sized R2R NIL system that realizes facile and handy parametric research without resorting to ponderous and expensive instruments.

Figure 2 schematically depicts the airbrushing process. A UV-curable nonvolatile resin is diluted in volatile solvent, which is smoothly airbrushed onto the desired flexible or rigid substrate to make a uniform thin film. Airbrushing can make uniform thin films over highly topographic surfaces at high speed, which is suitable for the continuous R2R processing principle. By regulating the resin concentration and airbrushing time, the initial thin film thickness as well as the residual layer thickness (RLT) in the R2R NIL-ed pattern can be readily

controlled. Figure 3 shows the core design of the R2R NIL system. The mold roll and backup roll can make conformal contact under a controlled force, while the supporting rolls afford smooth feeding of a substrate. We will demonstrate the detailed parametric investigation of the airbrushing and R2R NIL with varied resin concentration, airbrushing time, and NIL conditions, along with representative nanopatterning results. We will also discuss the effects of key parameters of each process towards optimized R2R NIL and potential applications in flexible and large-area photonic and metastructure devices.

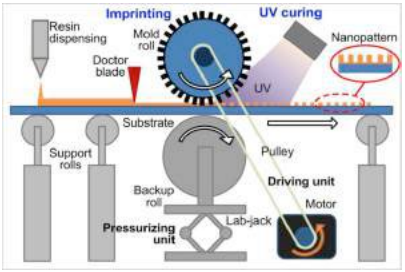

Figure 1 Conceptual scheme of a Roll-to-Roll nanoimprinting. The two main processes, imprinting and UV curing, along with the other necessary processes including the resin coating and motorized rolling are also marked

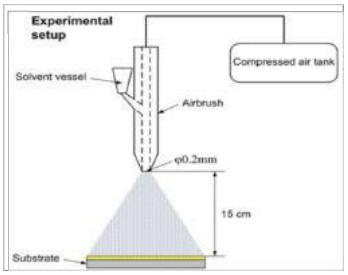

Figure 2 Schematics of airbrushing setup. The airbrushing nozzle is installed at a height 15 cm apart from the substrate, and is sprayed in a vertical direction at an injection pressure of 0.15 MPa.

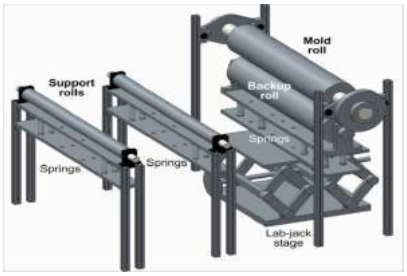

Figure 3 3D CAD drawing of an imprinting module; the mold roll and backup roll are responsible for pressurized imprinting, while the support rolls help secure uniform and continuous substrate feeding.

Graphene based nanohybrid material for photoluminescence enhancement with surface plasmon

Byeongho Park[1], Seung Won Cho[1], and Seong Chan Jun[1*]
[1]School of Mechanical Engineering, Yonsei University, Seoul, Republic of Korea
[*]corresponding author: scj@yonsei.ac.kr

Abstract- We made graphene based metal nanocompounds as an innovative fluorescent material. Such sample showed high photoluminescence characteristics and new emission peak in the visible range, since the strong light confinement obtained from the metal nanoparticles as an antenna remarkably enhace the light absorption. Our material with nanosphere structure provided broad emision after the hybridization between materials. It exhibited a photoluminescence quantum yield of ~ 25 %, which is better than twice of graphene's.

We developed a novel nanosphere including GQDs and Au. The UV light was employed to assembly of GQDs and Au with photo-excited electrons and reducing capability of Au^{3+}. The size of the GQD/Au nanospheres was 150–170 nm, which is larger than that of the intrinsic GQDs (4–7 nm). The photoluminescence was improved with two emission peak for blue and green at 468 and 529 nm of wavelength. Our material, GQD/Au nanospheres showed high emission efficiency with 26.9 % of quantum yield over double of typical GQD's. Such fluorescent material can be perceived as exceptional candidates for applications such as light emitting source, optoelectronic devices, and bio-imaging with intriguing emission wavelength and intensity.

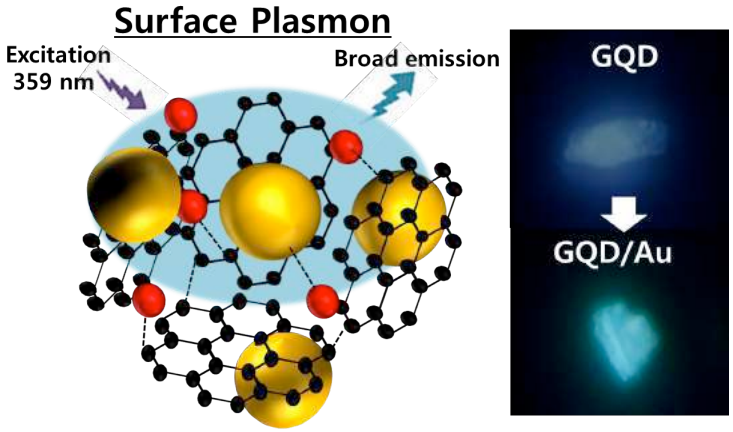

Figure 1. schematic of GQD/Au sample with enhanced photoluminescence of surface plasmon and fluorescence image of GQD and GQD/Au

Abstract- The shielding effectiveness (SE) and complex permittivity of Multi-walled carbon nanotubes and polyester (MWCNTs/PE) composites were investigated in the microwave frequency region from 8.2 to 18 GHz. A rectangular waveguide transmission line method was used to measure the complex permittivity and SE properties of MWCNTs (0-20%) composites. In the microwave range, composite samples with highest conductivity have the greater SE. The results show SE of the composites increased as the amount of the CNTs increased.

SUMMARY

In this work, samples under test were prepared by mixing MWCNT with resin (PE), and methyl ethyl ketone peroxide (MEKP) hardening agent. The MWCNTs/PE composites with different content of MWCNTs were used to fabricate as various shield materials. The MWCNTs weight ratios are shown in Table 1. The MWCNTS/PE samples were fabricated by using two different moulds, i.e., WR-90 and WR-62 moulds. The MWCNTS/PE samples were prepared in two different rectangular shapes, which fit into WR-90 and WR-62 waveguide sample holders.

Table 1. Multi-walled carbon nanotubes composites (%total weight)

Sample code	M1	M2	M3	M4	M5
Multi-walled Carbon nanotube (wt. %)	0	5	10	15	20

In this work, the samples were prepared precisely into 22.86 mm x 10.16 mm x 5mm and 15.799 mm x 7.899 mm x 5 mm to fit into the waveguide sample holder for SE and complex permittivity measurement at 8.2-12.4 and 12.4-18 GHz. The MWCNTS/PE samples were measured using two pairs of WR-90 and WR-62 waveguide flanges that were connected to an Agilent E8362B P-series Network Analyzer (PNA) with Agilent flexible coaxial cables. The complex permittivity of the MWCNTS/PE samples were measured in the frequency range of the X-band and the Ku-band using commercial Agilent Technologies 85071E software. Two pairs of WR-90 and WR-62 waveguide flanges were used to transmit the EM wave to the sample material and to receive transmitted signal. Figure 1 shows the mould (sample holder) that was used to fabricate the rectangular MWCNTS/PE

microwave absorbers.

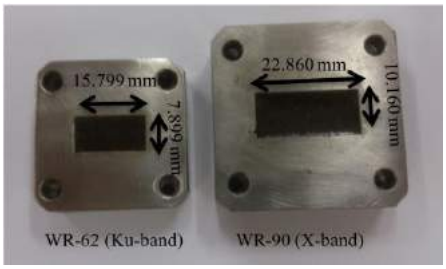

Figure 1. Mould (sample holder) used to fabricate MWCNTS/PE samples

Table 2. Dielectric properties of samples

Samples	Average value		
	Dielectric constant, ε_r'	Loss factor, ε_r"	Conductivity,(S/m)
M1	3.315	0.496	0.36
M2	9.647	3.274	2.33
M3	15.946	8.615	6.09
M4	21.778	15.455	10.92
M5	31.670	26.069	18.14

In this study, Multi-walled carbon nanotubes and polyester composites were successfully prepared. The complex permittivity and the EMI SE were measured in X-band and Ku-band frequency. The results showed that the MWCNTS/PE composite with 20 wt% MWCNTs had excellent EMI shielding ability, with SE > 35 dB in measured frequency range. The MWCNTS/PE composites with high dielectric loss were good candidates for use as EMI shielding materials over the 8.2 to 18-GHz frequency range. The results showed that the MWCNTS/PE composites have potential for applications as EMI shielding materials.

Abstract-This paper aims to present two types of carbon nanotubes composite materials (CNTs-composite) for antenna applications within sub terahertz (THz) frequency band. These composite materials consist of CNTs coated by copper and silver separately to construct CNTs-copper and CNTs-silver composite materials. The scientific comparisons between the dipole antennas of these structure materials with CNTs and copper dipole antennas are presented to exhibits the performance evaluation of presented dipole antennas. The mathematical modeling of CNTs-composite material is presented in this paper.

The presented CNTs-composite materials consist of CNTs coated by a thin layer of copper and silver separately, where the single-walled carbon nanotube (SWCNT) is the specific structure of CNTs utilized in this work. The main structure of CNTs-composite material is illustrated in Figure (1). In this figure, (r) represent the radius of SWCNT and (t) represent the average thickness layer of coating material. The mathematical model of presented structure derived based on the mixture rule [], for a simple parallel model of the radial interface of coating material and SWNT for a simple parallel model of the radial interface of coating material and SWCNT. The general formula of the electrical conductivity of CNTs-composite material was presented in Equation (1).

$$A_{Compisite}\sigma_{\text{Structure}} = C_{\text{SWCNT}}\sigma_{\text{SWCNT}} + A_{Coat}\ \sigma_{\text{Coat}} \quad (1)$$

Where, ($A_{Composite}$) represent the cross-sectional area of CNTs-composite structure, (C_{SWCNT}) represent the cross-section area of individual SWCNT (circumference of SWCNT) and (A_{Coat}) represent the cross-sectional area of coating material. While, ($\sigma_{Structure}$) represent the electrical conductivity of CNTs-composite material,

(σ_{SWCNT}) represent the electrical conductivity of SWCNT [1], and (σ_{Coat}) represent the conductivity of coating material. Then, the final formula of this conductivity was presented in Equation (2).

$$\sigma_{\text{Structure}}(w) = \frac{1}{(r+t)^2}\left[-j\frac{4e^2V_f}{\pi^2 h(w-jv)} + t^2\sigma_{Coat}\right] \quad (2)$$

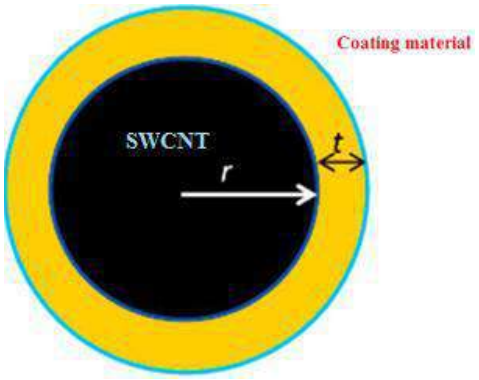

Figure 1: Structure of CNTs-composite material

The comparisons of simulation results for the CNTs-copper and CNTs-silver dipole antennas with SWCNT dipole antenna have been presented based on the similarity of dimensions of these dipole antennas. These comparisons are presented in Table (1).

Compact Tri-band Composite Right/left-handed Patch Antenna

Ting-Yuan Chen and Fu-Chiarng Chen*
Department of Electrical Engineering, National Chiao Tung University, Taiwan
*corresponding author: fchen@faculty.nctu.edu.tw

Abstract- In this paper, a compact tri-band microstrip patch antenna loaded with mushroom-like composite right/left-handed structure is presented. The mushroom-like structure is composed of a mushroom with two L-shaped slots. This composite right/left-handed structure can excite zeroth-order resonance (ZOR) mode and first-positive-order resonance (FPOR) mode. The first order resonance frequency can be adjusted by varying the spacing of two L-shaped slot such that the FPOR frequency can be reduced. As a microstrip upper patch stacked with the mushroom-like structure, the proposed antenna revealed triple-band behavior in 2.31 GHz, 2.92 GHz, and 3.7GHz.

Omini-directional antennas are widely used in the wireless communication systems such as WiFi and mobile communications. Dipole, monopole, and planar inverted F antenna (PIFA) are generally fabricated for producing omidirectional pattern. In recent years, with the rapid progress of metamaterials (MTMs), MTMs which include CRLH and periodic structures are used to design microwave circuits and antennas [1]-[7]. One kind of these applications is the zeroth-order resonance (ZOR) antenna [1]-[3]. ZOR antenna has many unique properties, for instance, the ZOR frequency is independent of the physical length due to the characteristic of infinite wavelength, and therefore the antenna size could be reduced. Mushroom structure is similar to the convention microstrip patch antenna, however, they have substantial different radiation patterns. Mushroom has monopolar radiation pattern because of its unique "equal amplitude/phase" electric-field distribution [4]. Recently, dual mode antennas with omidirectional and directional radiation pattern have been proposed [6]-[7]. In [6], the antenna utilized ZOR and first-order resonance for producing variant radiation patterns. Unfortunately, first-positive-order resonance (FPOR) frequency and first-negative-order resonance (FNOR) are generally restricted by the number of unit cells. Once the number of the unit cells is decided, the FPOR frequency cannot be adjusted. To overcome this drawback, we propose a modified mushroom-like structure by adding two L-shaped slots on a mushroom to control the frequency of the FPOR frequency. Our proposed antenna has dual mode antenna patterns including a monopolar radiation pattern and a patch-like radiation pattern. The ZOR frequency generates a monopolar radiation pattern, while the FPRO frequency generates a patch-like radiation pattern. We apply the stacked antenna technique [8] to add an upper patch over our proposed modified mushroom-like CRLH structure. In [8], dual-frequency behavior of stacked microstrip patch has been investigated. By using the stacking antenna technique, we can excite the third resonance frequency in our proposed antenna. Our proposed antenna only contains a unit cell of the modified mushroom-like structure. Therefore, the size of the antenna is small and easy to be fabricated. The antenna is designed to work in 2.31 GHz, 2.92 GHz and 3.7 GHz. The first operating frequency is the ZOR frequency, the second is the FPOR frequency, and the third frequency is determined by the top microstrip patch size. The antenna radiation patterns are shown in Figure 1. Both simulation and measurement results of the proposed dual-mode tri-band antenna will be presented and discussed.

Abstract

A super wideband microstrip patch antenna based on reconfigurable metamaterial is proposed in this paper. The ground plane of the proposed super wideband antenna is modified with the designed metamaterial structure to obtain the reconfigurable characteristics. The antenna has a zig-zag shape on the patch and the metamaterial structure consists of a ring resonator with two switching configurations. The characteristics of proposed antenna are varied with the effectively activate or deactivate by with the switches. Finite integration technique commercially available electromagnetic simulator is utilized to design and numerical investigation. The return loss (S_{11}) shows the super wideband from 31 to 52.50 GHz. In addition, the performance of the antenna is analysed with the changing of the switch configurations.

1. Introduction

In recent years, for the rapid development of wireless communication technology, the antenna is required to be capable of working with different polarizations or different radiation patterns to satisfy the variation of system working environments. Conventional single-functional antennas can't meet those demands since their characteristics are fixed and inflexible, and thus the system performance will be limited. To this end, antennas with reconfigurable characteristics have drawn much attention in recent years. Moreover, millimetre wave has been attracting attentions of many scientists and engineers of different fields for much higher channel capacity and better resolution in mm-wave radar/imaging systems. In addition, metamaterial is an engineered electromagnetic material having exotic electromagnetic properties and a metamaterial based millimetre wave reconfigurable antenna has the ability to acquire and track moving targets, 5G communication, change radiation pattern, radiation polarization, operating frequency, etc [1]. Few investigation have been done on the previous research in this study. V. G. Veselago first 1968 discussed about metamaterial. After a long time at 2003 R. W. Ziolkowski developed a metamaterial by capacitor loaded strips and split ring resonators, which exhibited negative permittivity and permeability both at the X-band frequency [2]. Later until nowadays a lot of research have been done on the metamaterial characteristics and its applications, such as Hasan et al. proposed a compact z-shaped double negative metamaterial for C- and X-band operations. The metamaterial structure single unit cell was 10×10 mm2 and effective medium ratio was more than 4 [3]. A negative index meta-atom, the resonance at C-, X- and Ku-band with wide negative refractive index bandwidth from 7.0 to 12.81 GHz was presented in [4]. Moreover, the meta-atom presented negative index characteristics at X- and Ku-band. A circularly polarized reconfigurable millimetre wave antenna was presented for achieving low-cost beam steering in 32.5 GHz with the axial ratio <1 dB. The antenna was constructed by placing a periodic array of transverse strips along the surface of a dielectric waveguide [5]. A microstrip line fed star-star fractal antenna with notch loaded semi-elliptical ground plane was proposed for super wideband applications. An impedance bandwidth of 4.60 to 52.0 GHz, which was a bandwidth ratio of 11.31:1 was achieved for VSWR less than 2. The simulated resonances were at the frequencies of 5.60, 8.50, 14.30, 18.0, 21.0, 30.0, 33.50, 36.50, 41.0, 43.50, 46.0, and 48.0 GHz as well as the measured resonances were at 5.60, 8.50, 14.30, 18.0, 29.80, 33.20, 36.20, 41.10, 44.10, 46.30, and 47.40 GHz [6]. A fractal antenna with triangular slot for super bandwidth from 3.0 to 35.0 GHz was suggested, which designed by the triangular slot on a hexagonal metallic patch with tapered microstrip feedline. The SWB antenna total dimension of 20.0×33.4×1.57 mm3, a bandwidth ratio of 11.6:1, and gain varies from 2.2 to 11.2 dBi in the frequency range of 3.0 to 35.0 GHz [7]. A star-triangular fractal monopole SWB antenna with a semi elliptical ground plane was designed to operate the frequency band between 1.0 to 30.0 GHz for VSWR less than 2.0 [8]. In this paper a textile fractal SWB antenna was proposed that the total electrical size of 0.28×0.285×0.00875λ and the antenna based on the triangular circular patch and a modified elliptical ground plane. The proposed SWB antenna showed the operation band from 1.40 to 20.0 GHz [9]. A SWB antenna that consisted of a hexagonal radiation patch with two iterations of Sierpinski square slots for the operating bands, 3.81 to 29.64 GHz and 31.34 to 36.79 GHz [10]. Hossain et *al*. presented a frequency reconfigurable metamaterial antenna using a coupled-resonator structure and the effects of resonator structure are altered by closing and opening the splits using switches [11]. A compact 12.0×12.0×1.128 mm3 antenna was developed in 2017 for

operating higher frequency from 57.0 to 64.0 GHz, high gain <8 dBi, an isolation of better than 25 dB between the transmitting and receiving antenna in [12]. A metamaterial of electromagnetic band gap (EBG) was incorporated to an antenna for frequency re-configurability. The EBG consisted of two identical unit cells that provided multiple band gaps from 1.88 to 1.94 GHz, 2.25 to 2.44 GHz, 2.67 to 2.94 GHz, 3.52 to 3.54 GHz, and 5.04 to 5.70 GHz with different EBG configurations. Subsequently, an EBG structure was added with antenna to achieve different reconfigurable frequencies at 1.60, 1.91, 2.41, 3.26, 2.87, 5.21, and 5.54 GHz respectively. The antenna had the potential to be implemented for Bluetooth, Wi-Fi, WiMAX, LTE, and cognitive radio applications [13]. Further, a planar polarization reconfigurable antenna array using complementary square split ring antenna element based on SIW technique was investigated. The polarization states of the proposed antenna element could be reconfigured between the LP, LHCP, and RHCP modes. The antenna array had an impedance bandwidth (S11<-10dB) of 7.98 to 8.75 GHz and a 3-dB axial ratio bandwidth of 8.18 to 8.45 GHz for the two CP modes, and had an impedance bandwidth of 8.01 to 8.24 GHz for the LP mode. In addition, the maximum gains of the two CP modes and the LP mode were respectively 10.47 dBi, 9.9 dBi and 10.75 dBi [14]. Ding et *al*. introduced a millimetre wave pattern reconfigurable antenna, which adopts a linear array structure with three radiating elements with three reconfigurable modes in 2013. In addition, the three reconfigurable patterns point to -550 to 30 and -550 to +620 in the elevation plane [15]. In 2007 Liu et *al*. invented a dual band reconfigurable fractal patch antenna where the switches etched in the antenna slots and by changing the status of the switches the radiation patterns of the antenna were changed around 60.0 and 80.0 GHz, covering the elevation angles of 130 to 450, -130 to -450 around 60 GHz and of 150 to 500, -150 to - 500 around 80 GHz [16].

In this paper, a super wideband (SWB) antenna based on reconfigurable metamaterial is presented, which has a zig-zag shape on the patch and the metamaterial structure consists of a ring resonator with two switching configurations in the splits on the resonator. By changing the switching state, the performance of proposed antenna is varied. The return loss (S11) of the antenna show the super wideband from 31.0 to 52.50 GHz (bandwidth of 21.50 GHz). At present, in order to support increased traffic capacity, high data rate transmission bandwidths are required in the millimetre wave frequency range (more than 30 GHz) for the communication. This presented antenna includes the frequency bandwidth spectrum from 31.0 GH to 52.50 GHz. As a result, the mentioned bandwidth of the antenna is applicable for the millimetre wave frequency range applications.

2. Reconfigurable Antenna Design

The proposed reconfigurable SWB antenna is designed by a radiating patch where a zig-zag shape on the patch. The slotted ground plane of the antenna is modified with a metamaterial structure to obtain the reconfigurable characteristics. The metamaterial structure consists of a ring resonator with two switching configurations (switch-A and switch-B) between the splits in the resonator. Moreover, the total dimensions of the antenna and the unit cell structure are respectively, 50×40 mm2 and 50×40 mm^2.The schematic views of the radiating patch, metamaterial based ground plane, and the metamaterial single unit cell is shown in figure 1(a-c). The proposed SWB antenna has been printed on a Rogers RT 5880 material (thickness of 1.575 mm, dielectric constant of 2.2 and loss tangent of 0.0009). Copper is used as a resonator on the dielectric substrate with an electrical conductivity of σ=5×8 s/m. The dielectric thickness, mainly helps the coupling between the electric resonance occurred on the metallic resonators with the bottom metallic layer. This coupling creates a magnetic response and makes the effective impedance to be equal to the impedance of the free-space. The fabricated view of the antenna displayed in figure 1(d-e) and optimized dimensions of the designed antenna exhibited in table 1.

Table 1: Optimized dimension (mm) of the proposed SWB reconfigurable antenna.

Para.	L_A	W_A	L_1	W_P	W_f	W_1	W_2
Size	50.0	40.0	38.0	36.0	6.0	23.0	7.0
Para.	L_g	W_g	W_S	H_S	g_2	A	W
Size	9.0	40.0	8.0	2.0	41.0	30.0	22.0

The dimensions of the proposed reconfigurable metamaterial single unit cell structure are: length (A)= 30.0 mm, width (W)= 22.0 mm, metal (copper) width (d)= 4.0 mm, and gap (g)= 4.0 mm. To make the designed metamaterial as reconfigurable metamaterial two switches (S-A and S-B) is placed on the resonator structure in between the splits as shown in figure 1(c). Depending on the state of switches, three different configurations (Conf-1, Conf-2, and Conf-3) are considered. The '0' and '1' states of switch are used for open and close conditions of a switch, respectively. As described in table 2 configuration, Conf-1 consists of both switches (S-A and S-B) are open. The Conf-2, the configuration consists of switch S-A open and switch S-B close state as well as Conf-3 configuration consists of both switches (S-A and S-B) are close.

Table 2: State of the switch on different configuration.

Configuration	State of Switch	
	S-A	S-B
Conf-1	0	0
Conf-2	0	1
Conf-3	1	1

The simulation of the proposed antenna is performed by the CST Microwave Studio and measurement is done by the Agilent N5227A vector network analyzer, whereas the network analyzer is calibrated by the Agilent N4694-60001 to achieve the perfect over the entire super wide band (SWB) spectrum. To understand the characteristics of the metamaterial unit cell integrated on the antenna ground plane simulation of the unit cell is done in CST-MWS, whereas the electric boundary is set as an E-field and magnetic boundary is defined H-field. The Nicolson-Ross-Wire method has been utilized to retrieve the effective parameters, which are as follows [17],

$$Permeability, \mu_r \approx \left[\frac{C}{j\pi fd} \left\{ \frac{1-S_{21}+S_{11}}{1+S_{21}-S_{11}} \right\} \right] \quad 1$$

$$Permittivity, \varepsilon_r \approx \left[\frac{C}{j\pi fd} \left\{ \frac{1-S_{21}-S_{11}}{1+S_{21}+S_{11}} \right\} \right] \quad 2$$

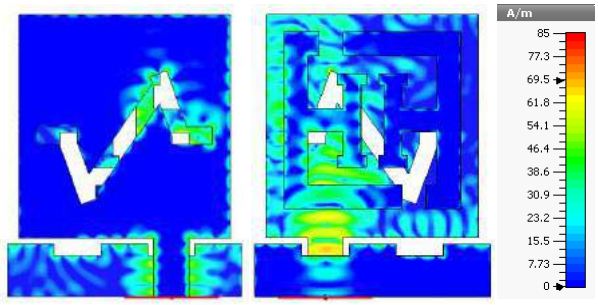
$$Refractive\ Index,\ n_r \approx \sqrt{\mu_r \varepsilon_r}$$

$$Refractive\ Index,\ n_r \approx \left[\frac{C}{j\pi fd} \sqrt{\left\{ \frac{(S_{21}-1)^2 - S_{11}^2}{(S_{21}+1)^2 - S_{11}^2} \right\}} \right] \quad 3$$

where, '*d*' is the thickness of the substrate, '*C*' is the velocity of light, 'S_{11}' is the reflection coefficient, and 'S_{21}' is the transmission coefficient.

3. Antenna Performance

The metamaterial structures provide a resonant lumped circuit behavior in some certain frequency bands. The ground metamaterial structure resonator metal strips behave like inductors and the gaps as capacitors. To illustrate how the structure works when placed in an electromagnetic field region, the surface current distribution is presented in figure 2. It can be observed from figure 2 that the current is uniformly distributed along the surface of radiating patch, feed line and the ground plane. The magnetic field shows a similar distribution as the current supports that the resonances are obtained of magnetic type. Moreover, a close examination of the current distribution in figure 2 leads to the observation of some gaps. These gaps occur at current minimum points and this provides an additional capacitance-like response. The electric field is highly localized around these gaps and the reason of the high concentration around the actual gaps is the capacitive effect at these regions.

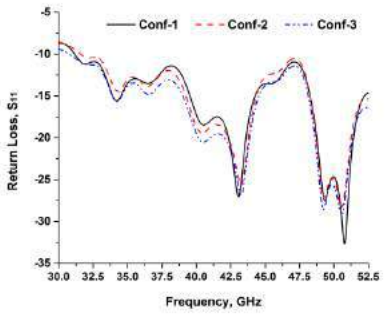


(a) (b)

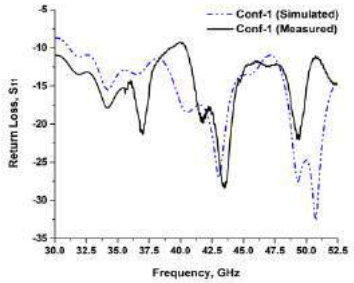
Figure 2: Surface current distribution at 42.99 GHz in: (a) Radiating patch (front view), (b) Ground plane with the reconfigurable metamaterial (back view).

The full wave simulation of the design antenna with three different switching states, which explained above are shown in figure 3. In figure 3(a) the simulated return loss (S_{11}) of the antenna for three different configurations (Conf-1, Conf-

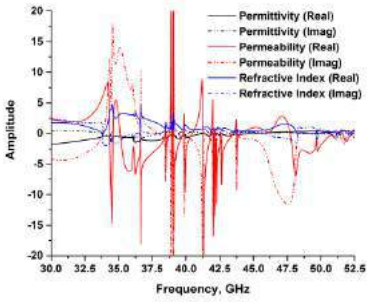
2, and Conf-3) are displayed. The simulated resonances at 34.14, 43.0, 49.41, and 50.71 GHz are found quite similar to the proposed antenna three different configurations (Conf-1, Conf-2, and Conf-3), whereas the measured results only for Conf-1 in displaying when the both switches (S-A and S-B) are open state. The measured return loss shows resonance peaks at 34.20, 36.96, 41.82, 43.50, and 49.41 GHz when the both switches (S-A and S-B) are open state in figure 3(b). The measured results are slightly different from the simulated results due to the effects from Sub Miniature Version A (SMA) connector soldering with feed line, proper calibration characteristics and toleration of the measurement. Basically, the proposed metamaterial single unit cell structure of the ground plane has strong negative characteristics in the higher frequency and remove the high frequency band of the antenna to create a stop band. Figure 3 (c) depicts the effective medium parameters (permittivity, permeability, and refractive index) curve of the integrated metamaterial. From the graph negative permittivity is from 30.0 to 46.80 GHz and the permeability is shown two negative regions from 35.11 to 40.75 GHz and 48.12 to 51.16 GHz. Moreover, at the resonance points of the reflection coefficient (S_{11}) the amplitude of the permittivity, permeability and refractive index are respectively -0.45-0.29j, 8.33+4.12j, 1.10-1.89j at 34.14 GHz, -0.45+0.12j, 0.64-0.30j, 0.53+0.036j at 43.0 GHz, 0.32-0.05j, -2.53-0.23j, 0.032-0.89j at 49.41 GHz, and 0.37-0.15j, -2.0-0.66j, 0.167+0.88j at 50.71 GHz. There is variation between the results of the permittivity, permeability and refractive index for the polarization effects on the internal structure of the materials. The loss depends on the effective medium parameters and defined by the ratio between the imaginary and the real magnitude of the effective permittivity or permeability. In addition, the imaginary components of the effective medium parameters attributed to bound charge and dipole relaxation, which gives rise to energy loss that is indistinguishable from the loss due to the free charge conduction. However, figure 3(d) shows the simulated results of the VSWR of the proposed antenna at different switching state, which are illustrated in table 2.



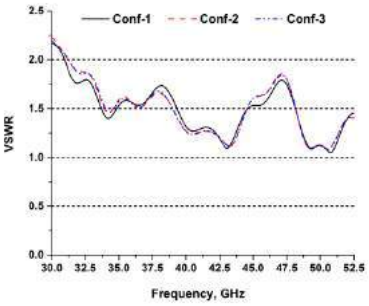
(a)



(b)



(c)



(d)

Figure 3: (a) Simulated return loss (S_{11}) at different switching state (shown in table 2), (b) Measured and simulated return loss of the proposed antenna at both switches (S-A and S-B) are open state, (c) Amplitude of the effective medium parameters of the designed reconfigurable metamaterial at both switches (S-A and S-B) are open state, (d) Simulated VSWR of the proposed SWB antenna at different switching state (shown in table 2).

The *y-z* (E-plane) and *x-z* (H-plane) radiation patterns of the proposed antenna at 42.99 and 49.06 GHz are shown in figure 4(a-c) and figure 5(a-c). It is observed from the plot that the radiation patterns are omnidirectional and stable in the *y-z* plane. In *x-z* plane patterns, few nulls have been observed in the broadside direction due to the diverse electric current distribution. With the raise of the frequency more nulls are observed with some ripples in the amplitude due to many refection into the field.

4. Conclusion

A SWB antenna with reconfigurable metamaterial has been analysed in this paper. This proposed antenna takes full advantage of the metallic patch with a zig-zag shape slot in the patch as an effective radiation element without introducing any parasitic elements. The performance of the antenna is significantly affected by the ground plane. Modification of a large ground plane into a partial phase decreased ground plane dependency, enhances the operating band, overcome design complexity and development difficulty. The reconfigurable technology is present in the integrated, switchable metamaterial structure in the ground plane of the antenna. By changing the switching state, the performance of the antenna is changed and the designed antenna shows the large bandwidth of the return loss for the millimetre wave applications. Moreover, a considerable amount of back lobe was observed, possibly because of the utilization of partial ground plane. A full ground plane can reduce this back lobe at the cost of low gain, low efficiency and narrow bandwidth. Finally, the controlling metamaterial structure characteristics of proposed antenna create a new way of designing reconfigurable antenna.

Abstract

A metamaterial based frequency reconfigurable antenna is presented for 5G communication. It is composed of a straight feed-line monopole with two double split-ring resonators (DSRR). The DSRR is developed by an outer and inner split ring resonators with inverse E-shape metal strips of copper are connected with the outer ring resonator. Commercially available electromagnetic simulator is utilized to design and numerical investigation. The return loss (S_{11}) shows the resonance in 32.08, 35.07, and 41.60 GHz. The performance of the proposed reconfigurable antenna is analyzed by activate or deactivate the DSRR. However, the designed metamaterial shows left handed characteristics and compact in size.

1. Introduction

The fifth generation (5G) networks are expected to use the higher frequency bandwidths due to the growing need for wider bandwidths and higher data rates. Compared with the cellular networks used today, 5G mobile networks will the proposed bands in the millimetre wave region are, 37.0 to 40.50 GHz, 42.50 to 43.50 GHz, 45.50 to 47.0 GHz, 47.20 to 50.20 GHz, which have allocations to the mobile service on a primary basis. Besides, 31.80 to 33.40 GHz, 40.50 to 42.50 GHz, and 47.0 to 47.20 GHz, which may require additional allocations to the mobile service on a primary basis for 5G wireless communications. Re-configurability of an antenna adds more versatility in the application, like frequency of operation, direction of the main beam, beam width, of a particular antenna. Metamaterials are an artificial material with more compact size compare with conventional structures and have some infrequent properties, which does not exist in the nature materials. Metamaterial based reconfigurable antenna can achieve a high performance by dynamically changing its physical structure. It is equivalent to having multiple antennas with different physical aperture [1]. So, the metamaterial based reconfigurable antenna can reduce the overall cost, weight, and size of a system. Moreover, few metamaterials based reconfigurable antenna has been investigated in this study. V. G. Veselago first 1968 discussed about the concept of metamaterial. After a long time at 2000, D. R. Smith and his colleagues invented a material that shown the negative permittivity and permeability at a same time with some infrequent properties [2]. The use of metamaterial in the antenna structure make the antenna structure compact, flexible for low or high frequency applications, etc. As a result, huge research had been done on metamaterial antenna from the past to present days. Such as a z-shaped double negative metamaterial had been proposed for C- and X-band operations in 2016. The metamaterial structure single unit cell was 10×10 mm^2 and effective medium ratio was more than 4 [3]. A negative index meta-atom, the resonance at C-, X- and Ku-band with wide negative refractive index bandwidth from 7.0 to 12.81 GHz was projected in [4]. A reconfigurable loop antenna with two parasitic Inverted-L grounded strips for modern smartphone devices was presented, which outer metal rim generates three loop modes and the inner parasite grounded strips provided two monopole modes. By merging these two types of antenna modes, it covered GSM 850/900 and LTE 2300/2500 operations with a compact antenna size of 945 mm2. For lower-band (from 824 to 960 MHz), the antenna gains and total efficiencies were approximately 0.3 to 1.7 dBi, and 45 to 60%, respectively, as well as for the upper operating band (from 1710 to 2690 MHz), gains and total efficiencies were respectively about 1.2 to 4.2 dBi and 47% [5]. In this paper a planar polarization reconfigurable antenna with a simple switching topology by utilizing the dual resonating-mode behaviour of the substrate integrated waveguide (SIW) cavity was introduced. Two input-ports were adopted to adjust the phase distributions of the radiating slots etched on the top surface of the SIW cavity. The LHCP, RHCP and linear polarization (LP) could then be realized by using the proper input port. The LHCP had a 3dB axial ratio bandwidth from 5.87 to 5.89 GHz and 5.86 to 5.89 GHz for the RHCP states. The bandwidth of return loss and gain for the LP state were respectively, from 5.65 to 5.9 GHz and 10.0 dBi [6]. A millimetre wave antenna (operation band from 46.0 to 70.0 GHz) consisted of two planar dipoles and a shorted patch, provided over 50% impedance bandwidth and almost 8 dBi gain, but radiates unidirectional with low cross-polarization and back radiation levels [7]. An advanced integration technique for the millimetre wave beam was analysed, where the operational bandwidth and true time delays of the technique were superior to millimetre wave beam steering for 5G wireless networks [8]. A bowtie antenna loaded with a metamaterial to generate a dual beam pattern from 55.0 to 68.0 GHz. The double-sided split-ring resonator structure arrays were integrated and tilted 15° to adapt the radiation beam and the antenna exhibited a high gain of 11.4 dBi in 62.0 GHz [9]. A negative index metamaterial based antenna

was presented, where the narrowband tuned over a broad frequency (from 1.60 to 2.23 GHz), while the higher band remained constant by using a varactor diode (capacitance from around 0.1 to 0.7 pF). Moreover, the total dimension of the antenna ware $0.056\lambda_0 \times 0.047\lambda_0$ and placed over a $0.23\lambda_0 \times 0.111\ \lambda_0$ CPW ground plane [10]. In 2007 Liu et al. invented a dual band reconfigurable fractal patch antenna where the switches etched in the antenna slots and by changing the status of the switches the radiation patterns of the antenna were change around 60.0 and 80.0 GHz, covering the elevation angles of 130 to 450, -130 to -450 around 60 GHz and of 150 to 500, -150 to - 500 around 80 GHz [11]. For the millimetre wave applications a dual band reconfigurable fractal patch antenna was proposed that showed similar operating frequencies, but different radiation patterns between the zeroth-order and the +1 order resonance mode [12]. A chiral metamaterial structure based on the inverse E-shape combined with the outer ring resonator printed on Rogers RT 5880 material was proposed, which showed resonance at C-band and 5.14 GHz bandwidth from 4.0 to 9.14 GHz [13]. A reconfigurable dipole antenna was suggested for 5G applications that maintained by the switches in square patches. The designed antenna was accomplished to switch the polarization among one linearly polarized and two orthogonal circularly polarized states. The antenna shown the bandwidth from 5.07 to 5.95 GHz 8.20 dBi stable gain [14].

In this paper, we present a metamaterial based frequency reconfigurable antenna that is composed of a straight feed-line monopole with two double split-ring resonators for 5G applications. The designed metamaterial single unit cell integrated with the antenna, which is developed by an outer and the inner split ring resonators with inverse E-shape metal strips of copper are connected with the outer ring resonator. The results show the resonances of return loss with DSRR or without DSRR or right side DSRR or left side DSRR are around at 32.08, 35.07, and 41.60 GHz. At present, in order to support increased traffic capacity 5G extend high data rate of transmission for communication. This includes a new spectrum from 30 GH to higher frequency. As a result, all of the mentioned resonance peaks is applicable for the 5G applications.

2. Structural Design of the Proposed Antenna

Figure 1(a-c) shows the detailed configuration of this metamaterial based reconfigurable antenna. As shown in figure 1 the proposed antenna is printed on a Rogers RT 5880 material (thickness of 1.575 mm, dielectric constant of 2.2 and loss tangent of 0.0009). The optimized size of the antenna is 20×22 mm2 and metamaterial single unit cell is 8×8 mm2. Moreover, the antenna is composed of a straight feed-line monopole with two double split-ring resonators (DSRR). The DSRR is developed by an outer and the inner split ring resonator with inverse E-shape metal strips of copper are connected with the outer ring resonator. A connector is attached to the port of the antenna that delivers a 50Ω impedance. However, the fabricated front and back view and the antennas with two DSRR, right side DSRR, left side DSRR, and without DSRR are shown respectively in figure 2(a-b), and figure 3(a-d).

Table 1: Optimized dimension of the proposed SWB reconfigurable antenna.

Parameters	L	W	W_L	W_R	W_f	W_1	W_2
Size (mm)	20.0	22.0	8.0	8.0	3.0	9.5	9.5
Parameters	L_{Lg}	L_{Rg}	L_{Ug}	g_L	g_R	L_g	W_g
Size (mm)	11.50	9.0	3.0	1.0	1.0	7.0	13.0

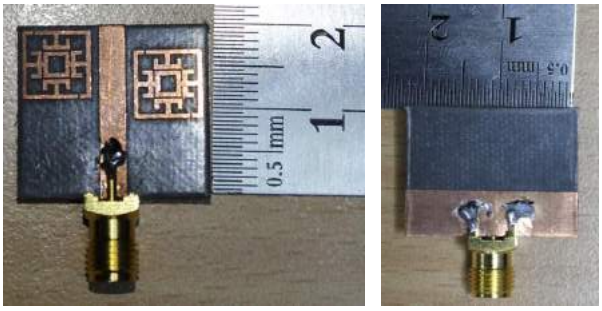
(c)

Figure 1: Schematic view of the proposed reconfigurable antenna: (a) Front view, (b) Back view, and (c) Schematic view of the designed metamaterial single unit cell.

The dimensions of the designed metamaterial single unit cell structure are: outer resonator length (L_L)= 8.0 mm, outer resonator width (W_L)= 8.0 mm, inner resonator length

(L_{IN})= 3.0 mm, inner resonator width (W_{IN})= 2.0 mm, C= 3.2 mm, and resonator metal (copper) width (d)= 0.5 mm.



(a) (b)

Figure 2: Fabricated view of the proposed antenna: (a) Front view, and (b) Back view.

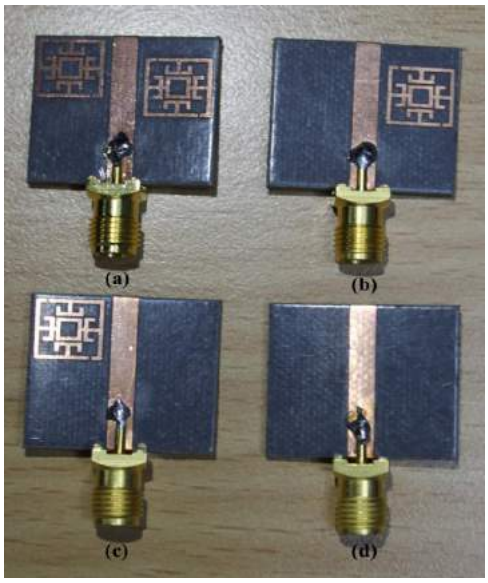


Figure 3: (a) Antenna with two DSRR, (b) Antenna with right handed DSRR, (c) Antenna with left handed DSRR, and (d) Antenna without DSRR.

The simulation of the proposed antenna is performed by the CST Microwave Studio software and measurement is done by the Agilent N5227A vector network analyser, whereas the network analyser is calibrated by the Agilent N4694-60001 to achieve the perfect over the entire super wide band (SWB) spectrum. To understand the characteristics of the metamaterial unit cell integrated on the antenna ground plane simulation of the unit cell is done in CST-MWS, where perfect electric and perfect magnetic boundaries are applied along x and y planes, so that the electric field is oriented along *x*-direction and magnetic field is oriented along *y*-direction. Nicolson-Ross-Wire method has been utilized to retrieve the effective parameters, which are as follows,

$$S_{11} \approx \left\{ \frac{R_1\left(1-e^{-2j\theta}\right)}{1-R_1^2 e^{-2j\theta}} \right\} \quad (1)$$

$$Similarly, S_{21} \approx \left\{ \frac{e^{-2j\theta}\left(1-R_1^2\right)}{1-R_1^2 e^{-2j\theta}} \right\} \quad (2)$$

$$Permeability, \mu_r \approx \left[\frac{C}{j\pi fd} \left\{ \frac{1-S_{21}+S_{11}}{1+S_{21}-S_{11}} \right\} \right] \quad (3)$$

$$Permittivity, \varepsilon_r \approx \left[\frac{C}{j\pi fd} \left\{ \frac{1-S_{21}-S_{11}}{1+S_{21}+S_{11}} \right\} \right] \quad (4)$$

$$Refractive\ Index,\ n_r \approx \sqrt{\mu_r \varepsilon_r}$$

$$Refractive\ Index,\ n_r \approx \left[\frac{C}{j\pi fd} \sqrt{\left\{ \frac{\left(S_{21}-1\right)^2 - S_{11}^2}{\left(S_{21}+1\right)^2 - S_{11}^2} \right\}} \right] \quad (5)$$

where θ= ξd, '*d*' is the thickness of the substrate, 'R_1' is the normalized impedance '*C*' is the velocity of light, 'S_{11}' is the reflection coefficient, and 'S_{21}' is the transmission coefficient.

3. Antenna Performance

To understand the operating principle of the antenna, the current distributions on the proposed antenna at 32.08 GHz is shown in figure 4. The current is distributed parallel and anti-parallel at the surface of metallic patches for the resonance frequencies. Parallel surface current distribution regulates the electrical resonance whereas antiparallel surface currents control magnetic resonance. The source of surface currents is a strong magnetic and electric coupling and the magnetic and electric resonance that pairs with external applied fields. The color in the figure indicates the intensity of the current, besides the directions of the current is shown by the arrows.

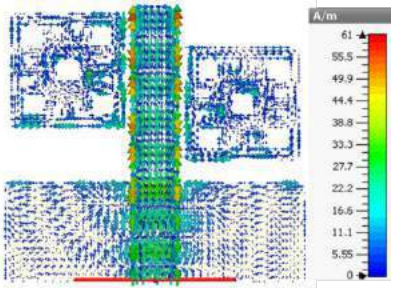

Figure 4: Surface current distribution at 32.08 GHz of the proposed antenna with two DSRR.

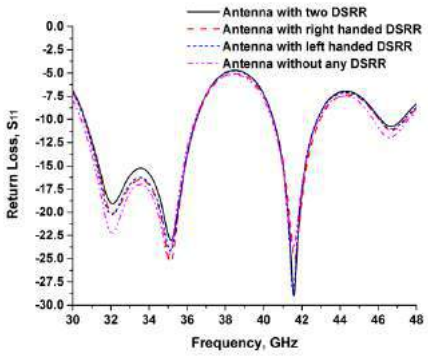
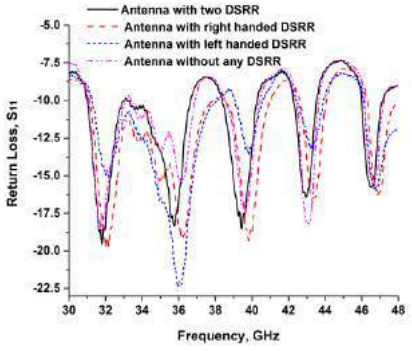
The antenna performance is described by the return loss (S_{11}), VSWR, gain, radiation pattern. The performance of the designed antenna is analysed by integrating the metamaterial structure at different position. The simulated and measured results of the proposed antenna are shown in

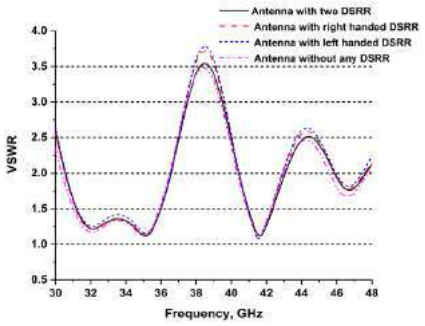
figure 5(a-b). In figure 5(a) the simulated results resonances at 32.08, 35.07, and 41.60 GHz are around similar for the variation of the proposed antenna configuration, whereas the measured results are in figure 5(b). The measured results are slightly different from the simulated results due to the effects from Sub Miniature Version A (SMA) connector soldering with feed line, proper calibration characteristics and toleration of the measurement. Figure 5(c) display the simulated voltage standing wave ratio (VSWR) of antenna with two DSRR, right side DSRR, left side DSRR, and without any DSRR. The properties of the metamaterial are characteristics by the effective medium parameters (permittivity, permeability, and refractive index ratio). Figure 5(d) exhibited the curve of effective medium ratio. From the curve real magnitude of effective negative permittivity from 30.0 to 44.42 GHz, negative permeability has two negative regions from 33.64 to 36.69 GHz and 41.64 to 47.14 GHz. In addition, at the points of the reflection coefficient (return loss) the permittivity, permeability, and refractive index amplitude are respectively, -1.41+0.40j, 0.62-3.77j, 1.81+0.57j at 32.08 GHz, -1.36-0.93j, -5.87+4.11j, 3.43-0.024j at 35.07 GHz, and -0.026-0.50j, -29.88-73.04j, 1.12+0.93j at 41.60 GHz. There is variation between the results of the permittivity, permeability, refractive index for the polarization effects on the internal structure of the materials.



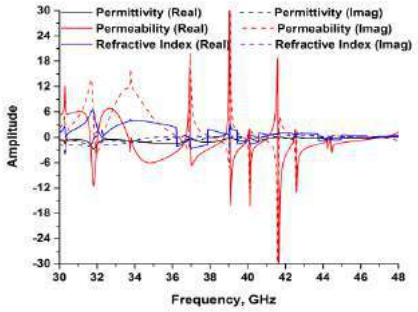
(a)



(b)



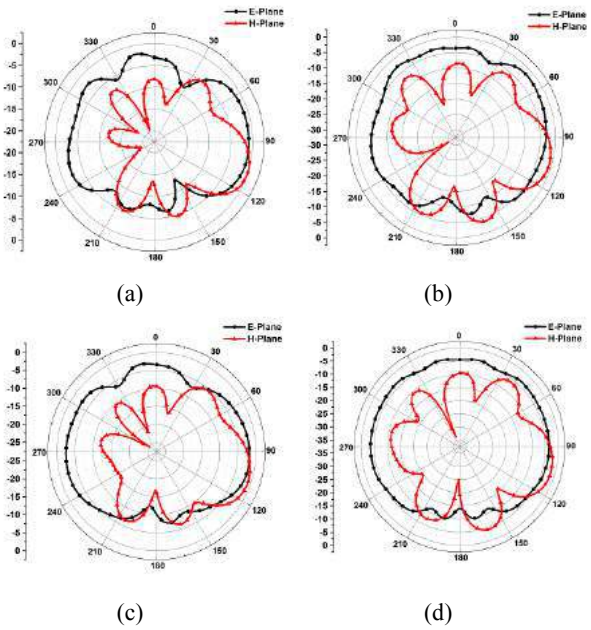
(c)



(d)

Figure 5: Proposed reconfigurable antennas: (a) Simulated results of return loss (S_{11}), (b) Measured results of return loss (S_{11}), (c) Simulated VSWR, and (d) Amplitude of the effective medium parameters of the integrated metamaterial.

The material can be characterized by the electrical permittivity and the magnetic permeability. From figure 5(d) the loss of the integrated metamaterial structure is defined by the amplitude ratio of the imaginary value of the (permittivity or permeability) and real value of (permittivity or permeability). If the ratio is more than 1 (<1) then loss positive and when it's less than 1 (>1) loss is negative. Moreover, the two dimensional (2D) radiation patterns at 32.04 and 42.60 GHz are demonstrated in figure 6(a-d) and figure 7(a-d), where both Phi =0° and Phi =90° are included as E-plane and H-plane, whereas the *y*-*z* plane is considered as the E-plane and the *x*-*z* plane is considered as the H-plane. It is seen from figure 6(a-d) and 7(a-d) that the radiation patterns at Phi = 0° are nearly omnidirectional. The results of the *y*-*z* plane in radiation pattern at similar resonance frequency seems almost same for all of the different configuration of the proposed antennas. At the lower frequency the number of the side lobes reasonably less, but with increasing frequency, the patterns have more side lobes and slightly directional. There are few nulls are observed at lower frequencies due to lower order harmonics, the antenna exhibits stable radiation patterns throughout the operating band. The ripples in the radiation patterns may be due to the refection into the field.

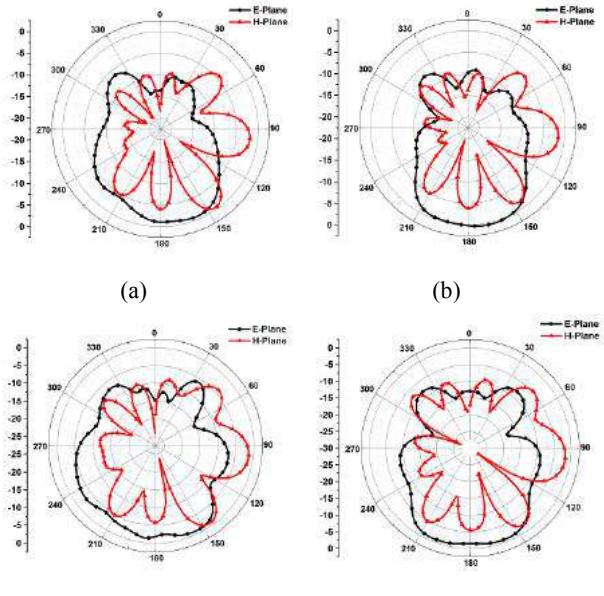


(a) (b)

(c) (d)

Figure 6: Simulated radiation pattern of the proposed antenna at 32.08 GHz: (a) with two DSRR, (b) with right handed DSRR, (c) with left handed DSRR, and (d) without DSRR.

A considerable amount of back lobe was observed, possibly because of the utilization of partial ground plane. A full ground plane can reduce this back lobe at the cost of low gain, low efficiency and narrow bandwidth.



(a) (b)

(c) (d)

Figure 7: Simulated radiation pattern of the proposed antenna at 41.60 GHz: (a) with two DSRR, (b) with right handed DSRR, (c) with left handed DSRR, and (d) without DSRR.

4. Conclusion

The field of wireless communication has witnessed tremendous growth as the technological facility of telecommunications infrastructure, improved significantly in the last decade. Irrespective of the applications, most of the reconfigurable antenna has similar requirements of increased functionality, improved operation, small size and most importantly low system cost. However, the demand on the basic requirement a metamaterial based reconfigurable antenna is proposed by utilizing a metamaterial unit cell integrated with the antenna structure in this paper. The performance of the antenna is varied and investigated by changing the position of the metamaterial with the antenna feed line. As a demonstration, the antennas are designed with a 1.575 mm thickness Rogers RT 5880 substrate material. Experiments are carried out to verify the designs, which show well agreement with the designs. The proposed antenna is showing resonance in higher frequency above 30 GHz, which are desirable for the 5G communication applications. So, the proposed reconfigurable antennas can be used for the diverse applications of the high speed wireless system.

Abstract - Plasmonic colour printing based on engineered metasurfaces has revolutionized colour display science due to its unprecedented subwavelength resolution and high-density optical data storage. However, advanced plasmonic displays with novel functionalities have remained in their infancy. Here we demonstrate a dynamic plasmonic colour display technique which enables all the aforementioned functionalities using catalytic magnesium metasurfaces. Controlled hydrogenation and dehydrogenation of the constituent magnesium nanoparticles, which serve as dynamic pixels, allow for plasmonic colour printing, tuning, erasing, and restoration of colour.

In this work, we demonstrate a dynamic plasmonic display technique based on catalytic Mg metasurfaces. Different from other hydrogen-storage metals such as palladium (Pd) and yttrium, which are associated with poor optical response, Mg exhibits excellent plasmonic properties at high frequencies. For example, Mg nanostructures have been used for chiral sensing in the UV spectral range and for hydrogen sensing in the visible spectral range[1-4]. Most importantly, the unique hydrogenation/dehydrogenation kinetics of Mg nanoparticles is ideally suited for creating dynamic plasmonic systems.

The grey-dotted lines indicate the colour vanishing times in the two cases.

Here, we demonstrate successively plasmonic microprint displays with high reversibility, plasmonic animations with subwavelength resolution, and highly secure plasmonic encryption. Our work will stimulate fascinating colour display applications utilizing plasmonic dynamic pixels with nanoscale controllability.

Abstract- In this work, we developed a variety of colour utilizing the metamaterial based perfect absorber based on a coupled nanocrystals (NCs). It is essential to produce two optical absorption spectra with broad bandwidth for the vivid colours. Previously, a conventional metamaterial absorbers, typically made of metals such as silver, gold or aluminum are limited to a narrow bandwidth, and it have difficulty for generation of distinct colours. The chemically coupled NCs (metals, semiconductors and insulators) are newly designed materials in this study for the controlled optical properties of metamaterials. In the corresponding results, the developed NC based absorber in visible wavelength showed the high absorption above 98% in two absorption spectra containing a high reflectance peak, and we tuned the desired colour of varying NC type and nanostructure.

Metamaterial absorbers have great potential in applications for a solar energy harvesting devices, an image application such as digital displays and so on due to their partial absorption spectra. With the point towards higher color resolution and a various color generation in reflective displays, a high absorption property is necessary in partial wavelength. In this study, we focus on the coupled NCs based metamaterial perfect absorber for the color generation in the visible and NIR regions.

NCs can be used as new material in metamaterial building block because their optical properties are different with their type, shape and size. When the coupled NCs which are either same materials or different materials are covalently linked via short ligand on surface of each NC, the optical properties can be controlled. In this study, the coupled Ag NCs and the Ag based hybrid NCs were developed, and the metamaterial structure which consists of NCs were fabricated by nanoimprinting lithography and lift-off method. Also, perfect absorbers were successfully developed containing with the nanodisk array or nanohole array for the variation of absorption wavelength.

Finally, the simulated and fabricated metamaterial perfect absorber using NC showed the high absorption above 98% in visible and NIR range. As the materials are changed and metamaterial structures are controlled in perfect absorbers, the absorption property could be tuned, and the specific vivid colours were generated. Color reproduction, or color gamut, represents about 19%.

Dual-color plasmonic pixels for high-density information storage

E. Heydari, [1] **J. Sperling,** [1] **S. Neale**[1] **and A.W. Clark**[1*]
[1]School of Engineering, University of Glasgow, UK

Abstract- We demonstrate a new plasmonic approach to high-density optical data storage; using dual-color plasmonic nano-pixels to encode two information sets into the same unit area using single arrays of two-state metal nano-apertures.

The ability to effectively separate discrete colors from white-light lies at the heart of how we record and view optical information; whether that be the arrangement of colored inks in painting and printing applications, or the spectral filters that enable many modern image display and recording technologies. In each case, color separation is typically provided by organic compounds; dyes and pigments that absorb and scatter particular wavelengths of light, leading to their distinct color profiles. Recently, structural color systems based on engineered nanophotonic materials have emerged as an appealing alternative to absorptive dyes [1]. Among these examples are color filters based on plasmonics; filters which rely on the resonant interaction between incident photons and the free-electrons of nano-scale metal structures. Plasmonic filters hold several dimensional and stability advantages over their micro-scale, dye-based counterparts. As a result, they have been positioned as new technological solutions for sub-wavelength color printing [1], RGB splitting for image sensors [2], anti-counterfeiting measures [3], and optical data storage [4]; thus representing one of the most promising, commercially relevant areas of current plasmonic research activity.

Here, we demonstrate a method for patterning full-color images and codes, at subwavelength resolutions, that exhibit dual, polarization-dependent information states. Our individual pixels are comprised of asymmetric cross-shaped nano-apertures in a thin film of aluminum; each aperture engineered to exhibit 2 independent plasmonic color resonances that can be individually tuned across the sRGB spectrum. This enables us to encode 2 arbitrary information sets into the same unit area using the same array of nano-pixels. We show that using a standard optical microscope, color separation can be controlled down to 2x2 nano-pixels (approximately 370 x 370 nm), while retaining polarization selectivity. This, in turn, defines our maximum data storage capability; each 2x2 pixel area acting as a 2-state data bit that can be read optically. The maximum data density we can achieve using this technique is approximately 1.46 Gb/cm^2, with the added ability to further encode each of those pixels using the full visible-color spectrum.

Abstract- Resonators and antennas that operate in the visible spectrum have enabled color printing by controlling the local geometry of nanostructures. These color prints exhibit unique properties, e.g. polarization dependent colors, ultra-high resolution ~100,000 dpi, and fade resistance. Recent developments of laser printing, active color tuning, stacked plasmonic colors, and scale-up to large areas have been demonstrated. To a large extent, nanostructures of silver, gold, and aluminum have been investigated. However, rapid developments in high-index dielectric nanoantennas have shown great promise in overcoming some of the shortfalls in plasmonic nanostructures, i.e. ohmic losses, and heating effects. In this talk we will discuss our latest investigation of the potential of dielectric nanostructures in high-resolution color prints.

Dynamic Full Color Plasmonic Surface and Active Addressing

Abstract- We demonstrate a liquid crystal-plasmonic system capable of producing the full RGB color basis set solely as a function of voltage. This is achieved through surface morphology induced polarization dependent color and liquid crystal effects which manifest at different voltages. We further show the integration of such a surface with a thin-film-transistor array to display arbitrary images.

Plasmonic nanostructures have many advantages for novel color and display applications including: diffraction limited color, the ability to control polarization and phase, and post-fabrication tuning through control of the surrounding media. The later of these phenomena could lead to dynamic color changing surfaces and displays, however current demonstrations have been limited in the range of color tuning achieved. Here, we show an increase in this ability and span the full RGB color basis set.

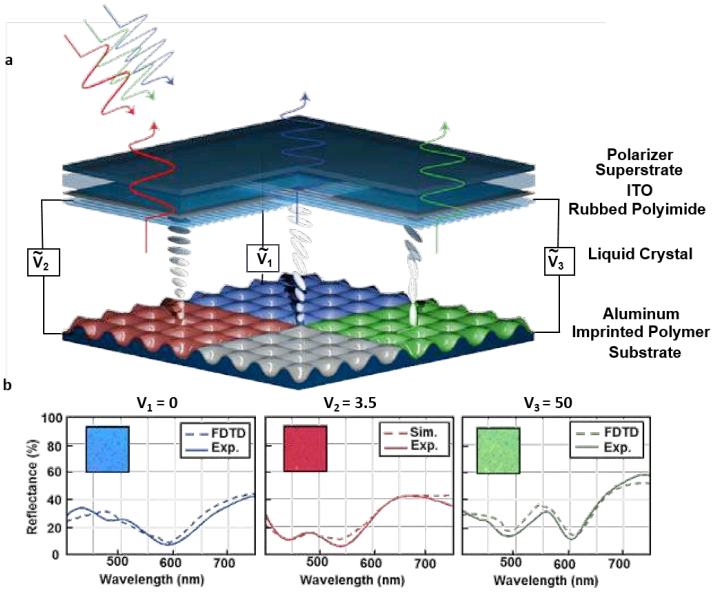

Figure 1 | Liquid crystal-plasmonic device. (**a**) Schematic illustrating the system and its three voltage states which reflect red, green and blue. (**b**) Reflection spectra and matching simulation. Line colors are obtained through the CIE color matching functions and insets are microscope images.

The liquid crystal-plasmonic system is shown in Figure 1a. Ambient white light passes through a polarizer, a traditional LC cell (glass, ITO, rubbed polyimide) and a high birefringent LC (LCM1107). The light is then incident upon a nanostructured plasmonic surface consisting of 30 nm of aluminum deposited on a nanoimprinted polymer. The pattern is a 2D sinusoidal grating 300 nm in periodicity and 100 nm in amplitude. The structure hosts grating coupled surface plasmon resonances within the visible domain, the spectral location of which depends on the orientation of the LC near the surface. The resonance further depends on the surface morphology of the deposited aluminum and through which we control the degree of polarization dependence of the reflected color. We use this to create a device which reflects blue or red light in the 0V (V_1, Off State) given the orientation of the top polarizer. For the given orientation of Figure 1b, this results in a blue reflection.

At voltage V_2 ($3.5V_{rms}$), the bulk LC reorients and rotates the polarization of the incident light to that of the orthogonal state, resulting in a red. Lastly, at the high voltage of V_3 (50 V_{rms}), the LC near the aluminum nanostructured surface reorients to a near vertical state. This red-shifts the plasmonic resonance resulting in a green and the loss of the surface's polarization dependence. These voltages are given for a cell gap of 8.5 um, however we believe they can be lowered by reducing this cell gap.

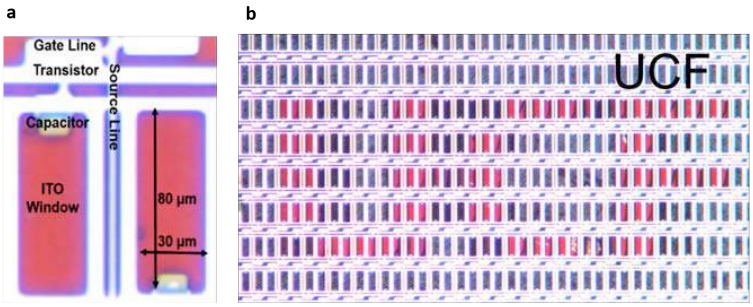

Figure 2 | TFT integrated liquid crystal-plasmonic surface. a) Microscope image (x10) showing the unit cell of the TFT array. (**b**) Display of the text "UCF" through a computer interface.

To show the system's compatibility with preexisting LCD technology, we have integrated the surface with a thin-film-transistor (TFT) array to create an actively addressed plasmonic surface. We procured a conventional transmissive LCD panel (Adafruit, ID: 1680) and harvested the TFT array and attached electronics by removing polarizers, backlight, diffusers and ITO glass. The plasmonic surface is then UV glued onto the TFT with 8.5 um spacers and filled with LCM1107. A microscope image of the device is shown in Figure 2a. Here, the plasmonic surface (red) is imaged through the TFT glass and contacts. By keeping the electronics attached to the TFT intact, individual pixels can be controlled through an HDMI-to-TTL converter and a laptop. Figure 2b shows the letter "UCF" displayed through a text editor. While this device can be used to display arbitrary shapes, images and video, there are several engineering problems to still overcome. Namely, the white reflection from the TFT metallic lines and the lack of high voltage drivers needed to display green.

Here we have shown a dynamically tunable LC-plasmonic surface that spans the full RGB color basis set with a single metallic nanostructure. We further demonstrate the system's compatibility with existing LCD technology by integrating it with a commercial TFT and display arbitrary text. We believe this could lead to a new class of displays.

Abstract- Transparent conducting oxides (TCOs) exhibit low loss plasmonic properties in the near infrared region of the electromagnetic spectrum and their carrier density can be tuned by doping. In this talk, we will present details on the properties of TCOs, such as Sn-doped In_2O_3 and Al-doped ZnO, and VO_2 along with light trapping metamaterial devices consisting 1D and 2D metallic gratings and TCO, which forms a Schottky contact with Si, for solar cell applications with enhanced photocurrent.

Noble metals such as Au and Ag have been used traditionally for plasmonic devices in the visible spectral range due to their strong interaction with light and good ohmic contact. However, conventional metals are not suitable for near infrared plasmonic applications due to their relatively large optical losses at these wavelengths. Transparent conducting oxides (TCOs), on the other hand, have been considered for low loss metallic components in the near infrared region of the electromagnetic spectrum because they can provide a tunable carrier density (10^{20} - 10^{21} cm^{-3}) by doping. For example, the zero-cross-over permittivity values of TCOs can easily be tuned from 1.2 μm to 3 μm by adjusting doping levels (Figure 1). Optical losses in devices made from these metal oxide materials are generally found to be much lower than those obtained with conventional metals. We have investigated various metal oxides such as Al-doped ZnO, Sn-doped In_2O_3 and VO_2. The details of electrical and optical properties of these metal oxides will be presented [1-3].

In order to extend Si sensitivity to infrared region without impacting visible response in Si solar cells, we have developed light trapping metamaterial devices based on TCO-Si heterostructures. The metamaterial structure consists of metallic 1D or 2D gratings, which couple light through a thin dielectric layer into the thin TCO layer, which forms a Schottky contact with Si. In this configuration, 1) surface plasmons interact strongly with incident light at the plasmon resonance, resulting in enhanced light concentration into the TCO layer, 2) IR photons absorbed as hot electrons in the TCO, and 3) these hot electrons move across a Schottky barrier into the Si substrate, resulting in enhanced photocurrent (Figure 2). We will present details on the optimization of geometric properties of the metal gratings (dimension, pitch) and tunable properties of the TCO layer (thickness, carrier density).

Compressive sensing and enhanced detectors with plasmonic metasurfaces.

A.M. Urbas
Air Force Research Lab, Dayton, Ohio
augustine.urbas@gmail.com

Metamaterials provide the ability to design materials properties to meet the unique needs of applications beyond what is possible with conventional materials. From spatially tailored dielectrics to tunable, dynamic material properties and unique nonlinear behavior, these systems offer tremendous flexibility to application engineers. Applications across the electromagnetic spectrum have been proposed; from novel RF antennas to devices utilizing optical magnetism. Researchers have pursued optical, RF and acoustic materials and applications. The aim of this work is to gauge the readiness and maturity of metamaterials for the field. Within AFRL, applications spanning the electromagnetic spectrum have leveraged metamaterials. The work we have pursued utilizes the unique traits of meta systems to match broadly different wavelengths and to have dramatic changes in response as a function of wavelength to develop novel communication and sensing systems. Looking to the future, dynamic and tunable metamaterials will be pursued. In the near term, detecting optical signals in the mid and long wave infrared are significant to a range of Air Force technologies and drive the research to increase performance and functionality. Both spectral and spatial information is obtained in images with hyperspectral. New challenges arise as detector pixel counts increase and the information desired from image data is more widely used. Limitations on data communication rates provide a bottle neck for acquiring and processing the increasingly large data sets. Compressive sensing may allow for more efficient acquisition data with higher information content, while preserving mission utility. Our research develops a combined method to integrate plasmonic and micro-optical elements onto detector structures which can both improve the performance of detector systems and provide a means to introduce compressive sensing and computational imaging methods. By coupling a variety of simulation environments which cover the optical, plasmonic, and electronic domains, we can efficiently comprehensively model detector function and performance for a wide range of designs and incorporate compressive sensing into the design loop. We will present the results of several design studies and experimental verification of modeled device performance for several device configurations such as the one pictured below.

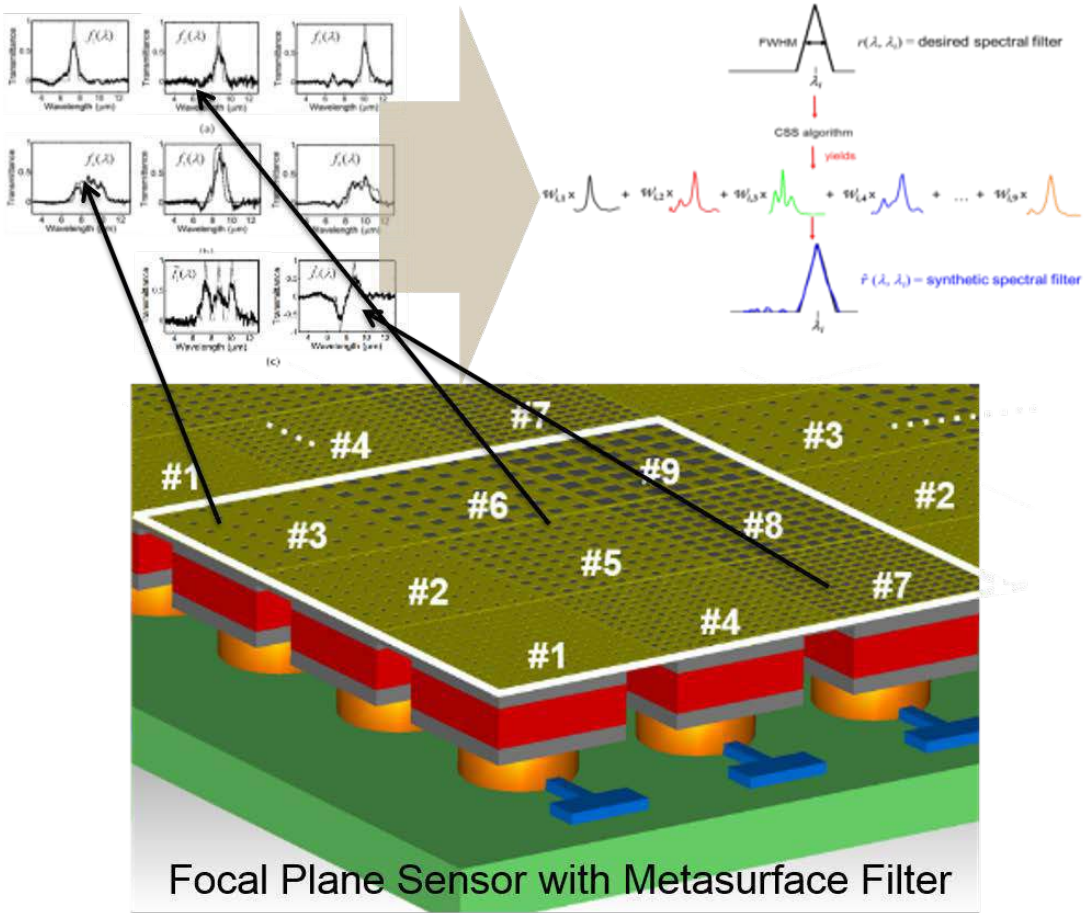

Figure 1: Metasurface filters integrated at the pixel level are engineered to modify the pixel responsivity. This forms the basis set for compressive spectral sensing of images where many spectral bands can be synthesized from linear combinations of the response of the basis set.

The 2D, 1D, and 0D Tightly Coupled Array Antennas

Hakjune Lee[1], **Sangwook Nam**[2*]
[1]Electronics and Telecommunications Research Institute (ETRI), Daejeon, Korea
[2] Department of Electrical and Computer Engineering, INMC, Seoul National University, Seoul, Korea

Abstract-Tightly Coupled Dipole Array (TCDA) is a ultrawideband array antenna proposed by Munk [1]. The operation principle of the TCDA is cancellation between inductive reactance of the ground plane at low frequency and capacitive reactance of coupled capacitance of neighboring element dipoles. In this paper, we present variety dimensions (2D, 1D, and 0D) TCDAs which can be used at electric warfare.

First, we propose the low-profile wideband 2D TCDA. To obtain the low profile and wide bandwidth, we control the impedance of element dipole antenna using vertical gap to operate at low frequency. The common mode and unwanted resonances are adjusted by shorting posts and via holes, respectively. The proposed element antenna is presented in Fig. 1, and its S-parameter response is shown in Fig. 2. The simulation shows that the bandwidth of the proposed array antenna is 3.37:1 (from 1.97 to 6.66 GHz) and low profile of 1/12.7 λ at lowest operating frequency.

Second, we propose the dual-polarized 1D TCDA. To maintain 2D TCDA characteristics, we locate the additional structures which consist of conducting wall with vertical slits and ferrite sheets beside the 1D arranged TCDA as shown in Fig. 3. The simulated -10dB reflection coefficient bandwidth is 2.83:1 (from 1 to 2.83 GHz) for both polarizations with 1/5 λ height at lowest operating frequency when it radiates broadside as shown in Fig.4.

Third, the dual-polarized 0D TCDA is proposed. The additional structures which is used at the 1D TCDA are locates around the horizontal and vertical polarization dipoles that use discrete port feeding at the center of the unit cell, respectively, as shown in Fig. 5. In Fig. 6, the simulated bandwidth of the 0D TCDA is 2.27:1 (from 1.22 to 2.77 GHz) with 1/6 λ height at lowest operating frequency.

The details of the design procedure and other characteristics of the three antennas will be discussed at the conference.

Abstract-In this presentation, we demonstrate an electromagnetic wave focusing using reconfigurable metasurface. We made a metasurface which can modulate microwave spatially. Each unit structure constituting the metasurface is controlled electrically. With optimization process, we could concentrate electromagnetic wave energy into a spatially localized spot.

The concept of metasurface was proposed due to readily fabricated using lithography method. Therefore, metasurface is a thin layer made of an array of unit structure with spatially varying geometrical parameters. [1] Because of its strong electromagnetic wave spatial modulation capability even with very thin thickness, metasurface fits to application such as flat optics. Recently, study on metasurface is extending toward accomplishing active and dynamic functionalities with a fast switching speed. [2-5]

In this presentation, we demonstrate a modulating spatial distribution of electromagnetic waves in microwave range using electrically controlled metasurface. We developed a spatial microwave modulating metasurface using readily available electronic components. Each unit structure in the metasurface is controlled electrically and changes electromagnetic wave locally. With optimization process, electromagnetic wave modulated by the device could be localized into a specific spot. Our electromagnetic wave spatial scanner shows that electromagnetic wave modulated by the metasurface can be focused into a localized area and it is different from the beam forming of microwave. We expect our device can be used in many applications such as wireless power transfer, microwave imaging, and indoor radar.

Abstract-We designed microwave absorber metasurfaces consisting of three layers: a patterned conductor, an insulator and a conductor, and developed ultra-fine mechanical machining technologies for manufacturing of the designed metasurfaces. The patterns of the conductor should be accurately machined for avoiding decrease in absorbance of the metasurfaces. We optimized a few machining parameters, and succeeded to manufacture the microwave absorber metasurfaces without machining errors (delamination, warpage and burr). The developed technology can be applied to microwave absorber.

Stealth function is much important for protecting soldiers and expensive weapons. Generally, the paint absorbing the microwaves is used for fighting planes and warships. However, this method needs frequent maintenance which cost too much. Therefore, we suggested a film-type microwave absorber metasurfaces and mechanical machining technologies for easy mass-production in this study.

The suggested metasurfaces consist of three layers: a patterned conductor, an insulator and a conductor. The shape of the patterns on the patterned conductor determines the range of microwaves and the absorbance, thus, it is much important to design the high-performance pattern shapes and to manufacture them accurately. We designed discrete channel patterns having the width of about 100um and verified high absorbance of microwaves by numerical analysis. The ultra-fine planing technology which is one of the mechanical machining technologies was used for manufacturing the designed patterns. A few kinds of machining errors such as delamination, warpage and burr at the machined patterns could be sorted out by optimization of the machining parameters. The width of the cutting tool affected warpage and burr, and the depth of cut affected delamination. Finally, we succeeded to manufacture the accurate microwave absorber metasurfaces having the discrete channel patterns on a conductor.

Absorber using a split eight equal Circular Sectors Resonator

N. T. Trung[1*], and S. Lim[2]
School of Electrical and Electronic Engineering
Chung-Ang University, Seoul 156-756, Korea
sungjoon@cau.ac.kr, nguyentoantrung28190@gmail.com.

Abstract-In this paper, a polarization-insensitive metamaterial absorber is proposed. The unit cell of the metamaterial is designed with a split eight equal Circular Sectors Resonator is introduced for the polarization -insensitivity of the MM absorber. A vertically and horizontally symmetric structure of unit cell enables polarization-insensitivity. The performances of the proposed absorber are demonstrated with full-wave simulation and measurements. Under normal incidence, the fabricated absorber shows 98% absorptivity at 9.26 GHz for all polarization angles, while for oblique incidence, the fabricated absorber maintains an absorptivity higher than 91% for incident angles up to 70˚ for both transverse magnetic (TM) and transverse electric (TE) modes.

Electromagnetic metamaterials (MTMs) are defined as artificial and effectively homogeneous electromagnetic structures with unusual and unique properties that do not exist in the nature. Basically, to design an absorber, we have to maximize the absorption coefficient. It is equivalent to minimize both the transmission (T) and reflection (Γ) coefficients in the Eq. (1), where A is absorption coefficient.

$$A = 1 - \Gamma - T \tag{1}$$

The geometry of the proposed fabricated absorber prototype is shown in Fig. 1. A split eight equal circular sector is realized on the top pattern and the bottom layer is fully covered with a copper sheet. The absorptivity of the unit cell is varied for different incident angles. It is demonstrated from a full-wave simulation that the proposed complementary circular sector enables absorptivity insensitive to incident angles. When the EM wave incident to the absorber, there are the reflected wave and the transmitted wave.

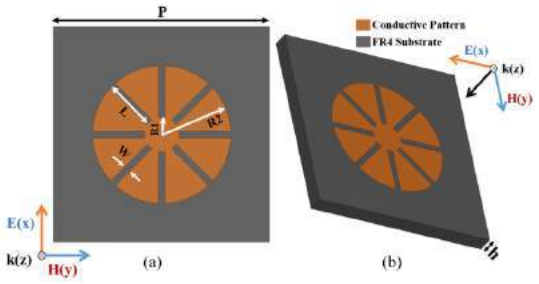

Figure 1: (a) Top view and (b) 3D view of the proposed absorber.

To verify the MM absorber was fabricated consisting of 20×20 unit cells. As shown in Fig. 2, the fabricated prototype is observed. The metallic structures on the top and bottom layers of the substrate are is fully covered with a copper sheet. The substrate of absorber is FR4 with thickness of h = 0.8 mm. Its relative permittivity and dielectric loss tangent are 3.9 and 0.02, respectively.

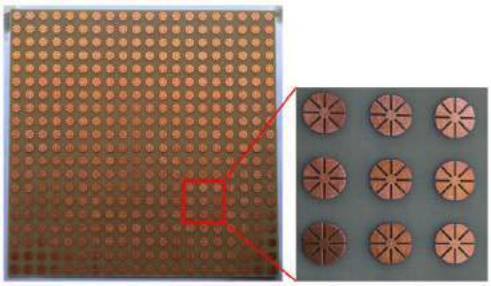

Figure 2: Fabricated absorber prototype absorber

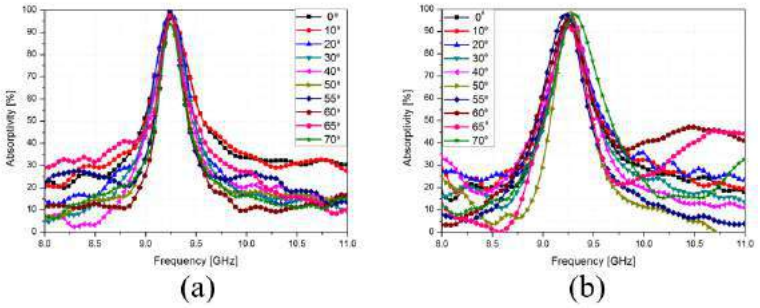

Figure 3: Measured absorptivity of the fabricated prototype absorber (a) for incident angles θ ranging from 0˚ to 70˚ in (b) TE and (c) TM mode.

The measured under oblique incidence, both of TE (Fig. 3. (a)) and TM (Fig. 3. (b)) modes, the absorptivity at 9.26 GHz exceeded 91% even for incident angles (θ) varying from 0˚ to 70˚.

In this paper, a novel planar metamaterial absorber has been proposed. It is observed that the metamaterial absorber is polarization insensitive for both transverse electric (TE) and transverse magnetic(TM) waves. The measurement and simulation results are in very good agreement.

Aircraft infrared signature control using metamaterials

Hyung Hee Cho
Department of Mechanical Engineering, Yonsei University, Korea
hhcho@yonsei.ac.kr

Abstract - Infrared signals from the stagnation region where the aerodynamic heating occurs due to supersonic flow and engine and surrounding hot parts of aircraft are detectable and directly related to survivability. To implement the infrared stealth, it is necessary to reduce the contrast radiant intensity (CRI), the difference of intensities between object and background. We have designed metamaterials to control the spectral infrared emissivity, suppresses detectable band emission and enhance non-detectable band. Finally, the infrared stealth performance of metamaterial was evaluated.

The stealth is a technology that prevents detection from enemies and it is being developed to operate independently or integrally with detection areas such as visible, acoustic, infrared, and radar, depending on the operating environment. The most actively developed radar stealth has been studied in the direction of reducing the radar reflection wave of the object and already applied to the aircraft. Thus, the new detection systems have been developed to neutralize radar stealth technology, and the number of weapons systems that detect infrared signal of targets. Infrared is a kind of electromagnetic wave that radiates when all objects have a temperature of above 0K, which is proportional to the surface temperature and the emissivity of surface. Therefore, the infrared signal can be reduced by cooling down surface temperature or controlling surface emissivity. The quantitative index of infrared stealth is evaluated by the difference between the infrared signal of the background and the object, and the lower the CRI value means the better the infrared stealth performance. Therefore, to calculate the reliable CRI value of an aircraft, not only the surface temperature distribution but also the infrared characteristics of the atmosphere should be considered.

The infrared signal of the aircraft analyzed for 3~5 μm and 8~12 μm bands, considering the infrared transmission characteristics of the atmosphere, 5~8 μm opaque band due to strong absorption of CO_2 and H_2O. Infrared signals in the band of 3~5 μm and 8~12 μm were generated in the aircraft engine and surrounding hot parts. In stagnation regions, such as nose, leading edges and engine intake where aerodynamic heating occurs, infrared signals in the 8~12 μm band mainly occurred. In this study, the gas radiation from hot plum was not considered but only aircraft fuselage infrared signal was evaluated.

We analyzed the infrared signal of a combat aircraft of a single jet engine flying at an altitude of 5000 m with Mach 1.5. To accurately calculate the aircraft surface temperature, two numerical analyzes were conducted in an iterative manner. Ansys Fluent was used to obtain aerodynamic heating and heat transfer coefficients on the aircraft surface and RadthermIR was used to calculate conduction, convection, and surface to surface radiation. The bidirectional reflectance distribution function (BRDF) IR image and CRI of the aircraft were calculated by considering the surface temperature distribution of the aircraft and infrared transmittance of atmosphere from the Modtran module of RadthermIR.

In order to reduce the infrared signal of the aircraft, it is necessary to lower the surface temperature or lower the surface emissivity. The method of lowering the surface temperature is not practical because it requires

additional equipment and increases aircraft weigh. Therefore, it is effective to reduce the CRI value by controlling the surface infrared emissivity of the aircraft. However, if the surface emissivity is kept low in the entire infrared band, the radiative cooling performance is significantly reduced, and the surface temperature may increase. Therefore, in this study, we designed and fabricated metamaterials that keeps high emissivity at only undetectable 5 ~ 8 μm band and low emissivity in detectable 3~5 μm and 8~12 μm bands.

The metamaterial composed of metal-dielectric-metal (MDM) can keep the high emissivity in the selected wavelength band depending on the shape, size of the upper metal structure and thickness of the intermediate dielectric layer. And it maintains low emissivity in the non-resonant wavelength region. We fabricated infrared emissivity controlling metamaterial using photo lithography with gold and ZnS. The thickness of metal layer and upper structure was 100 nm and the thickness of intermediate dielectric layer was 200 nm. Since the upper metal structure, circular disk array with same pitch distance, determined resonance wavelength, the selective emission property of MDM structure could be effectively controlled. MDM structure spectral emissivity is measured with FT-IR spectroscope and applied to surface emissivity when calculate CRI of aircraft. Finally, the aircraft CRI is reduced to 1/4 of blackbody surface by applying MDM metamaterials at same flying condition.

Lossy acoustic bipolar cylindrical cloak with negative index metamaterial

Y. Y. Lee[1] and D. Ahn[2,3]*

Abstract- While, it was shown that for the lossless acoustic cloak the illumination direction independent cloaking can be achieved with the structure with compressed geometry and complementary media, the effect of the material loss have not been fully explored yet. Here, we show that realistic cloaking materials with moderate loss still works when complementary media is introduced but with attenuated back scattering waves. However, the advantages of introducing complementary media are almost lost when the loss tangent of cloaking shell becomes large.

Most of the existing works[1-5] on acoustic cloaking is based on using analogy between the acoustic equations and the transverse electric (TE) polarizations of the 2D electromagnetic field equations. However, it is found that for the electromagnetic fields the cloaking performances of the cloak is superior for the transverse magnetic (TM) polarizations than the TE polarizations because the scattering coefficients for the latter do not vanish completely.[6] Previously, we have the studied[7] the lossless acoustic cloaking using the analogy of acoustic equations and the TM polarizations of the electromagnetic field equations and showed that the acoustic cloak with both cloaking shell and complementary media has the illumination direction independent cloaking properties when the loss can be ignored. The material parameters for the acoustic cloak were obtained by comparing 2D Maxwell's equations in the TM polarization with acoustic field equations for general curvilinear coordinates with the effective medium theory.[7] In this work, we consider a more realistic lossy acoustic cloak and show that the cloak with loss still works but attenuated back scattering waves exist. Dispersive full-wave finite-difference time-domain (FDTD) method[6] is employed for the numerical analysis.

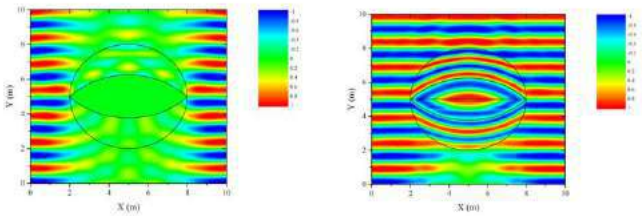

Fig. 1 Comparision of the lossy cloak without (left) and with (right) complementary media.

In Figure 1, the p wave distributions propagating along the negative y direction, respectively, are depicted for the

operation frequency of 1 KHz for a loss bipolar cylindrical exterior cloak without the complementary media (left) and with lossy complementary media (right). We assumed the loss tangent as tan (δ) = 0.01 and tan (a_m) = 0.01 both for the cloak and the complementary media. In the later case, the acoustic cloak is observed to be working, but due to the presence of losses in the cloaking materials, there are shadowing effects on the fields behind the cloaking shell along the direction of wave propagation. It is remarkable that loss in the complementary media does not affect the cloaking performance significantly when the loss tangent is relatively small and one can see that the advantage of employing complementary media.

Abstract-Metamaterials consisting of Helmholtz resonators exhibit compressibility several times larger than that of air but tuning range is limited. Here we present an acoustic metamaterial based on internally connected double Helmholtz resonators. The wall separating the two Helmholtz resonators has two holes one of which is simply open whereas the other is covered with a thin taut membrane. We experimentally demonstrate tuning the effective compressibility continuously from zero to 10 relative to air. Applications include tunable acoustic lens.

Photoelectric Properties of CdSe/ZnS Quantum Dot/Graphene Thin Films Enhanced by Silver Nanowire

Abstract- In this study, we used reduced graphene oxides (rGOs) and CdSe/ZnS QDs to fabricate rGO-QD-rGO sandwich-structure films. The sandwich structure is willing to alleviate the deterioration of QDs in surroundings by virtue of the covering of graphene. We found that the optoelectronic conversion efficiency of the QD-graphene system was significantly improved by incorporating silver nanowires (AgNWs) into the QD layer.

Over the past decade, QDs have been widely studied on the application of solar cells, sensors, light emitters, and bioassays. Recently, many studies revealed that the excited energy of QDs could be transfer effectively to graphene because of the high conductivity and luminescence quenching ability of graphene [1]. In generally, the quenching possible mechanism can be ascribed to the following routes: Forster resonance energy transfer, surface energy transfer and photo-induced electron transfer [2]. Some studies have shown experimentally that the quenching of QDs by graphene was assigned to surface energy transfer. In this study, we prepared the reduced graphene oxide (rGO)-CdSe/ZnS quantum dots (QDs) hybrid films on a three-layer scaffold that the QD layer was sandwiched between two rGO layers. The photocurrent was induced by virtue of the facts that the rGO quenched the photoluminescence of QDs and transferred the excited energy. Unlike graphene, the metal nanostructural surfaces, nanoparticles, or nano-holes not only quench but also enhance the PL of QDs through the excitation of localized surface plasmon resonance (LSPR) of metal nanostructures, which amplifies the local electric field to alter the optical properties of QDs. As a result, both the PL quenching and enhancement are observed after the excitons of QDs coupling with LSPR of metal nanostructures.

Besides exciting and quenching the PL of QDs, AgNWs may absorb and scatter the incident light by the localized surface plasmon resonance and the large diameter, respectively. Therefore, the effect of AgNWs on optoelectronic conversion efficiency of QDs is still vague. We incorporated AgNWs into the QD layer and found the AgNW incorporation can enhance significantly the photocurrent. While the addition of AgNWs changed from 0 to 300 μL, the photocurrent density increased from 22.1 to 80.3 μA cm^{-2}, a near 3.6-fold enhancement. However, too much AgNW incorporation reduced the photocurrent enhancement as a result of the high extinction coefficient and the large scattering effect of AgNWs. In order to realize the mechanism of AgNW enhancement on the photocurrent, the PL spectra of rGO-QDs with/without AgNWs were measured (Figure 1). Although rGO shows the ability of quenching the PL, the AgNW incorporation can enhance the suppression on the PL, being more efficient to transfer the exciton energy. We evaluated the influence of the various shapes of silver (AgNPs, AgNRs, AgNWs) on the optoelectronic conversion efficiency. Figure 2 shows the photocurrent response of the rGO3-QD/AgNW3, rGO3-QD/AgNR, and rGO3-QD/AgNP hybrid films. The photocurrent density increases in the following sequence: rGO3-QD/AgNP < rGO3-QD/AgNR < rGO3-QD/AgNW3. We

infer that the enhancement on the optoelectronic conversion efficiency may arise from the strong quenching ability of silver and the rapid electron transfer of AgNWs.

Introduction of Office of Naval Research Global

Simin Feng[1*]
[1] Office of Naval Research Global, USA
[*]corresponding author: simin.feng.civ@mail.mil

Abstract- Office of Naval Research Global (ONRG) is a funding organization within the United States Department of the Navy to support worldwide basic scientific research in the areas of Navy interest. This talk will provide an overview about the ONRG mission and funding opportunities.

The Office of Naval Research (ONR) is an organization within the United States Department of the Navy that coordinates, executes, and promotes science and technology programs of the United States Navy and Marine Corps. ONR-Global is the international arm of the ONR that assists the ONR to execute its mission by fostering international collaborations, promoting fundamental researches, and building partnerships around the world in the areas of mutual interest to the partner countries and United States. Through the positive engagements, the ONRG brings the full spectrum of worldwide science and technology to Navy and Martine Corps. The ONRG has forward physical presence on five continents with headquarter in London, United Kingdom. Other regional offices are located in Chile, Japan, Australia, Singapore, Czech Republic, and India.

We all live on the same planet. Scientific knowledge has led to remarkable innovations that have been of great benefit to humankind. Fundamental research is universal and should be open to general public. The ONRG mission is to foster international collaborations, promote basic scientific researches, build partnerships, and contribute open source data to global technology awareness. The ONRG has three funding programs to execute its mission:

- Collaborative Science Program (CSP): Support international workshops, conferences, and seminars of navy interest held outside the United States.
- Visiting Scientist Program (VSP): Support short term travel for international scientists to US to interact with researchers and socialize S&T ideas/findings with the NRE that advance basic research through collaboration.
- Naval International Cooperative Opportunities in Science Program (NICOP): Provide direct funding support to international scientists to conduct fundamental research and insert innovative science and technology into core ONR and Naval Research Enterprise Programs.

Above programs aim to promote innovative long-rang basic researches, advance sciences and technologies of mutual benefits, and foster a culture of communications and networking. The seed funding from ONRG will provide opportunities for worldwide talented young scientists and engineers, as well as senior professionals, to expand their careers and grow their researches into the full potential.

Abstract - We demonstrate that multilayered hyperbolic metamaterial (HMM) substrates alter charge transfer (CT) dynamics by showing that both charge separation and recombination characteristic times are increased by factors of 2.4 and 1.7, respectively, resulting in longer-lived CT states. We successfully rationalize the experimental data by introducing image dipole interactions in Marcus theory to tune the driving force. The number of metal-dielectric pairs induces a non-local effect formalized in the dielectric permittivity, and is presented as an analogue to local solvent effects.

Charge separation (CS) and recombination (CR) are crucial phenomena which impact numerous phenomena[1], in electronics[2], magnetism[3], biology and photosynthesis[4], and chemistry[5]. Understanding and artificially tuning charge transfer (CT) dynamics are then of the greatest importance. We experimentally evidenced that organic semiconductor CT dynamics depends on substrate nanostructures[6]. Charge separation (CS) and charge recombination (CR) characteristic times from triphenylene donor to perylene acceptor in columnar dyad were both increased by factors up to 2.5 and 1.7, i.e. slower by ~ 140 and 73 %, respectively[7]. Marcus theory could qualitatively describe this trend when including Coulomb interactions and image dipoles in the multi-layered system to reveal the role of HMM image dipole interactions in manipulating dielectric permittivity with non-local effects. The reported control of the CT dynamics is analogous to the use of solvents presenting different dielectric permittivity. This solvent effect is well known, but, to the best of our knowledge, unheard of in solid HMM nanostructured substrates. Furthermore, the relatively small variation of the non-local dielectric permittivity compared to a more traditional solvent effect needed to get a comparable CT dynamic rate alteration is attributed to the very different mechanisms involved. In the former case, directional image dipole interactions apply to a D:A thin films, whereas the latter relies on variation of the polarity of the solvent molecules

surrounding each and every single of the D:A moieties.

Marcus theory finds applications in numerous systems from solutions to interfaces and solids. The present work represents an original extension of it towards solid multi-layered media. Image dipole interactions are influenced by dyad-HMM interface separations, dipole orientations, charge separation within the dipole, as well as HMM periodicity and pair number. From this general features, one can then envisage that more HMM layers should induce a stronger CT dynamic alteration. Similar behaviors are expected for any nanostructured media allowing the periodic formation of image dipoles. We focused on layered Ag:Al_2O_3 but other inorganic and organic materials as well as dissymmetric substrates should provide some control over CT dynamics.

Isospectral transformations for disordered photonics

Sunkyu Yu*, Xianji Piao, Choonlae Cho, and Namkyoo Park
Photonic Systems Laboratory, Department of ECE, Seoul National University, Seoul 08826, Korea
*corresponding author: sk8513e@gmail.com

Abstract-We introduce isospectral transformations for disordered light-matter interactions. Exploiting supersymmetric transformation, we show a novel disorder having perfect bandgap and confined modes, and demonstrate the switching of disordered light without loss of information. We will also discuss the Householder transformation for interdimensional phase matching.

Global phase matching between eigenspectra [1], *i.e.* isospectrality, allows collective controls of multimodes for high information capacity. For the eigenvalue equation $H\psi = \lambda\psi$, a proper transformation operator A constructs the isospectrality $AH\psi = H_s(A\psi) = \lambda(A\psi)$, when the new Hamiltonian H_s is physically allowed. Here we introduce physically allowed isospectrality in optics, imposing disordered properties on optical phenomena.

First, we discuss supersymmetric (SUSY) transformation [2-4] which derives transformed optical potentials while preserving the entire eigenspectrum except the ground state. Figure 1a,b represents SUSY-transformed crystal and quasicrystal having perfect bandgaps despite disordered potential landscapes [3]. We will show that degrees of disorders and spatial widths of eigenmodes (Fig. 1c,d) can be controlled by multiple SUSY transformations, implementing a new type of bandgap media. We also introduce the SUSY transformation for integrated optics, which enables the switching of random waves without any loss of information (Fig. 1e,f, [4]).

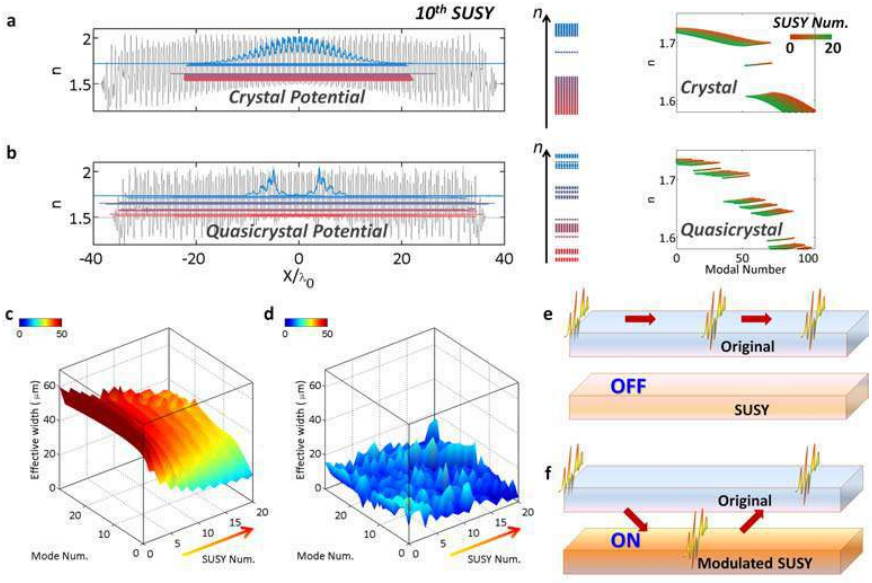

Figure 1. (a,b) SUSY-transformed (a) crystal and (b) quasicrystal with potential landscapes and bandgap evolutions. (c,d) Spatial widths of eigenmodes in SUSY-transformed (c) crystal and (d) quasicrystal. (e,f) SUSY paired potentials for random wave switching: (e) OFF state and (f) ON state.

In the talk, we also discuss the Householder transformation which derives isospectral optical structures each in different dimension [5]. We show that the 2-/3-dimensional disordered structure without degeneracy has a 1D partner structure (Fig. 2a) having a same eigenspectrum (Fig. 2b). From this interdimensional phase matching in a global spectrum, we implement the lossless transfer of light waves between different dimensions (Fig. 2c).

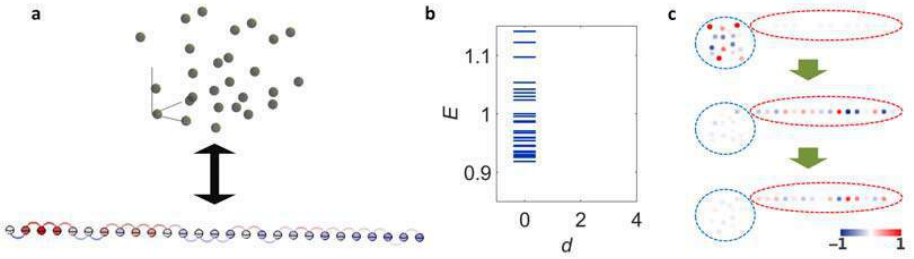

Figure 2. (a) An isospectral pair of different dimensional structures. (b) The identical spectrum of disordered 1D and 3D structures in (a). (c) Wave transfer between 1D and 2D optical structures.

Direct and quantitative measurement of far-field light scattering of a single optical nanostructure

Jinhyung Kim[1], Donghyeong Kim[1], and Min-Kyo Seo[1*]
[1]Department of Physics and and Institute for the NanoCentury, KAIST, Rep. of Korea
[*]corresponding author: minkyo_seo@kaist.ac.kr

Abstract-We present for the first time the quantitative measurement of the far-field light scattering properties of a single optical nanostructure. A goniometer-based solid angle scanning enables us to overcome the limitations of the conventional back-focal-plane method and quantitatively measure the differential scattering cross-section of a single metal nanorod and its far-field distribution over the full hemisphere. We expect that the angle- and spectrum-resolved far-field measurements will be highly useful for evaluating the performances of optical nano-devices and metamaterials.

Strong light scattering of optical nanostructures enables to effectively interface free-propagating electromagnetic waves to localized near-fields and vice versa[1]. In recent decades, the resonant light scattering has been widely investigated and used to facilitate various applications, including highly-efficient light-emitting, nonlinear signal generation, photovoltaics, spectroscopy, and optomechanics[2]. In the novel applications to optical metasurfaces and metamaterials, it is also required to measure and understand the far-field scattering characteristics of individual nanostructures, which make up the metasurfaces and metamaterials. However, quantitative measurements of the far-field scattering distribution and cross-section of a truly single nanostructure on the wavelength scale or less have not yet been reported. Conventional back-focal plane imaging suffers from optical distortion and aberration and covers only a limited solid angle determined by the numerical aperture of the objective lens[3]. Only the total scattering or extinction cross-section has been measured for an array or colloid of nanostructures[4].

In this study, we demonstrate for the first time the direct and quantitative measurements of the far-field scattering properties of a single metal nanorod. A home-built goniometer-based solid angle scanning system measured the differential scattering cross-section of the single metal nanorod with a high signal-to-noise ratio of ~27.4 dB and its far-field distribution over the full hemisphere of 2π steradians. The differential and total scattering cross-sections are the most fundamental parameters for characterizing the far-field scattering properties. Based on the systematic measurements, we experimentally revealed that the differential and total scattering cross-sections of the metal nanorod depend on different mechanisms, the phase-matching conditions to the free-propagating radiation and the Fabry–Perot resonances of surface plasmon polaritons, respectively. In addition, we also performed angle- and spectrum-resolved far-field measurements of the far-field light scattering of a single metal nanowire and investigated its physical behaviors in the energy (wavelength)–momentum (wavevector) space. The measured far-field scattering cross-section and distribution show excellent agreement with numerical simulations and analytic models. We believe that our novel far-field measurement scheme will be highly useful for investigating and evaluating not only optical nanostructures but also metamaterials and metasurfaces.

Overlapped multiple Mie resonances in high-index dielectric structures

I. C. Seo[1], E. Lee[1], B. H. Woo[1], and Y. C. Jun[1*]
[1]*School of Materials Science and Engineering, Ulsan National Institute of Science and Technology (UNIST), Ulsan 44919, Korea*
[*]corresponding author: ycjun@unist.ac.kr

Abstract - We investigate multiple Mie resonances in high-index dielectric structures. Especially, we study spectral (Fano resonances and Superscattering) and spatial (Beam steering) features that occur in overlapped multiple Mie resonances. We also explore the possible applications of these dielectric structures in sensing and spectroscopy.

It is known that high-index dielectric structures (e.g. semiconductor structures) can support various Mie resonances [1]. When these multiple Mie resonances overlap together, various spectral and spatial features can appear: Fano resonances, Superscattering, Beam steering, etc. The spectral positions of Mie resonances can be controlled by engineering the geometry of subwavelength dielectric blocks. And these could find useful applications in sensing and spectroscopy.

For example, we theoretically investigate sharp Fano resonances in the mid-infrared spectral region and consider active tuning of those resonances. Two kinds of dielectric resonators, InSb cylinder and coupled block pair array, are considered [2]. We exploit InSb-based dielectric resonators to take advantages of high refractive index and low optical loss. Firstly, we consider a simple cylinder array. The representative electric field distribution of the Fano resonance is depicted in Fig. 1(a, b), which occurs as a result of the interference between quadrupolar Mie resonance and broad resonance. If the dielectric structure is optically pumped to generate carriers, Fano resonances can be gradually tuned.

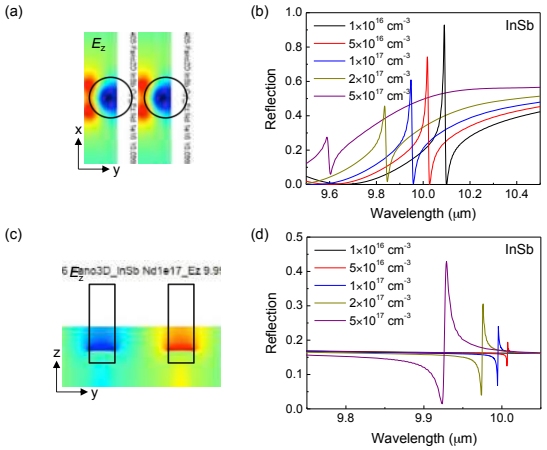

Figure 1 (a) Electric field distribution of Fano resonance and (b) resonance tuning for various carrier densities of cylinder arrays. (c) Electric field distribution of Fano resonance and (d) resonance switching for various carrier densities of block pair arrays.

The block pair array shows different behavior. The two blocks are assumed to have the same physical size, but different carrier density. If only one block is optically pumped, the Fano resonance can be effectively switched on and off. Fig. 1(c, d) depicts the antiparallel displacement field distribution and spectrum of Fano resonance originating from symmetry breaking. Intriguingly, as the carrier density increases, the resonance sharpness decreases but the resonance intensity increases. To understand this behavior, we adopt the two coupled oscillator model. Our studies on multiple Mie resonances can be extended to other spectral region too.

Abstract— Transient optical rotatory power (ORP) of chiral metamaterial is measured to clarify the temporal development of ORP by exciting d-band electrons to the conduction p-band of Au using a circularly polarized light pump beam. Three distinct transient behaviors are identified, resulting from different energy relaxation processes of hot electrons that occur during a period of a few picoseconds after pumping. Theoretical analysis of the transient ORP is carried out by introducing a temperature-dependent dielectric function and finite-difference time-domain simulation.

Time-resolved pump-probe measurement is a well-known tool used to clarify microscopic electron dynamics responsible for a macroscopic temporal response in optical materials. For example, temporal evolutions of the spectral shift and broadening of the localized surface plasmon resonance (LSPR) of metallic nanostructures have been studied to relate the geometry of nanostructures with LSPR spectral changes in terms of hot electron energy relaxation processes in the confined geometry. [1, 2, 3]

When chirality is introduced to the geometry of a metallic nanostructure, it becomes circularly birefringent, giving rise to optical rotatory power (ORP) for linearly polarized light. Since chirality exists in an inversion-symmetry broken structure, it carries a sense of right-/left-handedness. Transient dynamics of handedness changes in natural chiral molecules have been studied via an ultrafast, time-resolved chirality measurement. [4]

In this work, we introduce a plasmonic chiral metamaterials (CMM) and investigate how ORP evolves in an ultrafast timescale via a time-resolved pump-probe measurement with circularly-polarized light (CPL) pump beam. Three different temporal regions are identified where distinct behaviors of transient ORP are observed. Nonthermal hot electrons follow the electric field of a pump beam almost instantaneously in region 1, while electron-electron and electron-boundary scatterings are dominant in region 2. In region 3, where an electron-lattice interaction couples two thermal baths of electrons and lattices, electron temperature is determined using a two-temperature model. The dielectric function of Au at an elevated temperature is obtained, with which an FDTD theoretical simulation is performed to find ORP at elevated temperatures.

The transient behavior of chirality can be characterized by measuring circular dichroism or optical rotatory dispersion, which are related by Kramers-Kronig. To compare with the static ORP spectrum, the temporal behavior of ORP is directly measured using a time-resolved pump-probe setup. The polarization-bridge configuration is employed to attain the maximum sensitivity of polarimetric measurement, with the linear polarization direction of the probe beam being horizontal.[5, 6] Parallel and perpendicular polarization-components of a linearly polarized probe beam are separated by a Wollaston prism, and transient ORP at a given wavelength is extracted from the intensities of two orthogonal polarization-components.

First, we study the transient behavior in the temporal region of $t \leq 2ps$. The differences in ORPs for opposite pump beam CPL helicities are negligible at both 640 nm and 720 nm wavelengths. However, the sign of $\delta\theta/\theta$ is negative at both 640 nm and 720 nm, regardless of pump beam CPL helicity. Second, in the temporal region of $0.9 < t < 2ps$, there is a non-vanishing negative value of the difference between differential ORPs $\Delta\theta/\theta$ at both 640 nm and 720 nm .

That is, at both 640 nm and 720 nm, RCP (σ) pumping results in a more weakened ORP than LCP ($\sigma+$) pumping, i.e., the transient ORP depends on pump beam CPL helicity. Third, in the temporal region of $0 < t < 0.9ps$, a large transient ORP occurs with opposite signs of the difference between differential ORPs $\Delta\theta/\theta$. At 640 nm, RCP ($\sigma-$) pumping results in a very large positive $\delta\theta$ and LCP ($\sigma+$) pumping results in a small negative $\delta\theta$. On the other hand, at 720 nm, RCP ($\sigma-$) pumping results in a small positive $\delta\theta$ and LCP ($\sigma+$) pumping results in a very large negative $\delta\theta$. At both 640 nm and 720 nm, RCP ($\sigma-$) pumping gives rise to a positive $\delta\theta$, with the magnitude being larger at 640 nm than at 720 nm, while LCP ($\sigma+$) pumping gives rise to a negative $\delta\theta$, with the magnitude being larger at 720 nm than at 640 nm.

The dynamics of hot electrons in plasmonic chiral metamaterials are studied to relate electron energy relaxation processes with transient optical rotatory power in the visible spectral range. Time-resolved pump-probe measurement in a polarization bridge configuration reveals that there are three distinct temporal regions showing different transient behaviors of optical rotatory power during a period of a few picoseconds after pumping using a circularly polarized light beam.

In the first and second temporal regions ($0 < t < 2ps$), nonthermal hot electrons experience the Lorentz force from an inverse Faraday effect and electron-boundary scattering, yielding a pump beam circularly polarized light helicity-dependent transient optical rotatory power. In the third temporal region ($t \geq 2ps$), hot electrons are in thermal equilibrium with the lattice due to electron-lattice coupling, where electron energy is distributed among occupied states, as described by Fermi-Dirac statistics. In $t \geq 2ps$, the transient optical rotatory power is found to be independent of pump beam circularly polarized light helicity. For thermal hot electrons, the temporal behavior and pump beam circularly polarized light helicity independence of optical rotatory power are well explained by a two-temperature model of the electron cooling process and the selection rule of electron excitations.

Theoretical analysis of the transient optical rotatory power in terms of the energy relaxation of thermal hot electrons is carried out by introducing a temperature-dependent dielectric function and finite difference time domain theoretical simulation of the optical rotatory dispersion. It is found that the magnitude of optical rotatory power at an elevated temperature is reduced to less than that at room temperature. Identification of three distinct temporal behaviors of hot electron energy relaxation processes elucidates how information regarding the handedness of a chiral nanostructure is carried to a transient optical rotatory power during a period of a few picoseconds after pumping. [7]

Abstract- High-refractive-index dielectric nanoparticle (NP) has been extensively viewed as one of a prominent building block for optical metamaterial. Recent progresses have shown that a strong magnetic responses with a significantly low loss can be driven from silicon (Si) NP. However, currently available synthesis methods hinders its practical and universal application in devising all-dielectric nanoantenna and nanophotonic device. Here we report high-index-dielectric perovskite NPs by one-pot and mild method and their assembly as a practical way for efficient optical magnetism.

Split ring resonators (SRRs), landmark features of metamaterial, have been conventionally used for artificial magnetism at gigahertz [ref1], terahertz [ref2], and near infrared domains [ref3]. However, at visible range, such structural motifs doesn't hold promise anymore due to inherent losses in noble metal and technological limitations for fabrication [ref3]. Different approaches have undertaken to circumvent these limitations including assembly of metallic nanoparticles (NPs) into ring motifs [ref4]. However, these metallic NP assembly methods still suffers from intrinsic ohmic losses.

Seungwoo Lee 23/3/17 13:14
Supprimé: .

To harness low loss, yet strong magnetic response, high-refractive-index dielectric material has paved new road map for metamaterial [ref5]. According to theoretical prediction based on Mie theory, a single dielectric NP with high-refractive-index can exhibit low loss and strong magnetic responses at visible frequency [ref6]. Thus, growing consensus of using high-refractive-index NP, for example, silicon (Si), has been considered extensively as building block for low loss metamaterial. However, practical access to uniform Si NP poses great challenges, as harsh chemical conditions with extremely high pressure and temperature and multiple reaction steps are required. [ref5, 7].

In this work, we suggest another type of dielectric NP made of high-refractive index perovskite (refractive index: ~2.4), which can be accessible with relatively versatile hydrothermal synthesis method. [ref8]. Various shapes and sizes of perovskite NPs with high uniformity were successfully obtained in a reliable and simple way.

Subsequently, AFM nanomanipulation was used for a deterministic assembly of perovskite NP into the rationally designed cluster. As such, the peculiar resonance features resulting from an isolated or coupled magnetic mode were systematically studied including directional scattering and Fano resonance. This low-loss magnetic resonance available with perovskite NP enriches the material library for all-dielectric metamolecules and metamaterials, which could be widely used toward highly efficient nanoantennas and optical filters.

Abstract- Hyperbolic metamaterial (HMM) enables to manipulate nonlocal dielectric environment to control photo-induced energy and charge transfers. Here, we address how nonlocal effect of HMM modifies ICT emission spectral features in a way distinct from local effect. A 7nm blueshift is observed in intramolecular charge emission from DCM dye dispersed into a polymer matrix, accounted for by 7% reduction of nonlocal dielectric constant based on Lippert-Mataga formalism. Such a capability of spectral shift control opens new means of designing devices.

Tuning of the photophysical properties of dyes (*i.e* spectral shift, photoluminescence quantum yield (PLQY), decay rates) is essential to obtain efficient devices that could be readily commercialized. To this end, plasmonic nanostructures have been extensively used in order to control photophysical processes such as spontaneous emission and energy transfer owing to the importance of technological applications such as optical sensing, imaging, solar cells, and light-emitting devices.[1] Among the plasmonic nanostructures, hyperbolic metamaterials (HMMs) displaying hyperbolic dispersion have been studied intensively for emission rate control making use of high photonic density of states over a broad spectral range, characteristic of hyperbolic dispersion.[2-8] However, little is known on the nonlocal effect of HMM structure on photoluminescence of organic dyes. In this context, we inspected this effect on photoluminescence arising from π-π* transition and intramolecular charge transfer transition (ICT *i.e.* in push-pull type of systems) by using perylene bisimide and 4-dicyanomethylene-2-methyl-6-(*p*-dimethylaminostyryl)-4*H*-pyran (DCM) laser dye, respectively, blended in polymethyl methacrylate films. To this end, HMM structure consisting of 10 nm thick Ag and Al_2O_3 alternative thin films deposited on fused silica were used with the number of bilayer varying from 1 to 4 and compared the photophysical properties to the one obtained on fused silica. We demonstrate that various thin films containing ICT dyes could result in emission blueshifted by using HMM structure. In addition to the spectral shift, we examined the fluorescence radiative decay rate and non-radiative decay rate as well as photoluminescence quantum yield (PLQY) and found significant changes in these properties based on the effect of HMM structure. In particular, we focus on the effects of local and nonlocal dielectric constants on the emission characteristics of dyes dispersed into polymeric thin films. As such, we used Lippert-Mataga (L-M) formalism to elucidate the difference and similarities between local and nonlocal dielectric constant in evidencing the appearance of spectral changes of the ICT emission. Within those dyes, the decrease of PLQY and of fluorescence lifetimes originate mainly from the hyperbolic dispersion effect as observed with other dyes on HMM structures. However, a noticeable spectral blueshift of ICT emission in the presence of HMM substrate was evidenced, which

indicates that HMM structure can nonlocally affect the ICT energy level which cannot be related to hyperbolic dispersion. This shift continuously increases as the number of metal-dielectric pair increases. We demonstrated that this phenomenon has the same analogue as negative solvatochromic (hypsochromic) shift based on L-M formalism. Around up to 7.2 % decrease in non-local dielectric constant was demonstrated by comparing DCM monomer with liquid solution. From this study, not only the experimental observation of CT energy level variation but also the same experimental realization of solvatochromic shift is evidenced. We believe that whole description of nonlocal effect from HMM structure is addressed in terms of both temporal and spectral properties of CT. As such, we established that fundamental underlying mechanism of nonlocal effect is the quasi electrostatic Coulomb interaction yielding a nonlocal dielectric constant affecting the film properties.

Metasurfaces for chiral sensing

SeokJae Yoo and Q-Han Park*
Department of Physics, Korea University, Seoul, Korea
**E-mail:qpark@korea.ac.kr*

Metasurfaces as ultrathin flat metamaterials induce substantial phase changes in the propagating light thereby enabling a new field of planar photonics. However, the ability of metasurfaces to create non-trivial strongly localized near fields has not received much attention. Here, we address applications of metasurfaces to the sensing chiral molecules by utilizing highly inhomogeneous near fields created by metasurfaces. We establish underlying physical theories for chiral molecule sensing and explain the role of metasurfaces in enhancing sensing signals.

The circular dichroism (CD) spectroscopy is the optical technique to measure signals of chiral molecules, containing their stereochemical information. Recently, it has been demonstrated that CD signals of chiral molecules can be enhanced by plasmonic nanostructures and metamaterials [1-4]. Few theoretical models have been suggested to describe the surface-enhanced CD signals of chiral molecules adsorbed on the surfaces of nanostructures and metamaterials: the chiral field generation (Figure 1) [1, 2] and (2) the circular differential scattering (Figure 2) [3]. In particular, CD signals of chiral molecules is shown to be proportional to the optical helicity of the local electromagnetic fields[1]. Therefore, the strong optical helicity generated by nanostructures and metamaterials can be used to enhance molecular CD signals [1, 2]. Equally important, but so far ignored, factor to the enhancement is the asymmetric scattering of left- and right-circularly polarized lights by nanostructures and metamaterials in the presence of chiral molecules [3].

Here, we provide a complete description on the metasurface-enhanced CD signals of chiral molecules [5]. We provide a simple theoretical account for the two major mechanisms of the surface-enhanced CD signals. We show that the circular differential scattering of nanostructures and metamaterials plays a crucial role in the surface-enhanced CD signals, rather than the chiral field generation. We exlain how our results can provide a design principle for the surface-enhanced CD spectroscopy using nanostructures and metamaterials.

Abstract- Through experiments, numerical simulations, and theory we explore the behavior of 2D rf SQUID (radiofrequency superconducting quantum interference device) metamaterials, which show extreme tunability and nonlinearity [1 - 2]. The emergent properties are sensitive to the degree of coherent response of the driven metamaterial. Coherence suffers in the presence of disorder, which is experimentally found to be mainly due to a dc flux gradient. We investigate methods to recover the coherence, specifically by varying the coupling between the SQUID meta-atoms and reducing the SQUID tunability [3]. We also investigate the SQUID metamaterial as a nonlinear medium through detailed two-tone intermodulation (IM) measurement over a broad range of tone frequencies and tone powers [4]. The response of nonlinear metamaterials and superconducting electronics to two-tone excitation is critical for understanding their use as low-noise amplifiers and tunable filters, for example. A sharp onset followed by a surprising strongly suppressed IM region near the resonance is observed. Using a two time scale analysis technique, we present an analytical theory that successfully explains our experimental observations. The theory predicts that the IM can be manipulated with tone power, center frequency, frequency difference between the two tones, and temperature. This quantitative understanding potentially allows for the design of rf-SQUID metamaterials with either very low or very high IM response.

Abstract-We have proposed a new methodology based on transformation optics to manipulate mode properties of dielectric cavity such as directionality, chirality of resonance modes while maintaining High-Q values. The novel mode properties can be realized in inhomogeneous dielectric cavities which can be defined by imposing spatially-varying refractive index derived from the transformation optics theory.

Optical whispering gallery modes (WGMs) in a dielectric disk cavity exhibit a very long lifetime (ultrahigh Q-factor), and this extreme feature is a crucial requirement for cutting-edge photonic devices, such as ultralow threshold micro-lasers, nonlinear optical oscillators, and highly sensitive sensors[1]. Despite this outstanding merit, the WGMs have been considered inefficient in certain practical optoelectronic applications due to their rotationally uniform (isotropic) radiation. Hence, considerable efforts have been devoted over the last 15 years to achieving directional emission without Q-spoiling. However, in all methods that have been proposed to date, the introduction of directionality inevitably causes substantial Q-spoiling due to the destruction of WGMs. Here, we showed that the optical mode properties of dielectric cavities, such as quality factor and emission directionality, can be tailored at will by using transformation optics[2-3]. In this work, we present a novel scheme to manipulate mode properties of dielectric cavity such as directionality, chirality of resonance modes, without Q-spoiling. The key idea is to restore Whispering Gallery mode in a deformed dielectric cavity by utilizing the angle-preserving feature of conformal mapping from the transformation optics. The spatially varying refractive index profile can be implemented by drilling subwavelength-scale air holes in a dielectric slab. The proposed design scheme of microcavities based on the transformation optics will open a new horizon of application beyond the conventional microcavity application

Abstract

CNT/ZnO and N-CNT/ZnO thin films were prepared using sol gel method, to extract their usefulness in photovoltaic applications. The optical and electrical properties have been investigated in this research. The electrical conductivity has found to be more imperative for ZnO films filled with N-CNTs. This finding is pretty explained by the electronic conduction hold by nitrogen as charge carriers within carbon nanotubes which provide higher performance to the active layer.

1. Introduction

Transparent conductive oxides (TCOs) are required as a front side electrode for efficient thin film solar cells, since a metallic grid as used in crystalline silicon solar cells cannot be used. Numerous metal oxides with different doping materials can be used as a TCO. In general, a compromise between conductivity and transparency of the TCO must be made. Transparent conducting oxides (TCOs) are employed as transparent electrodes in electrochromic windows, flat-panel displays (FPDs), solar cells and light-emitting diodes (LEDs) [1–4]. Many researchers reviewed on many Photovoltaic applications recently [5], where TCOs are working as front electrode in solar cells. Although there are imperative secondary requirements for such transparent electrodes such as chemical stability, interfacial properties, etc.), the primary requirements are good visible transparency (in thin film form) and high electronic conductivity. In addition, band alignment matching with the active absorber components is important. For organic conductors, the band alignment at the TCO interface is expected to depend directly on TCO work function [6, 7]. For inorganic thin film solar cells, knowledge of the TCO surface potentials such as Fermi level and ionization potential) provides important standards for interpreting band alignment at TCO/inorganic interfaces. Typical TCOs employed in several types of solar cells, adapted from Fortunato et al. [5], including CdTe solar cells, which commonly employ F-doped SnO2 front electrodes [8,9]. Although these same oxides have been employed for organic photovoltaics (OPVs), Fortunato et al. highlight the need for TCOs with higher work functions than are currently available [5].

The aim of this work is to prepare ZnO; CNT/ZnO and N-CNT/ZnO systems using sol-gel method. Several analyses of prepared samples have been performed by optical and electrical characterization techniques. It is found that, the calculated fundamental band gap of ZnO is close to the experimental one and in a good agreement with other theoretical calculations.

2. Experimental Methodology

Sol-gel method was used to make the N-CNT/ZnO thin films. Initial material Zinc acetate dihydrate $Zn(CH_3COO)_2$. $2H_2O$ was selected to proceed the experiment. Two-methoxy ethanol was used as solvent and monoethanolamide (MEA) was used as a stabilizer. Zinc acetate dihydrate and N-CNT were first dissolved in a mixture of solvent (MEA) and stabilizer (two-methoxy ethanol) at room temperature. The zinc acetate concentration was about 0.35 M while the molar ratio of MEA to zinc acetate $Zn(CH_3COO)_2$ was 1.0. To get a clear and homogeneous solution, this mixture was stirred at 60 °C temperature for time of 2 h. After cooling the mixture at room temperature, it was served as the coating solution. After the 24 hour preparation of mixture, coating was made. The solution was poured onto glass substrates, with the rotation cycles of 1000 rpm for time of only 30 s. Once the spin coating has been done, the gained films were dried at a temperature of 400°C for the time of 20 min on a hot plate. The purpose of this experimental process was to evaporate the solvent and remove organic residuals. This whole procedure was repeated twelve times so that the thickness of the sintered films should approach 800 nm.

3. Results and Discussion

The XRD characterization was carried out using a diffractometer of Bruker D8 Type where X-radiation from the Kα emission of copper, with wavelength λ = 1.5406 Å, X-ray diffraction provides information on the crystallographic growth directions of the ZnO layers. The

comparison with the data of the ASTM files indicated that the obtained layer of undoped ZnO is of wurtzite structure.

The measured optical transmittance revealed that the ZnO films are more transparent in the visible region (600nm) 87%. It can also be observed that the MWCNT addition has a profound effect on the film's optical transparency; with decrease in transparency down to 65% and great decrease in N-CNTs/ZnO samples Fig. 1. (a). The reduction in optical transmittance is due to the fact that the CNTs are not transparent and absorb the incoming light and increase the light scattering. The optical bandgap of the ZnO/CNTs and ZnO/N-CNTs thin films was determined by assuming that ZnO is a direct band-gap semiconductor.

From the transmission spectra we deduced the optical gap of the ZnO films using the relationship that links the coefficient of absorption α to the photon energy hv:

$$(\alpha .h\nu)^2 = B\,(h\nu - Eg) \qquad (1)$$

From the plotted graph of $(\alpha h\nu)^2$ versus the incident photon energy (hν), where α is denoted as the absorption coefficient, one can estimate the optical band gap by extrapolation of the straight line region into the x-axis $(\alpha h\nu)^2$. For MWCNT/ ZnO composite, the bandgap of around 2eV was obtained from the film doped with 0.5wt% of CNTs, whereas for N-CNT/ZnO thin film at the same doping rate, the extracted bandgap is around 1.5eV.The obtained band gap deviates from the pure ZnO due to the addition of MWCNTs which influences the overall carrier concentration and reduces the bandgap. The bandgap narrowing effect has been clearly observed in ZnO films doped with N-MWCNT. In fact, bandgap reduction is beneficial towards the photovoltaic efficiency of wide band semiconductors such as ZnO as it is more effective in utilizing the visible light.

The effect of number of CNTs and N-CNTS concentration as a function of conductivity has also been investigated in this research, which express high increase with the increase of concentration, however it's noteworthy that most significant increase happens when N-CNTs are inserted according to previous study this phenomenon is explained by the conduction mechanism of nitrogen as dopant element 15.

Several approaches have been suggested to understand the relationship about the optical properties and the electrical properties. One of these approaches can be utilized to guide the study of our materials it is written as follow16.

$$\sigma = ne\mu \qquad (2)$$

Where the σ is the conductivity of the materials, n is the number of charge carriers, e is the quantity of the charge, μ is the mobility. All of the mentioned parameters are supposed to be explaining the charge transport within the conductive materials, and obviously the conductivity is related to the number of the charge carrier and the mobility of materials which is conventionally translating the movement of electrons within the conductive solid materials 10, also it has been proved that the mobility is proportional to the magnitude of the band gap17.

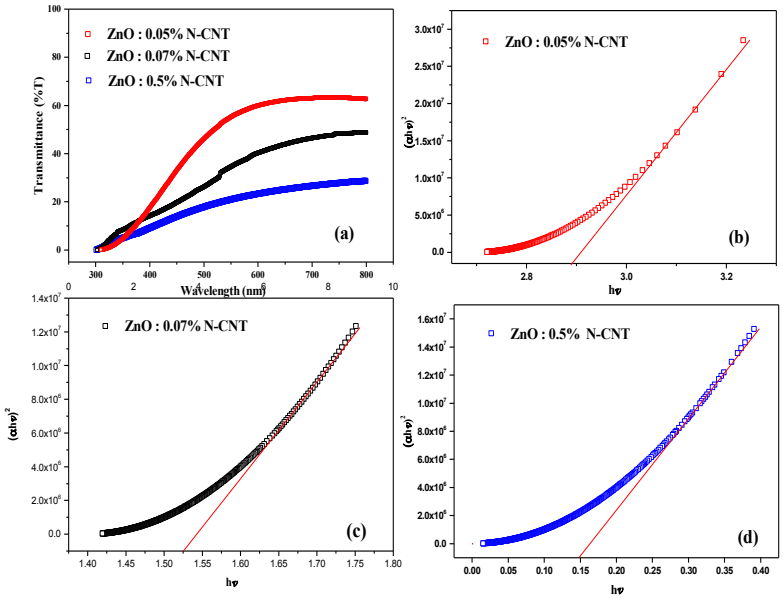

Figure.1. (a): Optical transmittance of the N-CNT/ ZnO samples and (b), (c), (d): $(\alpha h\nu)^2$ versus energy plot for Tauc gap extraction

4. Conclusion

In this work, we have successfully prepared via sol-gel method N-CNT/ZnO which is regarded as a semi-transparent p-type TCO with 80 % visible transmission. The undoped ZnO films were confirmed to be amorphous by X-ray diffraction experiment. We succeeded to see the effect of growing the dopant concentration of our material. For doped ZnO cases, the average transmittances in the visible region are decreased owing to the induced N-CNT and CNT as absorption elements. Fundamental structural, optical and electronic properties of prepared thin-films were significantly studied. Observed results exhibit an enhanced opto-electronic property than undoped and merit further exploration for advanced-device development.

Abstract- Merging multiple microprocessors with high-speed optical networks has been considered a promising strategy for the improvement of overall computation power. However, the loss of the optical communication bandwidth is inevitable when interfacing between optical and electronic components. Here we present an on-chip plasmonic switching device consisting of a two-dimensional (2D) disordered array of nanoholes on a thin metal film that can provide multiple-input and multiple-output channels for transferring information from a photonic to an electronic platform. In this device, the surface plasmon polaritons (SPPs) generated at individual nanoholes become uncorrelated on their way to the detection channel due to random multiple scattering. We exploit this decorrelation effect to use individual nanoholes as independent antennas, and demonstrated that more than 40 far-field incident channels can be delivered simultaneously to the SPP channels, an order of magnitude improvement over conventional 2D patterned devices. With the increased channel capacity, we demonstrated the delivery of far-field optical image to the output channels of SPPs.

Wavefront engineering for high resolution in-vivo deep tissue imaging

J. H. Park[1]
[1]Department of Biomedical Engineering, UNIST, Republic of Korea
[*]corresponding author: jh.park@unist.ac.kr

Abstract- Multiple scattering of light is a general phenomenon that occurs in all types of tissue. In this work, we describe methods to control the wavefront of the incident beam to enable subcellular resolution imaging deep inside living animals.

Optical imaging holds unique advantages for bio imaging with its molecular specificity, non-invasiveness, and high spatiotemporal resolution. However, due to multiple scattering induced by the inhomogeneous distribution of cells constituting tissues, high resolution imaging is typically confined to superficial layers or require sectioning of samples. To understand life, we must image it dynamically while in its true state of function. In this regard, controlling the incident light for high resolution deep tissue imaging, without harming the subject of interest, holds many opportunities for bio imaging. Here, we will describe our recent developments that enable high resolution imaging through the skull as well as large area functional imaging of the deep brain.

Aberration Correction of an Optical System for High-resolution Synthetic Aperture Imaging

Changsoon Choi, Kyung-Deok Song, Sungsam Kang, and Wonshik Choi*

Abstract- Short working distance of objective lenses often limits high-resolution imaging of targets located deep within a tissue. Condenser lens supporting high numerical aperture and long working distance can be a good alternative, but strong aberrations induced by the lens causes strong image distortion. Here we propose a method that can eliminate aberrations of condenser lens up to the numerical aperture of 1.2, and demonstrate high-resolution synthetic aperture imaging of biological cells and *c. elegans*.

High numerical aperture (NA) objectives are one of the most essential elements for high-resolution optical imaging. However, their relatively short working distance, which typically ranges up to a few hundred microns for oil-immersion type objectives, has been a major limiting factor for deep-tissue and high-resolution imaging.

As a solution for this problem, we used a pair of oil-immersion type microscope condenser lenses (1.4 NA, Nikon MBL78700) for both illumination and detection, and set up a holographic phase microscope in transmission geometry. Since their working distance is an order of magnitude longer than that of objective lenses, our optical system can deliver images of relatively thick targets up to high NA. However, the condenser lenses are not manufactured for imaging, but for introducing incoherent illumination to the samples. Therefore, they tend to have strong aberrations that distort images and degrade spatial resolution.

We acquire three sets of holographic phase images with a few thousand different illumination directions. The number of required images depends on field of view and NA. Each set consists of images of illumination, the specimen, and a test target positioned at different image planes, respectively. From these data, input and output aberration maps are identified by maximizing intensity of the synthetic aperture image. By applying the identified aberration maps of the imaging system to the acquired images of biological specimens, we could recover diffraction-limit resolution up to 1.2 NA. We demonstrated high-resolution imaging for the working distance of a few millimeters, an order of magnitude improvement over conventional microscopes.

Abstract- Micro and nanophotonic structures allow miniaturization of diverse and broadband imaging systems. Spherically arranged microlenses mimic insect's eyes and provides wide FOV imaging, fast motion detection, and enhanced image resolution. Binocular microprisms also enable an ultrathin stereoscopic camera in the visible range. Furthermore, optically patternable metamaterial simply defines polymer patterns below the diffraction limit and also subwavelength silicon hole arrays can serve as a planar silicon lens. In this work, we overview diverse photonic structures for broadband compact imaging systems.

Small scale photonic structures allow miniaturization of diverse and broadband imaging systems such as ultraviolet nanolithography, wide field-of-view (FOV) and stereoscopic visible imaging, and even THz spectroscopic imaging. Spherically arranged microlens arrays mimic insect's eyes and the biologically inspired ultrathin camera with multi-apertures provides wide FOV imaging, fast motion detection, and enhanced image resolution [1-5]. Some examples inspired from ultrastructures of a firefly lantern enhance light extraction from LED or OLED for lighting applications [6-8]. Binocular microprism arrays also enable an ultrathin stereoscopic camera that can be utilized for mobile or endoscopic imaging applications in the visible range [9]. Plasmonic nanoantennas also enhance laser induced acoustic signals for highly sensitive photoacoustic imaging [10]. In addition, optically patternable metamaterial with negative effective permittivity simply defines nanoscale polymer patterns below the diffraction limit using a conventional photolithographic equipment. Subwavelength silicon hole arrays can also control effective index of silicon and serve as a planar silicon lens with a diffraction limit [11-17].

Abstract-We present a high-resolution endoscopic microscope free from back-reflection noise generated at an ultrathin image bundle fiber. To eliminate the back-reflection noise, we illuminate a sample through single individual core fibers in the bundle and detect the reflected signal from the sample by the other core fibers. The transmission matrix method is used for the pixelation-free sample image reconstruction. We confirm that our method enhances the signal to noise ratio of imaging 3.2 times better than conventional illumination-detection scheme.

Abstract- The advanced spatial light modulator technology typically offers controllable degrees of freedom up to ~10^6, but it is still bounded to the trade-off between the modulation's spatial extent and bandwidth. Here we challenge the traditional limitation using an ultrathin random metasurface as a static spatial frequency mixer rendering the ability to arbitrarily control optical wavefronts over their highest possible spatial bandwidth (i.e. the reciprocal of half-wavelength). We furthermore apply this technique for wide-field high-resolution imaging of fluorescence samples.

Optical metasurfaces, which are rationally designed arrays of subwavelength scatterers, have shown promise for manipulating an optical wavefront with unprecedented degrees of freedom, albeit passive to date[1–3]. The versatility in metasurface design has been proven effective to replicate various conventional optical elements, including high numerical aperture (NA) lenses and gratings, over a broad range of operating wavelengths. Nanofabrication technology provides a precise control of subwavelength scatterers that imprint a desired light manipulation at desired locations, allowing the arbitrary control of wavefront over a full range of transverse wavevector components up to k_0 ($=2\pi/\lambda$; λ is wavelength) in free space. The scalability of nanofabrication methods typically allows for the control of more than 10^8 individual scatterers, which are inherently orders of magnitude larger than the degrees of freedom available in state-of-the-art spatial light modulators.

Here we present a method to challenge the conventional trade-off limitation for spatial light modulation by leveraging the ultra-high degrees of freedom in a random metasurface. Random metasurface serves as a programmable scattering surface, providing a gateway to the maximal spatial bandwidth. The concept of "interferometric focusing" is then employed to reconstruct an arbitrary wavefront on demand through a random metasurface by controlling the limited degrees of freedom in SLM ($<\sim10^6$) [4,5]. This approach provides the addressable degrees of freedom in light modulation, which is equivalent to that of the random metasurface ($>10^8$), exactly at the price of the loss in efficiency.

With the scheme of Figure 1, we experimentally demonstrate an unprecedented flexibility for light focusing - scanning of more than 10^8 diffraction-limited spots with a tunable NA ranging from 0 to 0.95. Fluorescence imaging with this capability is shown to yield a high-resolution image of an enlarged field-of-view, which will be particularly useful for studying complex biological systems.

Metamaterials, artificially structured nanomaterials, have enabled unprecedented phenomena such as negative refraction. However, despite the great and promising science, making practical devices based on metamaterials have been one of the most important issues due to the difficulty in fabrication. In this abstract, I will discuss recent development of scalable large-scale nanofabrication efforts to make practical metamaterials-based devices. The example is realizing a super-resolution imaging device of wafer-scale hyperlens, which is the first experimental demonstration of near- to far-field imaging of biological living objects at visible light with resolution beyond the diffraction limit in two lateral dimensions. With proposed hyperlens array, we show the first bio-sample imaging experimental result of super-resolution imaging on hyperlenses by combining to conventional microscopy system for imaging biomolecules. Hippocampal neuron cells are imaged by visible light through the hyperlens array with resolution down to 150 nm, beyond the diffraction limit. The super-resolution imaging result of neuron at sub-diffraction size shows that hyperlens can be used as a useful imaging tool in biology, pathology, medical science and nanotechnology. Also, such a unique fabrication techniques mentioned in this talk will provide the opportunity to achieve practical metamaterial devices as the significant step making nanoscience to nanotechnology.

Abstract We demonstrated the measurement of optical anisotropy, which is called birefringence, of living cells. Multiple images were taken by using a 3D phase microscopic method and then processed into an enhanced 2D or a volumetric 3D image. Quantitative analysis was also presented.

Optical anisotropy, such as birefringence, is an unusual optical characteristic of a sample caused by the alignment of molecular structures in micro-scale. Materials having the optical anisotropy are present in substances constituting cytoskeletons, bones, cartilages, skins, and connective tissues. The anisotropic materials can be selectively imaged in label-free fashion using the characteristic polarization response to light. Quantitative phase microscopy has been used for quantifying the anisotropy of an object, however, its applications are limited only to non-biological specimens with large amount of birefringence. Due to the low level of polarization response, the birefringence associated with living cells has been difficult to be investigated in a quantitative manner.

Here we demonstrated the quantitative measurement of optical anisotropy for single living cells by using a 3D phase microscopic method. To achieve sufficient sensitivity for the measurements of such a small polarization response, multiple object images were taken by the standard tomographic measurements. The images were processed into a single 2D image to suppress the background noise. By the enhanced signal to noise ratio, the amount of birefringence of living cells was quantitatively evaluated. In addition, we also used the 3D tomographic reconstruction for the taken images to produce a spatially-resolved anisotropy map of the living cells.

Plasmonics and nanophotonics

Physical and chemical origin of spectral fluctuation in surface enhanced resonance Raman scattering at single hotspot between silver nanoparticle dimer

T. Itoh*

[1]National Institute of Advanced Industrial Science and Technology (AIST), Japan

*corresponding author: tamitake-itou@aist.go.jp

Abstract- Single molecule (SM) surface-enhanced resonance Raman scattering (SERRS) at a hotspot has exhibited both intensity and spectral fluctuations, resulting in difficulty in SERS reliable analysis. To reduce the degree of complexity, we quantitatively investigate the origin of SERS spectral fluctuation based on the EM mechanism. The physical origin is analyzed as molecular motion within several angstroms and the chemical origin is analyzed as creation-annihilation of defects inside the molecule. SERRS is only method to investigate such extremely fine fluctuations (Abstract).*n*

Raman cross-sections of single molecules (~10^{-29} cm^2) located in gaps or crevasses of a metal nanoparticle (NP) aggregate are enhanced by a factor of <10^{10} by plasmonic resonance.[1] This phenomenon is called surface-enhanced Raman scattering (SERS), and the locations are called SERS hotspots. SERS enables vibrational spectroscopy of single molecules (SMs) with the assistance of resonance Raman effect. SERS boosted by resonance Raman effect is called SERRS. SERRS opens up a research field for in situ probing few or single molecules on metal surfaces. SM SERRS has been applied to in situ ultrasensitive detection of analyte molecules, especially biomolecule under various conditions. Recently, SERRS is also expected to be a potential tool for clarifying such plasmon-modified molecular optical responses e.g. strong coupling molecular exciton and plasmon, ultrafast fluorescence, and so on.[2-3]

SERRS signals under ultralow analyte concentration conditions of <10^{-9} M are usually observed with both temporal and spectral fluctuations, known as “blinking”.[4] SERRS fluctuation itself has been an indirect evidence of SM observation. In 2007, a direct evidence of SM SERRS observation was achieved by a lack of simultaneous detection of isotopically differentiated dye molecules at hotspots in a concentration of ~10^{-9} M. Thus, the studies of the SERRS fluctuation can be now related to various physical and chemical processes, including ground state and excited state dynamics of single molecules such as molecular movement, desorption, structural rearrangement, chemical reaction, and decomposition. However, there are still many complexities in interpretations of the SERRS fluctuation because many of the aforementioned phenomena simultaneously taking place. Furthermore, the existence of two types of SERS mechanisms (i.e., EM and chemical ones) makes the interpretations difficult.

To reduce the complexities in the SERRS fluctuation, a basic understanding of the fluctuations is important. Thus, the presentation is focused on the SERRS fluctuation caused dominantly by EM and resonance Raman mechanisms. On the basis of these demonstrations, we introduce two kinds of studies of extracting detailed information of fluctuation with resolutions (not image resolutions) from several nanometers to a few angstroms.[4-6]

(1) We analyze blinking in SERRS and surface enhanced fluorescence (SEF) of rhodamine 6G (R6G) molecules as intensity and spectral instability by EM mechanism.[4,5] We systematically analyze SERRS and SEF from stable to unstable using single Ag nanoparticle (NP) dimers. The analysis reveals physical insights into fluctuation as follows. The intensity instability is inversely proportional to the enhancement factors of decay rate of molecules. The estimation using the proportionality suggests that separation of the molecules from Ag NP surfaces is several angstroms. This analysis provides us with a quantitative picture for intensity and spectral instability in SERRS and SEF within the framework of EM mechanism. The results are shown in Fig. 1. (2) We evaluate spectral changes in SERRS of near-single dye molecules in hotspots of single Ag NP dimers.[4,6] During the laser excitation, the number of SERRS lines decreased until finally two lines remained around 1600 and 1350 cm^{-1}, those are evidence of *G* and *D* lines of single sp^2 carbon clusters. Analysis of the *G* and *D* line intensity ratios reveals the fluctuation in the crystallite size of the clusters within several angstroms; whereas, splitting in the lines enable us for identifying directly the dynamics of various defects in the clusters. This analysis would be impossible to gain with other microscopic methods.

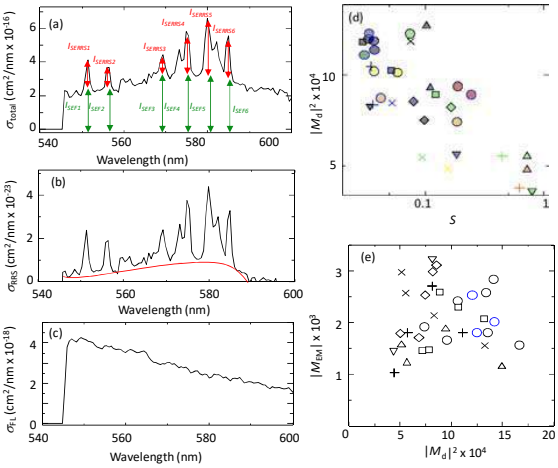

Fig. 1. (Color online) (a) Evaluation of I_{SERRS}/I_{SEF} for panels in (d). Total SERRS intensity I_{SERRS} and SEF intensity I_{SEF} were averaged over I_{SERRS1}/I_{SERRS6} (red arrows) and I_{SEF1}/I_{SEF6} (green arrows), respectively. (b) σ_{RRS} of spectrum R6G in an aqueous solution. Raman intensity is defined as the part above the red curve, which indicates back ground fluorescence. (c) σ_{FL} spectrum of R6G in an aqueous solution. (d) Normalized standard deviation scores S dependence of $|M_d|^2$ in the range of $0 < S < 0.6$ for eight dimers denoted by symbols (○, ○, □, Δ, ▽, ◊, +, and ×). (e) $|M_1|^2$ (~ $(I_{SERRS}/\sigma_{RRS})^{1/2}$) dependence of $|M_d|^2$ (= $I_{SERRS}/I_{SEF} \times \sigma_{RRS}/\sigma_{FL}$) for the same eight dimers as those in (d).

Photostability of photoluminescence (PL) from plasmonic nanostructures such as non-photoblinking and non-photobleaching is beneficial to exploit them as reliable optical probes. Antenna effect of the localized surface plasmon of plasmonic nanostructures concentrates light at the nanoscale allowing strong interaction with electromagnetic radiation, which can compensate relatively low quantum yield. However, recent studies on PL from plasmonic nanostructures have mostly been limited to lithographically fabricated structures or simple nanoparticles. Here we designed and synthesized interior nanogap-engineered cube-in-cube nanoparticles in high precision and a high yield via a galvanic void formation process.1 The cube-in-cube nanoparticles show significantly enhanced PL and the PL intensity and quantum yield are 31 times and 16 times higher than those of Au nanocubes, respectively, which have the highest PL intensity and quantum yield reported for metallic nanostructures. Based on plasmon hybridization model, we interpret the intense PL with super-radiant character of plasmon mode arisen from plasmonic coupling between the core and the shell. Finally, we check the long-term photostability of the PL signal under continuous illumination for 1 h.

Abstract- We present a comprehensive study via transient absorption spectroscopy (TAS) to investigate ultrafast exciton-plasmon dynamics of hybrid aggregates consisted of core-shell quantum dots (QDs) and Au Nanoparticles (NPs) leading to optical loss mitigation. The results suggest modifying the way of analyzing the transient absorption spectra of loss mitigated systems. We show that appropriate choice of the pump wavelength and by changing the pump power we can conclusively prove the existence of loss mitigation using UTAS.

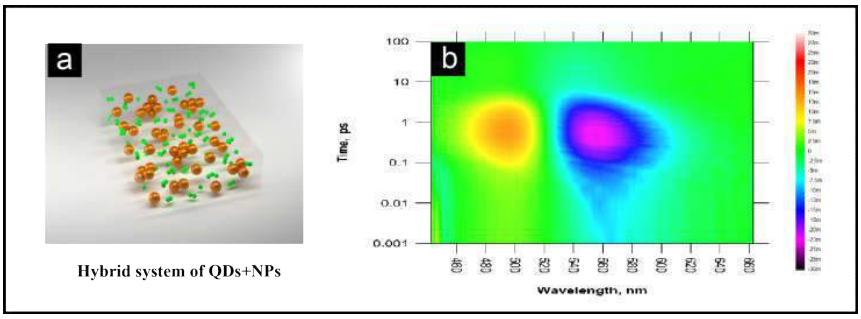

Fig. 1 a) A schematic of fabricated nanocomposite PDMS films with embedded mixture of Au NPs and QDs. **b)** Bird-eye view diagrams of NPs+QDs hybrid system for pump wavelength of 400 nm.

The extraordinary properties of the plasmonic systems arise from confinement of the electromagnetic wave beyond the diffraction limit, as a result of surface plasmons. However, the surface plasmons can be damped due to electron scattering events. In fact, the strong absorption and optical losses in the available plasmonic materials are the main obstacles for their promising applications. One of the most successful approaches to compensate the optical losses, while maintaining the electromagnetic sub-wavelength confinement, is to incorporate gain material in plasmonic systems, such that the gain emission spectrally overlaps with the plasmon resonance. The approach maintains the self-sustaining oscillation of the electromagnetic field while keeping the sub-wavelength field confinement in the vicinity of the NP.

In this work, we report a systematic and detailed transient pump-probe absorption spectroscopy study on loss compensation process of hybrid systems consisted of core-shell QDs aggregates and Au NPs (Fig. 1a). Our study provides a clear understanding of the ultrafast gain-plasmon dynamics to control optical losses in plasmonic

nanostructures, paving the way towards further promising scientific research aimed to enable their practical applications. We highlight that generating hot electrons in plasmonic NPs contribute to the transient differential absorption spectrum under optical excitation and is of great significance. The results suggest modifying the way of analyzing the transient absorption spectra of loss mitigated systems by taking into account the enhanced transmission due to permittivity modification of pumped NPs.

Frequency *pulling like effect* of the transient bleach signal towards the emission maximum of the gain material is reported based on power dependence TAS results as an evidence for loss mitigation process. Furthermore, considerably enhanced bleach signal of the hybrid systems than the combined bleach of only plasmonic NPs and core-shell QDs quantitatively proves the existence of loss mitigation.

Additionally, we study the implications of the coupling strength between the electron oscillation frequency and the phonon modes of aggregated NPs on loss mitigation efficiency and the transient quality factor of the plasmon band. Finally, we investigated the transient kinetics of all systems and showed that hybrid gain-plasmon systems have unique decay kinetics.

Abstract- We introduce a new plasmonic bulls-eye antenna to efficiently harvest the emitted light from diamond Nitrogen Vacancy (NV) centers. The designed structure shows a great performance even better than double-side corrugated structures. In addition, we study for the first time asymmetric structures to steer emitted beam in two-axis. Our results show that spatial off-axial steering angle over a cone is approachable by applying optimal asymmetries to grooves and ridges of the plasmonic antenna.

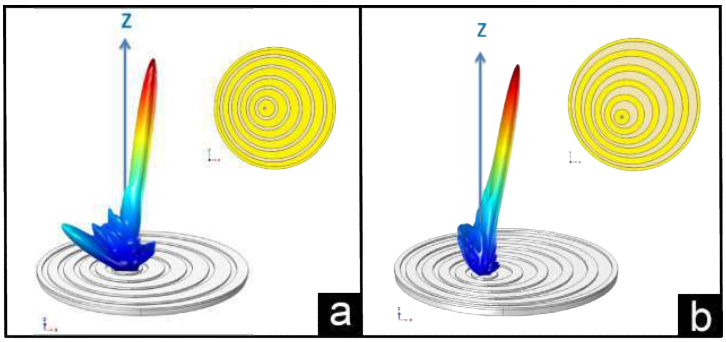

Fig. 1 3D far-field intensity distribution for a Bulls-eye plasmonic antenna with **a)** one main asymmetry plane and ridge asymmetry **b)** with two main asymmetry plane and groove asymmetry. The scheme of each configuration is presented in figure insets.

Sub-wavelength diffracted light sources are rapidly growing cutting edge research field for promising nano-photonic applications. Enhancing the photon collection efficiency and narrowing the emission directivity of such light sources are two critical aspects for their practical applications. For attaining this, one promising approach is to introduce symmetric or asymmetric periodic corrugations on the exit side of a single aperture in a metallic substrate. In this approach, the emitted light of nano-emitter is coupled into the antenna plasmonic modes, and then out-coupled by the antenna to the far-field, resulting in the enhanced light with desired orientation. Accordingly, various applications ranging from efficient photovoltaic light harvesting, polarization sensitive transmission control to precise bio-sensing are enabled. For such applications, recently diamond nitrogen vacancy centers (NV centers) have gained remarkable attention.

Here, we propose a new design of bulls-eye antenna by introducing a metallic sub-plate and dielectric layer below conventional structure. Our proposed design provides high degree of directionality and enhanced out-coupled field intensity of nano-emitter sources as compared to conventional designs. The antenna parameters

are optimized for the emission peak of diamond NV centers. In our model, we have considered diamond NV centers to be doped to dielectric layer and placed inside the central cavity. The structure is optimized by considering the underlying physics of the dielectric layer sandwiched between metal layers. Such an engineered structure provides higher out-coupled light intensity efficiency even better than double-side corrugated antenna.

It is also desirable to have control on the emission angle of out-coupled directive beam from plasmonic antennas. Several studies have been reported to approach angled emission or transmission from such structures. Here, we present trends for steering the radiated beam over the plate of the Bulls-eye plasmonic antenna. By introducing a modification on design of the proposed structure, a considerable off-axis beaming angle retaining high out-coupled light intensity is attainable. A full-asymmetric design approach is introduced for the first time to steer the directive beam on spatial angles over the antenna plate. Our results show that by introducing optimal asymmetries to grooves and ridges of the structure high degree off-axial steering angle are achievable in single-lobe or double-lobe regimes (see Fig. 1).

Finally, our investigations reveal that the far-field intensity for the asymmetric configuration with metal sub-plate is higher than that of a conventional symmetric structure, without perturbing directivity.

Abstract- Suprastructure has unique optical properties so many researchers try to make this kind of structure. In this study we specially synthesized suprastructure like core-shell nanoparticle under the wet chemistry environment. Covering Fe_3O_4 nanoparticles with Au shell has been tried and fully covered self-assembly of AuNPs on Fe_3O_4 nanoparticle was observed by TEM. Au shell can protects the magnetic core against oxidation and produces multifunctionality, special optical properties from suprastructure like Au shell and magnetic properties from magnetic nanoparticles. To form suprastructure like Au NP coating on Fe_3O_4 nanoparticles, ion reducing method assisted with layer-by-layer (LBL) structure of AuNPs and PEI on the surface of Fe_3O_4 nanoparticle were proceeded. This material was used as surface enhanced Raman scattering (SERS) substrate of rhodamine-B and graphene quantum dots (GQDs). Magnetically 1D self-assembled structure of the prepared core-shell nanoparticles and separately deposited nanoparticles were prepared as SERS substrate. Raman signals on these two substrate were obtained and compared.

Summary- Suprastructure like Fe_3O_4@Au core-shell nanoparticles were synthesized through a simple wet chemistry method. Core-shell nanocomposite with unique Au shell was obsereved by TEM. Highly enhanced raman signal was observed on this materials. When this nanoparticle was self-assembled with external magnetic field 3−4 fold greater enhancement of the Raman signal was obtained. Because of its novel structure with simple synthesis methods, this material can be applied for characterizing the electronics and magnetism in the nano-system.

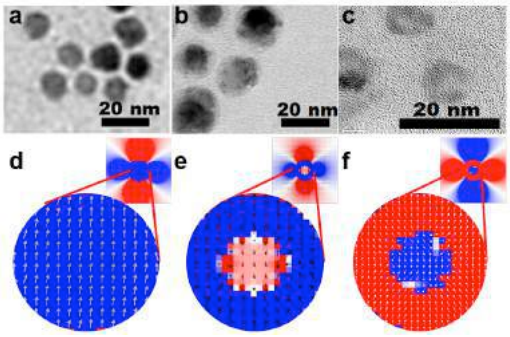
Abstract-Recently, the relationship between magneto-optics and plasmonics has been actively studied. But, localized surface plamonic resonance (LSPR) effect on magnetic phase, especially on the motion of magnetic dipole moments, is not confirmed yet. Here, solid, core-shell, and hollow-type of iron-based magnetoplasmonic (MagPlas) nanoparticles (NPs) are produced via thermolysis synthesis route. Different magnetic behaviors inside the magnetic NPs at the presence of plasmonic material are demonstrated based on Landau-Lifshitz-Gilbert (LLG) theory which represents ferromagnetic flux. It is experimentally proved, for the first time as we know, that adding electric field from plasmonic absorption and scattering of Au NPs to LLG equation adjusts magnetic anisotropic energy and thermal energy, which visualizes and explains by OOMMF and COMSOL micromagnetic simulation tool.

The design and synthesis of magnetoplasmonic (MagPlas) nanostructures have been attracted since they have the extraordinary properties not only for those combined functional natures of magnetic and plasmonic optical property but also for the characteristics of quantum mechanics such as size and shape-dependent differences in physicochemical property unlike their bulk counterparts [1, 2]. But plasmonic effects on magnetic property in these MagPlas nanostructure have been hardly described.

In this study, we synthesized MagPlas Au@FeCo and Au@FeNi core-shell, hollow FeCo nanocrystals to compare MagPlas properties. Previously reported studies related with plasmonic and magnetic nano-complexes usually have focused on magnetite as magnetic component or transition metals in core part, but we use soft magnetic element and apply it to shell on Au template. Furthermore, micro magnetic flux of the coated magnetic shell was simulated based on Landau-Lifshitz-Gilbert theory that describes ferromagnetic flux. Many studies on magneto-optic and MagPlas NPs explain magnetic effect on optical and plasmonic component. But, plasmonic effect on magnetic property in ferromagnetic NP regime was figured out here. It was observed that core-shell Au@FeCo NPs have the lowest magnetic anisotropy value among solid FeCo, MagPlas core-shell Au@FeCo, hollow FeCo NPs. This MagPlas nanomaterials can provide promising well-designed magnetic behavior as well as plasmonic property inside NPs to be one candidate for recording media, spintronics, optical device, magnetic hyperthermia, bi-functional medicine.



Figures and Tables: TEM and magnetization motion images of solid FeCo(a, d), MasPlas Au@FeCo core-shell(b, c), hollow FeCo NPs (c, f).

Abstract

Controlling and understanding the assembly of colloidal nanoparticles remain a challenging issue for optimizing magnetic-plasmonic devices for various applications including sensors, displays, bio-imaging and therapy. A magnetic field is successfully utilized to induce the fabrication of multidimensional structures composed of magnetite coated silver core/shell ($Ag@Fe_3O_4$) particles, which exhibit intriguing optical properties. An effective and highly controlled dip-coating technique for fabrication of one-dimensional (1D) structure of magnetoplasmonic particles on large-area surface is proposed by combining electrostatic and magnetic dipole interactions. This technique is demonstrated to be a very powerful approach to modulate optical properties of magnetoplasmonic particles. Moreover, a magnetic-field assisted coating technique for fabrication of two-dimensional (2D) amorphous photonic crystal (APC) film of the magnetoplasmonic particles on a filter membrane is proposed. The fabrication technique relies on combination of high porosity of filter membrane accelerating evaporation-mediated arrangement of particles and strong magnetic response of particles to external magnetic field. The magnetoplasmonic 2D APC exhibits strong dual reflected colors caused by structural scattering and plasmon resonance scattering. The water absorption ability of the membrane and

the high refractive index sensitivity of plasmon resonance scattering are utilized to fabricate a simple colorimetric humidity sensor. Additionally, a mechanical colorimetric sensor that exhibits instantly responses to both bending and stretching forces is fabricated by embedding the 2D APC film into PDMS substrate. Because of unique features including dual-color characteristic, flexibility and high plasmonic sensitivity, these kinds of platform could be highly promising as wearable devices for physical, chemical and biological sensing with naked eye detection.

Plasmonic Trapping and Antitrapping of Nanoparticles.

Abstract-Optical tweezers performance is investigated when the Gaussian beam is focused on the metal substrate with nanoparticle. When the beam is focused above the substrate optical force increases about an order of magnitude due to evanescent field of surface plasmon. Novel effect of repulsion from Gaussian beam ("anti-trapping") is obtained when the beam waist is moved below the substrate which is confirmed by both the analytical approach and finite element simulation.

The ability to manipulate small objects with focused laser beams opened a venue for investigating dynamical phenomena relevant to both fundamental and applied science. Nanophotonic and plasmonic structures enable achieving superior performance in optical trapping due to highly confined near-fields. In this case, the interplay between the excitation field, re-scattered fields and the eigenmodes of a structure can lead to remarkable effects, as it is shown here with an example of a particle trapped by laser light in a vicinity of metal surface. Surface plasmon excitation at the metal substrate plays a key role in tailoring optical forces acting on a nearby particle. Depending on whether the illuminating Gaussian beam is focused above or below the metal-dielectric interface, an order of magnitude enhancement or reduction of trap stiffness is achieved in comparison to standard glass substrates. Furthermore, a novel plasmon-assisted anti-trapping effect (particle repulsion from the beam axis) is predicted and studied. Highly accurate particles sorting scheme based on the anti-trapping effect is analyzed. The ability to distinguish and configure various electromagnetic channels through the developed analytical theory provides the guidelines for designing auxiliary nanostructures and achieving an ultimate control over the mechanical motion at the micro- and nano-scales [1].

Optical trapping characteristics in the proximity of the beam waist and the impact of the focus position with respect to the surface were studied. Gaussian beam is focused above or below the substrate and the force acting on a dielectric bead ($\varepsilon=3$) of radius R=15 nm is calculated. Three different scenarios were considered: glass ($\varepsilon_2=2.25$) and silver substrates, and in the latter case the plasmonic contribution to optical forces can be switched 'on' and 'off' by either including evanescent harmonics or not. For f=100 μm the bead lying on the substrate (centered at z=15 nm) experiences attraction to the beam center (trapping) at all the cases (Figure 1B). This is a typical behavior for a deeply subwavelength low-index bead which has no resonances and is usually attracted towards the axis of free-space Gaussian beam. Comparison between the force values favors the silver substrate,

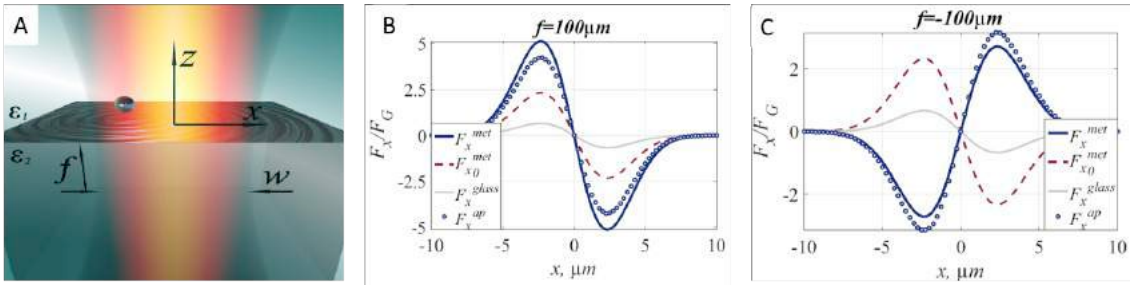

Figure 1. A) Schematics of the system. Gaussian beam with waist w is normally incident on a flat silver substrate; the focal position f along the z axis can be either above or below the interface. Optical forces acting on a spherical dielectric particle are formed by beam-particle, beam-substrate, and particle-substrate interactions. Optical force acting on a particle (ε=3, radius R=15 nm) in the Gaussian beam focused above (f=100 μm, B) and below (f=-100 μm, C) the substrate interface. Blue solid lines correspond to silver substrate; red dashed lines to the model without plasmon contribution; grey solid lines to the glass substrate. The beam waist diameter is w=10λ, the particle is touching the substrate.

which provides about an order of magnitude enhancement compared to the glass. Thus, the auxiliary metal substrate allows increasing the trap stiffness.

At the other hand, focusing the beam below the substrate (f=-100 μm) leads to completely different behavior (Figure 1C). While in both glass and 'silver with plasmon excluded' cases optical trapping is observed, real silver substrate leads to optical repulsion from the beam axis – anti-trapping, pushing the particle away from the region of high optical intensity. Anti-trapping stiffness (derivative of the force with respect to the coordinate) is several times larger than in the case of the glass substrate.

Abstract-We report a new method of integrating ferromagnetic and noble metal plasmonic nanostructures leading to strong magneto-optical (MO) responses with enhanced optical reflectivity. The structures under study consist of Ni and Au nanoparticles ordered into periodic checkerboard arrays. Diffractive far-field coupling between the individual emitters of the lattice results in the excitation of two orthogonal surface lattice resonance (SLR) modes. Local analyses of the radiation fields indicate that both the Ni and Au nanoparticles actively contribute to these collective resonance modes and, thereby, the MO activity of the hybrid arrays.

Ordering of ferromagnetic nanoparticles into a periodic array enhances the optical and MO activity due to the excitation of SLR modes [1,2]. Coupling between broad localized surface plasmon resonances (LSPRs) of single ferromagnetic nanoparticles [3] and diffracted orders of the array generates sharp and asymmetrical SLRs in the optical and MO spectra. Here, we report on the integration of Au nanoparticles into ferromagnetic nanoparticle arrays [4]. In our experiments, we use periodic arrays comprising a checkerboard pattern of Au and Ni nanoparticles (Fig. 1(a)). The ferromagnetic and noble metal emitters are separated by 450 nm and the diameter of the Au nanoparticles is varied from 80 to 120 nm to gauge its influence on the optical and MO activity (the diameter of Ni nanoparticles is fixed at 120 nm). All nanoparticles have a thickness of 30 nm.

The integration of Au nanoparticles into Ni nanoparticle arrays considerably increases the optical activity as demonstrated by high reflectivity (Fig. 1(b)). Yet, compared to pure nickel nanoparticle arrays, the orthogonal magneto-optical dipole retains its intensity (Fig. 1(c)). In other words, the MO activity is conserved while the optical response is substantially enhanced. Our results are explained by far-field diffractive coupling between the ferromagnetic and noble metal emitters, causing two main effects: (1) A magneto-optical dipole is induced on the Au nanoparticles and, consequently, the non-magnetic noble metal emitters actively contribute to the MO activity of the hybrid array. (2) Far-field diffractive coupling to Au nanoparticles enhances the optical and magneto-optical activity of the Ni emitters. Numerical calculations based on the discrete dipole approximation (DDA) and finite-difference time-domain (FDTD) simulations substantiate our experimental findings. Label-free biosensors based on the measurement of very small refractive index changes [5] and other magneto-plasmonic devices could make use of strong optical and magneto-optical responses in hybrid nanoparticle arrays.

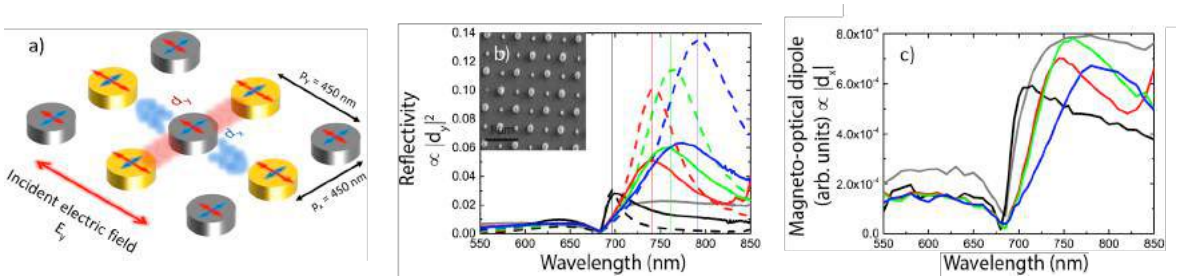

Figure 1 (a) Schematic illustration of a checkerboard array of Ni (grey) and Au (yellow) nanoparticles. (b) Optical reflectivity of Au-Ni nanoparticle arrays (black, red, green, and blue lines). Results for pure Au nanoparticle arrays (dashed lines) and a pure Ni nanoparticle array (grey line) are shown for comparison. (c) Magneto-optical dipole signal for Au-Ni nanoparticle arrays (black, red, green, and blue lines) and a pure Ni nanoparticle array (grey line). The colors of the spectra in (b) and (c) indicate results for Au nanoparticle with different diameter: d_{Au} = 80, 100, 110, 120 nm.

Abstract – Surface plasmons polaritons (SPPs) are electromagnetic surface waves that can be generated by and converted back into freely propagating light beams by applying metallic structures, such as gratings or slits. In this work we investigate experimentally whether SPPs in the process light beam → SPP → light beam convey the geometric (Pancharatnam-Berry) phase, which appears on passing a beam of light cyclically through a series of polarizing components.

Surface plasmon polaritons (SPPs) have been the workhorse in nanophotonics, resulting in the emergence of plasmonics [1] as a separate field covering cross-disciplinary physics, including subwavelength light control [2]. SPPs are known to be highly polarized surface waves [1]. A point on the Poincaré sphere [3] represents the state of polarization of a monochromatic electromagnetic beam. If such a beam passes through a succession of polarizing elements so that the initial and final states are identical, the polarization state traces a closed circuit on the sphere. In doing so the light beam acquires, in addition to the usual dynamic phase, also a geometric phase, known as the Pancharatnam-Berry phase [3]. It is equal to half the solid angle subtended by the circuit from the origin of the sphere [3,4]. Here we investigate experimentally whether, when a beam of light is converted into SPPs and then back into a freely propagating field, the geometric phase does survive? The conceptual scheme of the work is illustrated in Figure 1. The closed path ABCDEA on the Poincaré sphere corresponds to the successive polarization states. The geodesic arc BC (shown in blue) represents the path of the polarization state which results from the conversion of circularly polarized light (state B) first into SPPs and back into linearly polarized light (state C). By varying the solid angle of the closed path on the Poincaré sphere, the geometric phase changes. One way to do this is by rotating a linear polarizer and thereby moving the position of point D along the equator. In practice, the change in the geometric phase can be observed as a shift in the interference pattern [5] when two beams (in states A before and after the cyclic rotation) are combined again.

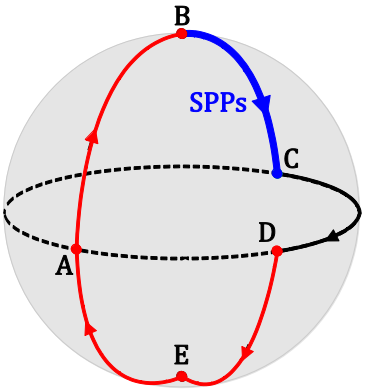

Figure 1. Schematic representation of the polarization-state changes on the Poincaré sphere.

The experimental demonstration [5] is carried out with a Mach-Zehnder interferometer using a He-Ne laser source with a wavelength of 632.8 nm. A linearly polarized light beam from the source is divided into two equal parts. One part undergoes a series of polarization changes, such as linear → right circular → SPPs (linear) → linear → left circular → linear passing through different polarizing elements, and follows the path ABCDEA as

shown in Figure 1. An aluminum grating is applied to generate SPPs which travelled towards a nanoslit that is located at a distance of 25 μm from the grating edge and were converted back into freely propagating field. This output field from the slit is represented as point C on the sphere and its polarization state is opposite to state A. A linear polarizer is placed after the slit with transmission orientation the same as that of the output field C. The polarizer is rotated to change the linear polarization direction along the equator, shown as point D on the sphere. Transformation from state D to left circularly polarized state E is performed using a quarter-wave plate. In the experiment, polarizing elements (linear polarizer and quarter-wave plate) after the slit are joined together. As a starting point, before taking the measurements, the polarizer position is adjusted in such a way that the output intensity is maximum; we call this position as 0°. Measurements are taken by rotating the polarizer left and right of the 0° position with an interval of 20°. This changes the solid angle on the sphere. The beam in the other arm of the Mach-Zehnder interferometer does not go through any polarization-state changes. Finally, both beams are combined and their interference is recorded on a CMOS detector. The presence of the geometric phase in one beam appears as a shift of the interference pattern. The variation of the peak shifts for polarizer rotation angles 20° and 40° on both sides of the maximum position 0° is shown in Figure 2 [5].

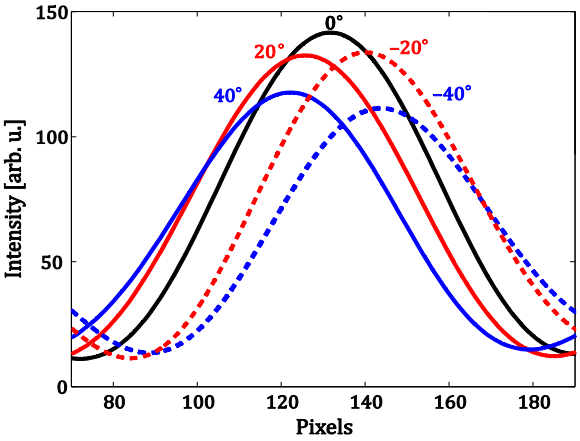

Figure 2. Shift in the interference pattern due to the geometric phase mediated by the SPPs for different angles of rotation of the polarizer. The black solid peak at 0° corresponds to the polarizer position in which the output is maximum (points C and D in Figure 1 coincide). Negative angles -20° and -40° are associated with rotations of the polarizer towards left of the maximum position. Measurements of the interference peak shifts for angles 0°, ±20°, ±40°, and ±60° are in precise agreement with Pancharatnam's rule [5].

The effect of the dynamic phase has been eliminated by aligning all optical components accurately. Hence, a consistent shift of the interference pattern clearly proves the presence of the geometric phase in one of the beams. The conclusion is that surface plasmons mediate the geometric (Pancharantnam-Berry) phase in nanoplasmonic transitions light → SPP → light, and that the geometric phase in such transitions obeys Pancharatnam's theorem.

Abstract-We proposed the tunable reflector formed by graphene in Metal/Insulator/Metal cavity. The structure can control the reflectivity not only effectively by strongly confined electric fields but also sensitively by variable permittivity of graphene. Consequently, we can control the reflectivity by modifying the gate voltage of graphene.

Graphene, famous two-dimensional material composed of carbon atoms, has many interesting optical properties due to its unusual band structure as shown in Fig. 1. In this band structure, the optical conductivity is sensitively changed by adjusting Fermi energy induced by gate voltage. The variation of the optical conductivity can be measured by observing change of reflectivity [1]. However, since graphene interacts with the electric field within one atomic width, there is an upper limit to the variation.

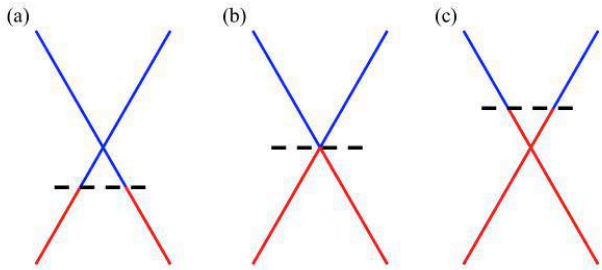

Figure 1: Band structure of graphene when Fermi energy is (a) smaller than, (b) equal to, (c) bigger than Dirac point.

Metal/Insulator/Metal (MIM) structure produces the key of breaking the limit. The MIM cavity strongly confines the lights within sub-wavelength thickness of the insulator layer. When the graphene in the MIM cavity, the light-matter interactions increase by strong field concentration. In addition, since the resonant wavelength of the cavity can be adjusted by changing the distance between the metals, the reflectance can be changed by changing the gate voltage [2]. The reflectivity is also controlled by tuning the resonant wavelength.

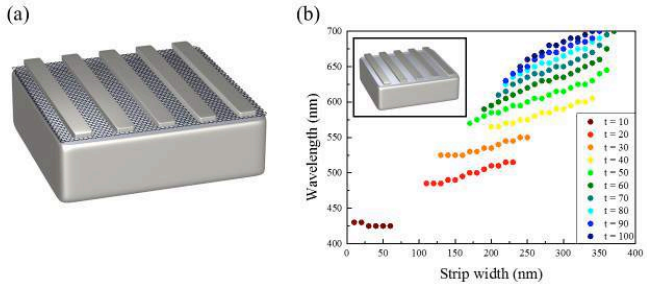

Figure 2: (a) Scheme of Metal/Insulator/Metal cavity with graphene. (b) Maximums of –R (reflectivity) for different width of silver strip and thickness (t) of indium phosphide layer.

In this research, we proposed the structure formed by graphene in MIM cavity as a way to change the reflectivity. The MIM cavity is formed by silver substrate, indium phosphide layer, graphene and periodic silver strips (Fig. 2(a)). As indicated by Fig 2(b), the resonant wavelength is already tunable without graphene by changing the width of silver strip and thickness of indium phosphide layer. However, with graphene, the resonant wavelength can be shifted in situ by using variable permittivity of graphene. The reflectivity is effectively changed because the strongly confined electric fields induced by MIM cavity enhance the interactions between graphene and electric fields. Therefore, we can control the reflectivity sensitively as well as effectively with proposed structure.

Abstract- Monolayer molybdenum disulfide (MoS_2) has intense attention in recent years for their unique optical properties. However monolayer MoS_2 suffers from insufficient light matter interaction because of its atomically thin nature. Plasmonic nanostructures can be easily integrated and boost the light matter interaction of 2D TMDCs. In this study, we demonstrated the enhanced Photoluminescence of MoS_2 using two different hybrid configurations of Au-MoS_2. Reported results allow us to engineer optical properties of two dimensional materials.

Among two dimensional materials atomically thin transition metal dichalcogenides (TMDCs) exhibit wonderful optical properties because of its optical band gap in the visible regime. Molybdenum disulfide (MoS_2) monolayers are a semiconducting member of TMDCs has unique characteristics to find promising place in future optoelectronics [1]. However monolayer MoS2 suffers from insufficient light matter interaction because of its atomic-thin thickness nature. Plasmonic materials facilitate strong light-matter interaction in Monolayer MoS_2 [2, 3]. In recent years MoS_2-nanoantenna hybrid structures are of great interest owing to its enhanced optical properties. In this study we present two different hybrid configurations of lithography patterned Au nanoantenna and Monolayer MoS_2 for spectrally modified photoluminescence enhancement in monolayer MoS_2.

The nanoantenna arrays were patterned by E-beam lithography technique and lift off process. While large area MoS_2 was grown by CVD method and it was transferred using soft lift-off/ transfer process. Figure 1 depicts the two different configurations of MoS_2-Au nanoantenna hybrid structures. In first configuration MoS_2 was transferred on nanoantenna array, while in second configuration the nanoantenna arrays were patterned on monolayer MoS_2.

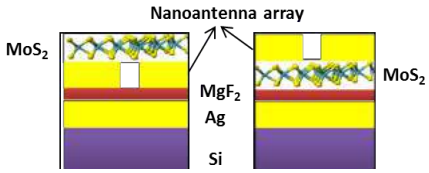

Figure 1: Schematic diagram of two different configurations of MoS2-Au nanoantenna hybrid structures

Figure 2a & 2b shows the optical image of two different configurations of MoS_2-Au nanoantenna hybrid structures. The former shows the successful transfer of MoS_2 on antenna array, whereas the later shows the successful patterning of nanoantenna array on MoS_2.

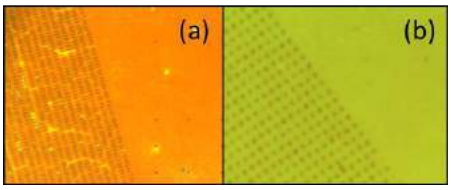

Figure 2: (a) OM image of MoS_2 transferred on nanoantenna array; (b) OM image of antenna array patterned on MoS_2

Using Lumerical FDTD solutions we simulated nanoantenna so as to have resonant wavelength to overlap the emission wavelength of MoS_2 because we are interested in the optical pumping of MoS_2 photoluminescence *via* plasmonic resonance. The blue dotted line in figure 3a shows the emission wavelength of MoS_2 and it's overlapped with the resonant wavelength of designed antenna. Figure 3b depicts the electric filed distribution of nanoantenna with the polarization along the antenna axis at a wavelength of 702nm.

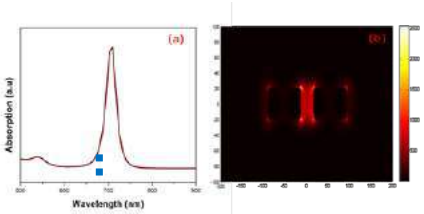

Figure 3: (a) Simulated absorption spectrum of nanoantenna; (b) Electric field distribution of nanoantenna at 702nm (resonant wavelength)

Further PL enhancement studies were carried out for two different hybrid configurations of MoS_2-Au nanoantenna with the 632.5nm laser. Figure 4 shows the PL enhancement for the hybrid structure for both configurations. In both the cases the local near field produced by nanoantenna interacts with the monolayer MoS_2 and this interaction leads to increased optical absorption and number of excitonic pair's photo generated in monolayer MoS_2 leading to PL enhancement of MoS_2. The PL enhancement for MoS_2 on plasmonic structure is high compared to the MoS_2 below the plasmonic structure. This is because of the light extraction efficiency due to plasmonic nanostructures in second configuration dominates the internal quantum efficiency blocking emission from MoS_2.

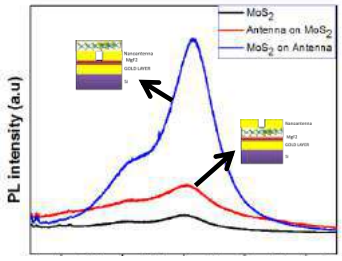

Figure 4: PL enhancement spectrum for two different configuration of MoS_2-nanoantenna hybrid structure

In summary, we have demonstrated the enhanced photoluminescence response of monolayer MoS_2 using surface plasmonic effect based on plasmonic nanostructures. The enhancement is shown when the emission wavelength, resonant wavelength of nanoantenna and incident laser energy is overlapped. The active control of exciton-plasmon coupling would find new opportunities in 2D material based Nanophotonics devices.

Abstract- We have demonstrated an asymmetric bow-tied plasmonic demultiplexer for a wavelength division multiplexing system to realize large-capacity information processing. The developed demultiplexer was designed based on a multimode interference structure consisting of patterned SiO_2 on a gold film. This demultiplexer selectively guides 1.31- and 1.55-μm-wavelength plasmonic signals to different output ports. The experimentally measured insertion loss and crosstalk at the developed demultiplexer were ≤ 8.4 dB and ≤ −2.3 dB, respectively.

Integrated circuits using surface plasmon polaritons (SPPs) as signal carriers have attracted attention because the circuits can realize high-speed and large-capacity information processing[1]. The wavelength division multiplexing (WDM) technique, which can transmit different wavelength signals through a single waveguide, is a powerful technique to process a large capacity of information. Recently, several plasmonic demultiplexers, one of the key devices for the WDM technique, have been proposed. Among them, a multimode interference (MMI)-based plasmonic demultiplexer employing dielectric-loaded SPP waveguides (DLSPPWs) enables strong light confinement in the waveguides[2]. Besides, a previous study numerically suggested that the length of the MMI can be shortened by introducing a symmetric bow-tied structure to the photonic MMI devices[3].

In this study, we have demonstrated a MMI-based asymmetric bow-tied plasmonic demultiplexer employing DLSPPWs, which can reduce the size of the demultiplexer and be producible using complementary metal oxide semiconductor compatible processes. Here, we used wavelengths of 1.31- and 1.55-μm-wavelength, which are the optical telecommunication wavelengths. Since the proposed demultiplexer is a linear system, it was necessary to have a long distance to increase the influence of the propagation parameters between the propagation of both wavelengths. The asymmetric structure, which enlarged a second tapered structure, was designed for securing the optical path length. Figure 1 shows a schematic diagram of the proposed demultiplexer. The demultiplexer consisted of four single-mode waveguides and one 1×3 bow-tied MMI structure. The fundamental operation mechanism of the demultiplexer can be explained via the MMI effect[4]. The bow-tied MMI structure can thus reduce the length of MMI devices.

At first, we numerically confirmed the operation of the proposed asymmetric bow-tied demultiplexer using a finite-difference time-domain method (Fujitsu, Poynting for Optics). Next, the designed demultiplexer was fabricated using Au vacuum deposition, SiO_2 sputtering, and subsequent focused ion beam milling (Figure 2). The size of the fabricated demultiplexer was approximately 4.9×11 μm, which cannot be operated at the rectangular MMI devices owing to its size. Figure 3 shows the SPP intensity distributions at the demultiplexer with wavelengths of 1.31 μm and 1.55 μm, as measured using scanning near field optical microscopy. As shown

in Fig. 3, Port1 and Port3 selectively output the 1.55 μm-wavelength signals, and Port2 outputs the 1.31 μm-wavelength signals. The insertion loss and crosstalk were experimentally evaluated to be ≤ 8.4 dB and ≤ −2.3 dB, respectively. The proposed asymmetric bow-tied plasmonic demultiplexer will contribute to the miniaturization of plasmonic demultiplexers and is highly compatible with production processes used to fabricate conventional electronic devices.

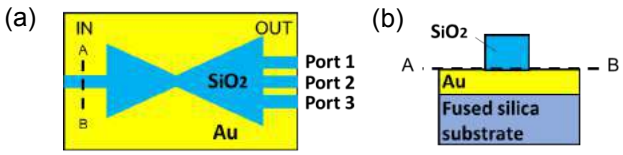

Figure 1. Schematic diagram of the proposed demultiplexer: (a) top view and (b) cross sectional view.

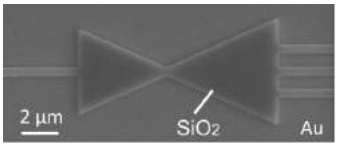

Figure 2. Scanning electron microscope image of the fabricated plasmonic demultiplexer.

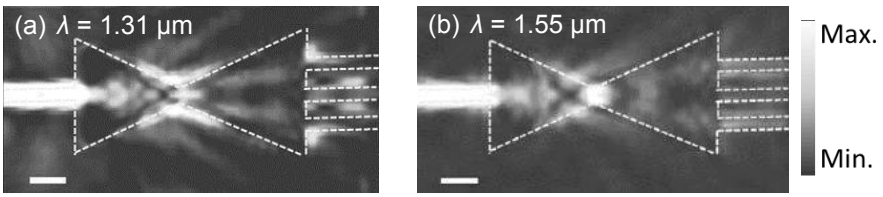

Figure 3. SPP intensity distribution measured at the fabricated demultiplexer, with wavelengths of (a) λ = 1.31 μm and (b) λ = 1.55 μm (scale bar: 2 μm).

Abstract- A sputtering process is presented that enables the deposition of aluminum-doped zinc oxide films with a significant carrier density and thus controllable plasmonic properties. These thin films were characterized using Ultraviolet–visible and Fourier transform infrared spectroscopy, and Hall-effect measurements. Analysis of the results shows a carrier concentration of up to 2.6×10^{20} cm^{-3}, as well as transmission above 80% for 500 nm thick films at wavelengths up to 1900 nm making them well-suited to plasmonic applications.

Transparent conductive oxides (TCOs) have recently been the focus of plasmonics research because of their high density of free electrons and negative permittivity at infrared wavelengths. Conventional gold-, silver-, and aluminium-based plasmonic materials with their very high carrier density of 10^{23} cm^{-3} operate mainly at wavelengths in the visible and UV range, whereas TCOs have the potential to extend plasmonics to a new range of applications in the infrared region of the spectrum that cannot be addressed by metallic plasmonic devices. Among the TCOs, we are especially interested in developing aluminum-doped zinc oxide (AZO) thin films and nanostructures for plasmonic applications [1], due to the relative abundance and non-toxicity of the chemical precursors compared with the widely used indium tin oxide (ITO) [2,3]. In the current study, a fabrication method was investigated that allows for the deposition of high quality AZO thin films with a thickness of 500nm and high transparency at visible and infrared wavelengths, controllable resistivity, and low radiation damage resulting from the fabrication process.

AZO thin films were deposited via off-axis RF magnetron sputtering [4] in order to limit radiation damage from the argon-based plasma used to induce sputtering [5]. This method enables us to achieve highly conductive and transparent AZO films on borofloat33 substrates, paving the way for a variety of plasmonic devices to be fabricated. XRD measurements show that our films have no inherent stresses, and are highly ZnO (002) textured, i.e., they are grown with the ZnO c-axis perpendicular to the substrate surface.

One key goal for our AZO study is to find the frequency where the real part of the permittivity crosses zero, as the film shows metallic behavior below this frequency. We expected this to occur in the near infrared (NIR) part of the spectrum. In order to calculate the exact frequency the carrier concentration of the AZO thin films was measured using Hall-effect system at room temperature with an applied field of 0.55 Tesla. The samples' n-type carrier concentration varies in the range of 3.1×10^{19} to 2.6×10^{20} cm^{-3}, with the higher value comparable to the results reported in [6], indicating desirable plasmonic properties. Using the carrier concentration to calculate the film's plasma frequency resulted in a plasma wavelengths of 1078 nm for the higher carrier concentration, which falls in the NIR part of the spectrum as required.

We are also interested in confirming the transparency of our samples for optical applications. Ultraviolet–visible (UV-Vis) and Fourier-transform infrared spectroscopy (FTIR) measurements indicate that samples are transparent in the visible and infrared ranges, i.e., within the 380 nm to 1900 nm wavelength range, transmission is higher than 80% while reflection is lower than 2%.

In this paper, we have successfully prepared AZO thin films with tuned carrier concentrations and plasma frequencies in the NIR which have the potential of application in plasmonic devices. The goal for future work is to improve the uniformity of our films, and increasing the carrier concentration by 1-2 orders of magnitude.

High-Performance Metamaterial-Based Transparent Conductive Electrode Using Nano-imprint Lithography Process

Dong-Sheng Su[1], Ta-Jen Yen[1*]

[1] Department of Materials Science and Engineering, National Tsing Hua University, Taiwan, ROC

Corresponding author: tjyen@mx.nthu.edu.tw

(MOST 104-2221-E-007-040-MY3)

Abstract- By applying the beauty of Drude's model, we design metallic meshes to reduce the effective plasmon frequency of metal down to near infrared range, which accomplishes a transparent metal. Due to its metallic nature, the DC conductivity of our designed metallic meshes is still superior to common ITO. Combining these two properties, we successfully realize a metamaterial-based transparent conductive electrode whose transmittance is up to 86.41% in visible spectra and sheet resistance is down to 8.77 Ω/□.

1. Introduction

Currently, indium tin oxide (ITO), which possesses high transmittance (> 80%) and low resistivity (~ 50Ω/□) is the widely used material as a transparent conducting electrode in photovoltaic devices. Yet, ITO suffers from the following five drawbacks including (1) low large-area conductivity, (2) low flexibility, (3) low cost to price value due to scarce indium, (4) low transmittance in blue light region and finally (5) low out-coupling efficiency. Therefore, it becomes a must to develop an alternative material for transparent conducting electrodes to improve the efficiency of photovoltaic devices.

To date, researchers have also focused on a few candidates such as graphenes[1], metal nanowires[2], conducting polymers[3] and so on to replace ITO. Although these alternative techniques own great potentials to replace ITO and even further increase the applications on photovoltaic devices, it is difficult for the abovementioned techniques to integrate with organic light emitting diode (OLED) since an anode should be flat.

On the other hand, low out-coupling efficiency restricts the development of ITO in the field of OLED. The out-coupling efficiency of ITO is only 20% due to mismatched impedances between ITO and free space. Recently, numerous methods have been reported to improve the out-coupling efficiency such as embedding photonic crystals in a glass subtract[4] to overcome the waveguide loss while building a micro-lens array[5] to decrease subtract losses.

In this project, we proposed a metamaterial-based TCE to not only possess high transmittance and low sheet resistance but also could further improve the out-coupling efficiency without any further modification.

2. Metamaterial-based TCE

2.1. Simulation process

We employ finite-difference time-domain (FDTD) simulation software to obtain the transmittance in the visible spectrum of our metamaterial-based TCE with a 1000nm periodicity, a 100nm linewidth and 50nm thickness of gold meshes. Besides, the out-coupling efficiency of our metamaterial-based TCE and ITO could be also extracted out from FDTD simulation by first setting a point light source in emission layer and then measuring the corresponding transmittance through the TCE and ITO beyond a glass substrate. From the simulation, the metamaterial-based TCE possesses reveals a transmittance up to 86% as shown in Fig. 1(a) and an increment out-coupling efficiency of 20% compared of ITO as portrayed in Fig. 1(b).

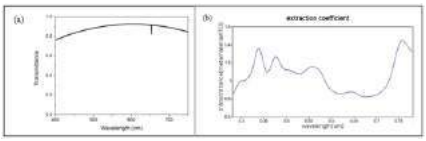

Fig. 1. Finite-difference time-domain (FDTD) simulation result of our metamaterial based TCE. (a) Transmittance in the visible region and (b) out-coupling efficiency normalized by ITO's.

2.2. Fabrication process

We apply a nano-imprint lithography (NIL) process to realize our designed metamaterial-based TCE. We first used an electron beam lithography (EBL) process to define our structure on a silicon substrate as a repeatable mold. We replicate the

pattern from the silicon stamp to a glass substrate with PMMA to define the complementary pattern on the glass substrate. We finally deposited gold on the substrate and carried out lift-off, then we can obtain the realized metamaterial based TCE. Figure 2(a) reveals the flowchart of fabrication process and the corresponding SEM and AFM pictures are shown in Fig. 2(b).

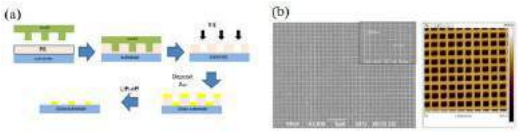

Fig. 2. (a) Fabrication flowchart of the metamaterial based TCE by applying a nano-imprint lithography (NIL) process. (b) SEM and AFM pictures of the metamaterial-based TCE.

3. Result and discussion

Optical transmission measurements were conducted via a UV-Vis with a focal point size of about 50 m in the center of the TCE at the wavelength from 400nm to 700nm, and we further normalize the transmission spectrum by the glass substrate. Figure 3 shows the measurement results of the transmission spectrum. A transmission dip occurs at the wavelength from 600nm to 650nm, which could be attributed to the excitation of surface plasmon polaritons (SPPs) along the individual wires. Furthermore, we also measure the sheet resistance of our metamaterial-based TCE by a multifunctional electrical property system. From the results of Fig. 3, we can conclude that there appears a trade-off between the transmittance and sheet resistance of our metamaterial-based TCE.

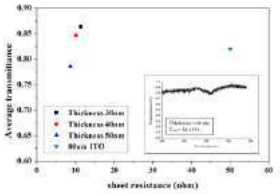

Fig. 3. Measurement result of metamaterial based TCE by UV-Vis with different metal thickness.

4. Conclusion

Metamaterial based TCE possess 3 main advantages to integrate with OLED, which are (1) great opto-electro properties, (2) architecture characteristic, (3) material properties. For opto-electro properties, metamaterial-based TCE could achieve an average transmittance of 86.41% in visible region, meanwhile a sheet resistance of 8.77Ω/□. For architecture characteristic, the nano-grid structure could further improve the out-coupling efficiency and the thin metal film is also beneficial to integrate with opto-electro devices. Finally, the material of metamaterial-based TCE is gold which possesses good ductility, low chemical activity, and high work function. By utilizing these talent of gold, the application of metamaterial based TCE is walking on a road with bright future.

Abstract-In this poster we present a method of fabricating nanogap arrays via a low-cost, versatile method of colloidal lithography. Combing various deposition technologies using colloidal crystal monolayer as initial template, we show here the possibility of obtaining nanogap structures with advanced optical properties with low cost and high throughput. The simulation results show clear Fano resonances occurring because of the presence of nanogap between stacked metallic layers.

Small gaps at nanometer-scale enabled noble metals to be perfect research of interest in the field of plasmonic sensing devices, optical antennas, and nanolasing systems[1]. Due to the ultra-small gap formed in between two metallic components, the coupling effect is usually enormous and hence extreme nanoscale confinement and enhancement of the near electric field intensity[2].

Despite the huge potential in these nanogap devices, challenges still remain in manufacturing the advanced devices with high throughput and reproducibility. Existing fabrication technologies are, in most cases, either time-consuming or of high-cost. Here we propose to fabricate nanogap structures with a combination of bottom-up assembly and top-down patterning strategy in the mean of lower cost and higher throughput. Monolayer of colloidal sphere crystal is used as initial template. By combining various deposition technologies we were able to fabricate nanogap structures of high quality and also over large area. The optical properties proven to be of high electric field enhancement with the possibility of exciting Fano resonances due to the plasmonic hybridization between two metallic parts forming the nanogaps.

Magneto-Optical Effect in Hybrid Plasmonic Nanostructures

Marion Rodier[1], Christopher Kelly[1], Affar Karimullah[1], Calum Jack[1], Ryan Tullius[1] and Malcolm Kadodwala[1]

[1]School of Chemistry, Joseph Black building, University of Glasgow, Glasgow G12 8QQ, UK.

Abstract The magneto-optical effect occurs in magnetic chiral media, and can be detected by use of polarised light. Although this effect is of interest in the study of the light matter interaction, it has not been studied in depth because of the strong magnetic field needed to observe it, and the weakness of the effect. Hybrid plasmonic nanostructures were used to detect a magneto-optical effect. The aim here was also to detect this effect at a low magnetic field with a high intensity.

The magneto-optical effect has been observed, in inorganic material, using strong magnetisation (about 60mT)[3]. The effect is rather small; indeed the change of the angle of polarised light is 1° per T. We propose to study this phenomenon at low magnetic field (8 mT). We therefore used a home design hybrid chiral plasmonic material, consisting of left and right handed nanostructures[4], coated by a layer of 100 nm gold and 100 nm nickel. The nanostructure we used, are called solid-inverse nanostrusture, because they consist in a solid structure (metal layer) and a void (inverse) identical to the structure. These solid and inverse modes can be associated respectably to a bright and a dark mode, by analogy with an orbital molecular diagram. The bright and dark mode being on top of each other can hybridize, giving rise to interferences. The non-linear optical technique, second harmonic generation (SHG) was used to generate S-polarised and P-polarised light. Our material was set up with a magnetic field directed parallel or anti-parallel to the plane of the sample. The absorption of the polarised light, in the magnetised chiral material, relative to the direction of the magnetisation, was recorded. We compared the results from the left and right handed structures with those of non-chiral media. The response changes between P-polarised and S-polarised light, because the polarised light is respectively parallel and perpendicular to the magnetic field. Results show an effect depending on the polarization of the light and the intensity of the magnetic field.

Abstract— A class of electro-optically tunable infrared plasmonic absorbers is designed and theoretically investigated. The spacer between a subwavelength metallic stripe grating and a ground plane is filled by a bilayer of indium-tin-oxide (ITO) and hafnium oxide (HfO_2). The application of a bias voltage across the dielectric gap induces a free-carrier accumulation layer at the ITO/HfO_2 that locally modulates the ITO permittivity and drastically modifies the optical response of the absorber. The carrier distribution and dynamics are solved via the drift-diffusion model, which is coupled with optical wave propagation studies in a unified finite element method platform. Optimized structures are derived that enable large modulation of the reflected wave amplitude as well as control over the spectral position of the plasmonic resonance.

The dynamic control of the amplitude and/or phase of optical signals is a key property in numerous photonic devices, such as tunable filters, modulators, and switches. Among the various physical platforms employed in the design of tunable photonic components, much attention has been recently focused on the electro-optic control of the free carrier concentration in semiconductors, such as silicon or transparent conducting oxides (TCO). More specifically, it has been demonstrated that the application of a control bias across a metal-dielectric-TCO junction can lead to a free-carrier accumulation layer at the TCO/dielectric interface. Such a layer locally modulates the TCO permittivity and can significantly affect the optical properties of the device, e.g. in the case of epsilon-near-zero-based silicon nanowire modulators [1]. The same effect has been recently extended in the demonstration of mid-infrared amplitude [2] and near-infrared phase [3] free-space modulators, based on plasmonic absorption in thin resonant films [4].

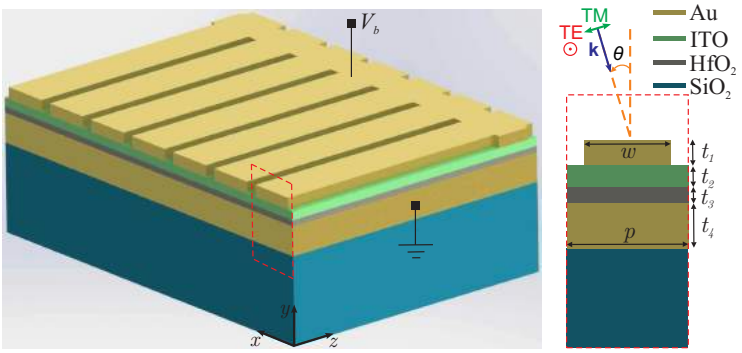

Figure 1: Schematic layout of the proposed electrically tunable near-infrared absorber. The dielectric spacer between the ground plane and an Au grating is composed of two thin films of haffnium oxide and indium-tin-oxide. By applying a bias voltage, a free-carrier accumulation layer is formed at the ITO/HfO_2 interface, which modulates the optical response of the absorber.

In this work, we present the design of electro-optically tunable near-infrared perfect plasmonic absorbers, based on the generic layout of Fig. 1. The resonant plasmonic cavity is formed between a

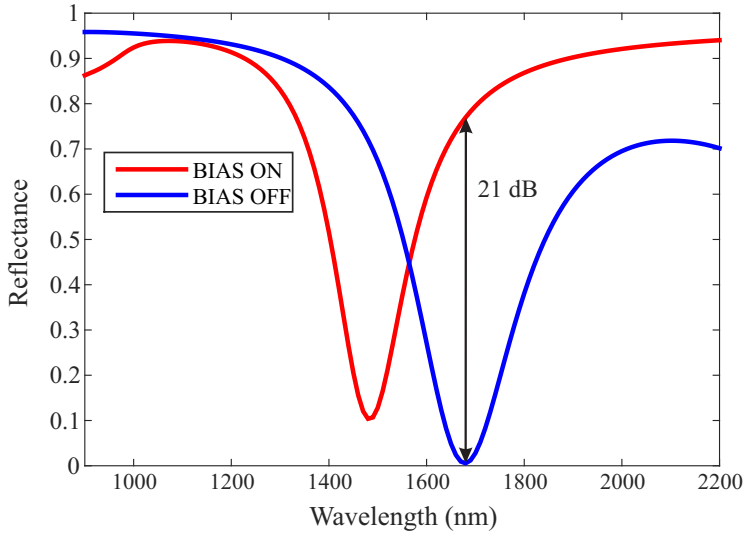

Figure 2: Modulation of the reflected light amplitude by switching ON and OFF the bias control voltage in the proposed TOC-based electro-optically tunable plasmonic absorber.

ground plane and a Au stripe grating patterned on a bilayer consisting of ITO and HfO_2. By properly selecting the geometrical parameters, critical coupling of the impinging planewave is achieved, such that 100% absorption is achieved at the resonant frequency. When a bias voltage V_b is applied, a nanometric thin layer of free-carriers accumulates at the ITO/HfO_2, locally changing the ITO permittivity, which progressively shifts from positive to near-zero and finally negative values. The optimization of the absorber's design leads to large amplitude modulation, as in the case shown in Fig. 2, which corresponds to a structure with $g = 190$ nm, $p = 220$ nm, $t_1 = 100$ nm, $t_2 = 3$ nm, $t_3 = 17$ nm, and $t_4 = 20$ nm.

Abstract— Surface plasmon resonance imaging is a very effective technique for studying surface phenomena in complex biological materials. However, its spatial resolution is limited by the propagative nature of the surface plasmons. In this work, we studied exhaustively by numerical simulations the excitation of surface plasmons on continuous films, and we demonstrate how a higher resolution can be achieved by nanostructuring the metal surface. This method can significantly reduce the surface plasmons propagation length from several micrometers to submicrometer distances.

Surface plasmon resonance imaging (SPRI) is a label-free technique sensitive to small variations of refractive index in a dielectric medium at the surface of a thin metal layer. However, the finite propagation distance of the resonant mode results in a directional blur along the direction of mode propagation, limiting the spatial resolution. It is especially problematic in high magnification microscope objective-based systems [1, 2] where diffraction-limited resolution is expected. In this work, we first give a description of the mechanisms involved in the coupling of a plasmonic mode, in particular the role of phase accumulation. Analytical and numerical calculations will be presented to describe such a mechanism for the simplest configuration used in SPRI, which is a thin continuous metal film. These results are also confirmed experimentally and show that the accumulation of phase required to stabilize the plasmon resonance, which is directly related to the minimum spatial resolution achievable, strongly depends on the system being in resonance or slightly off-resonance. The numerical model used for the simulations is a hybrid of the finite element method (FEM) and the periodic Fourier modal method (FMM) [3].

We studied the impact of nanostructuring the metal surface on the spatial resolution measured in SPRI. This effect is based on the properties of the hybrid plasmonic mode that can be excited in a periodic array of gold nanostructures, fabricated on a continuous gold film [4]. As stated previously, surface nanostructuring can enhance the spatial resolution, but not without compromise. Indeed, sensitivity and image contrast can be significantly diminished depending on the parameters of the grating [5]. To reduce these drawbacks, we have optimized the numerical simulations to take into account all key performance metrics of the plasmonic mode: bulk and surface sensitivity (S_b, S_s), penetration depth of the evanescent wave (L_y), and attenuation length (L_x). The bulk sensitivity represents the intensity variations (ΔR in %) at the operation point (angle of highest variation of reflectivity) for a bulk variation of refractive index in the dielectric medium (Δn=0.07), while the surface sensitivity corresponds to the ΔR resulting of a nanometric biological layer thickness change (n = 1.48). The performance metrics were compared with those of a continuous film (thickness chosen for optimal coupling) to evaluate the impact of nanostructuring. For example, we took a sample of BK7 glass/3 nm Cr/50 nm continuous layer Au/Water @ λ = 800 nm, and obtained the following: L_x = 9.68 μm, L_y = 342 nm, S_b = 42.9% and S_s = 6.47%. When the 50 nm layer was structured with a 2D grating (25 nm of continuous Au, 25 nm of nanostructures, grating period of 400 nm, lines width of 200 nm), we obtained the following: L_x = 2.0635 μm, L_y = 291 nm, S_b = 30.3% and S_s = 2.11%. While there was a drop in sensitivity (ΔS_b = -30%, ΔS_s = -67%) and in penetration depth (ΔL_y = -15%), the attenuation length was improved by a factor of 4.7. Subwavelength resolution can be obtained using a high index glass substrate.

In addition, nanostructuring the metal layer significantly reduces the oscillatory perturbations that arise from an abrupt variation of refractive index in the dielectric medium as shown in figure 1a,

where the reflected electrical field was estimated with an analytical model [6]. In this figure, conditions of resonance are optimized in water, and the abrupt variation of refractive index from water to PDMS (n = 1.33–1.4) results in multiple oscillatory perturbations of the electrical field. Those oscillations are almost completely eliminated due to the rapid attenuation of the hybrid plasmonic mode. Experimental results confirmed this impact on the oscillatory perturbations. Numerical simulations on 3D structures are currently ongoing and should present a higher confinement of the plasmonic mode and a reduced attenuation length.

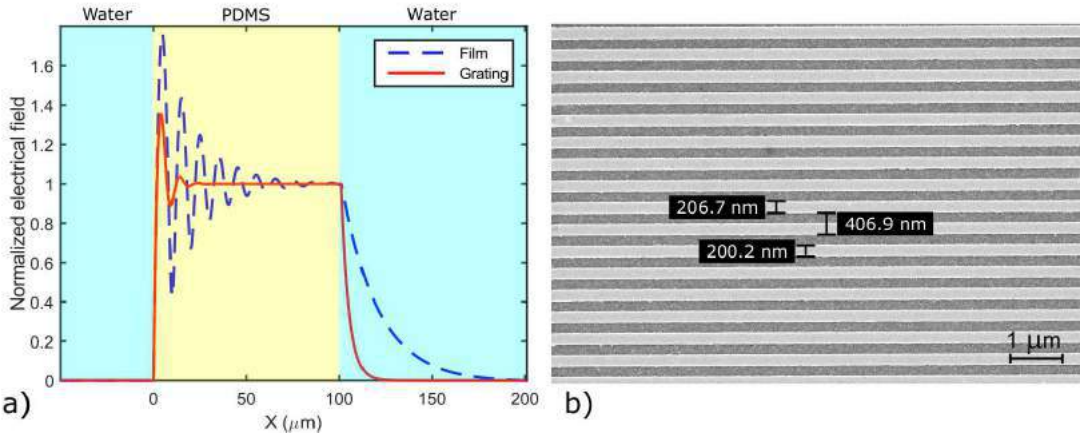

Figure 1: (a) Analytical modelling of an abrupt variation of refractive index in the dielectric medium (Δn=0.07). Amplitude of oscillatory perturbations less important with a grating structure. (b) Nanostructured sample fabricated by electrolithography. Gold line dimensions: 200 nm of width, 400 nm of period, 25 nm of thickness on a 25 nm thick film.

Abstract One way to obtain metallic nanoparticles with different shapes is employment of light in phototransformation method. In this approach one can obtain nanoparticles with the desired final geometry by changing wavelength of light used for irradiation. This method of synthesis of nanoparticles allows obtaining less contaminated nanoobjects. In this work we have also present the first example of phototransformation in oxygen-free environment (as an oxidizing agent 1,4-benzoquinone has been used).

Light is a very valuable tool enabling to obtain various silver nanoparticles. The first report of such approach describes phototransformation of silver spherical nanoparticles into nanoprisms through light illumination. After this report many other works about phototransformation of spherical nanoparticles to structures with different shapes and different optical properties have been published. For example, Zhang group utilized this method to obtain nanorods, and Kitaev group was able to obtain silver decahedrons from once spherical nanoparticles. The main advantage of this method compared with typical chemical approaches of synthesis of anisotropic nanoparticles is that the final solution of nanoparticles after phototransformation is significantly easier to purify. While in a typical chemical synthesis there is a need to use some compounds to drive specific shape transformation, there is no such need in phototransformation method because final geometry of nanoparticles depends on the wavelength of used light.

The phototransformation is a reaction incorporating two independent processes. The first one is a slow dissolution of silver nanoparticles under the influence of an oxidizing agent present in a solution. The second process is a photochemical reduction of silver ions at the specific sites of nanoparticles. As far as we know there was no previous report concerning phototransformation of silver nanoparticles in the deoxygenated solution (in all previous phototransformations oxygen has been used as an oxidizing agent).

In this work, we show the first example of phototransformation with 1,4-benzoquinone used as oxidizing agent instead of oxygen. We also investigated the SERS activity of obtained silver nanopartilces using 3 model Raman scatterers: crystal violet, rhodamine 6G and p-mercaptobenzoic acid. The nanoparticles obtained in the oxygen free phototransformation was about 2.5 times more SERS-active than the Ag nanoparticles transformed under air conditions.

Full Color display using extraordinary optical transmission in silver block array

Kihwan Moon[1], Young Jin Lee[1], Seokhyeon Hong[1], and Soon-Hong Kwon[1*]
[1]Dept of Physics, Chung-Ang University, Seoul 06974, Korea

Abstract-The transmission-type display requires high intensity of transmitted light. However, the metal structure has high reflectance and absorbance. To overcome disadvantages, we introduced extraordinary optical transmission (EOT). A transmitted light through subwavelength scale metal apertures is enhanced by EOT. In addition, EOT has narrow peak in narrow aperture. We obtained green and red colors, which have high transmittance over 80 %, and blue color transmission spectrum using cross-shape slit array consisted of silver nanoblocks.

Metallic structure with subwavelength scale apertures has transmission peak [1]. Phenomenon that transmission is enhanced in metal apertures, extraordinary optical transmission (EOP), is generated by incident light and various modes of surface plasmons. However Metallic devices using transmitted light need incident light with high intensity because of ohmic loss in metal. Besides, single peak spectrum is required to show vivid color.

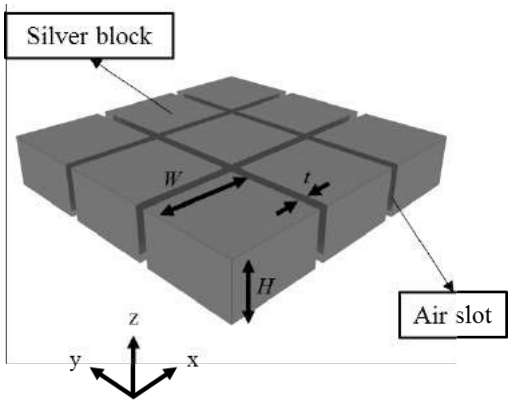

Figure 1. Schematic of color display using silver block array. Transmitted electromagnetic field through the air slit between silver block is enhanced by extraordinary optical transmission.

We demonstrate high transmittance color display using cross shape air slit array that is consisted of silver nanoblocks, as shown in figure 1. Incident light, that is linearly polarized, propagates along the z-direction. The y-direction width of silver block is set to same length with x-direction width for polarization independent transmission. The transmitted light through narrow air slit is enhanced by EOT and the peak wavelength of EOT can be controlled by change of size of silver block. The wavelength of EOT has strong dependence of height (*H*) of silver. The peak of wavelength is increased as the *H* increases.

The width (W) of silver block and thickness (t) of air slit are fixed, W = 250 nm and t =20 nmm as shown in figure 2 (a). In figure 2 (b), Blue color (H = 70 nm) has narrow linewidth and transmission of 60 %. Green (H = 110 nm) and red (H = 150 nm) colors show high transmittance over 80 %. Ex- and Ey-polarized incident light show same transmission spectrum (figure 2 (b)). Optical properties of proposed structure are simulated by using finite-difference time-domain method, and colors are represented by CIE RGB [2].

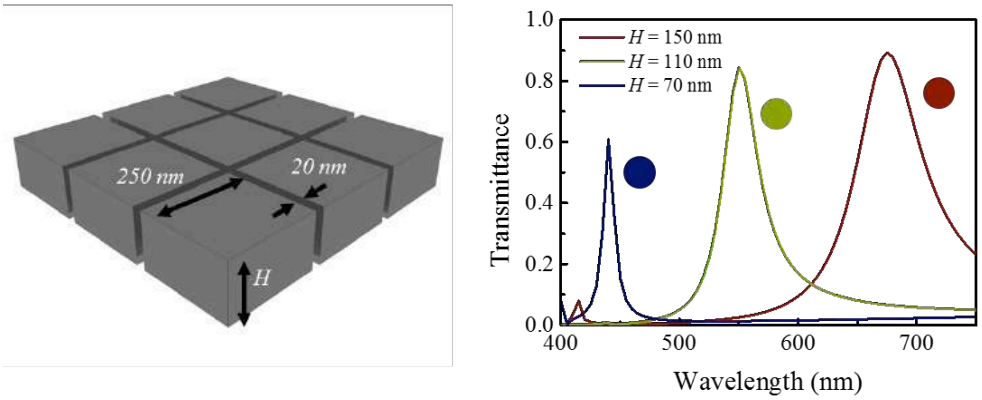

Figure 2. Optimized structure and transmittance spectrum of Red, green, blue. The width of silver block and slit thickness are 250 nm and 20 nm, respectively. Three line colors represent the color samples with heights of 70, 110, 150 nm.

In this research, we suggest the high transmittance color display consisting of silver nanoblock. Blue, green and red colors can be implemented by changing only the size of nanoblock. In addition, proposed structure has advantages, high transmittance in metallic device and low optical loss by independence of polarization. Therefore, silver nanoblock array can be used for full color transmission-type display.

Abstract- Net Photoluminescence enhancement of Alq_3 on Ag was estimated, changing the Alq_3 thickness by removing the optical interference effect occurring inside the film. Enhancement difference observed for devices with different Alq_3 thicknesses can be explained by aggregate behavior of the energy transfer of excitons to surface plasmons.

Light loss due to surface plasmons (SPs) is still one of the fundamental considerations in the design of high-efficiency organic light emitting diodes. The energy converted from excitons to SPs can be extracted as output light again by SP scattering caused by naturally formed submicrometer-scale surface roughness of the cathode metal. So far, we have pointed out that experimentally obtained light enhancement could not be explained by the previously reported calculation formula for the plasmon scattering rate, and that simultaneous plasmon generation from excitons in phase is probable to occur[1)]. To discuss the phenomenon, it is important to estimate the true light enhancement. To that end, the optical interference effect must be removed from measured results, and the rate of radiation distribution along the film thickness is vital to take into account in the calculation of the optical interference. The distribution of remaining excitons in the direction of film thickness which is involved in light emission, affects the estimation of the interference effect. In this study, angular dependence of light enhancement was measured for Alq_3 films with different thicknesses on Ag. They were compared with the results obtained by the optical interference calculation factoring in the above respect to obtain the net enhancement.

Figure 1 (a) shows the result of photoluminescence enhancement obtained by the light output of Alq_3/Ag/glass divided by that of Alq_3/glass/Ag. The use of Alq_3/glass/Ag as a reference device instead of a normal Alq_3/glass was because when using Alq_3/glass, fluorescence which was emitted toward a glass substrate brought ambiguity to the subsequent optical interference calculation. The both thicknesses of Alq_3 were 60 nm, and the excitation was done with a 405-nm laser diode. Solid lines show the enhancement at 0 (normal to the substrate surface) and 60 degrees.

In the optical interference calculation, the coherence length of photons estimated from a phase coherence time of ~100 fs at room temperature was 36 μm. This was equivalent to an absorption coefficient of 2.8×10^2 cm^{-1}, and was smaller than the Alq_3 absorption coefficient of ~10^3 cm^{-1}. Thus, the latter value was used in the optical interference calculation. Compared to the florescence rise time of ~10 ns of Alq_3, the time of exciton-to-SP conversion was much shorter. Thus, it is reasonable to assume that the exciton distribution is determined a priori before light emission in the calculation[2)]. The radiation rate for *s*-polarization at a certain positon comes from remaining dipoles at that position oscillating parallel to the surface of the metal. Parallel and perpendicular dipoles contribute *p*-polarization. Absorption of the excitation light measured for the two devices

through the reflection was taken into the calculation. Figure 2 (a) shows the observed enhancements and calculated results for 60-nm Alq_3, which reached to 2.3 and 3.1 at 0 and 60 degrees. It was assumed in the calculation that oscillating dipoles below 40 nm didn't emit radiation in our devices. Actually, the emission power lowered rapidly, when the Alq_3 thickness was less than 40 nm. This was probably because nonradiative components were formed in early phase of evaporation. Measured light enhancements were 3.0 and 3.3 at peaks at 0 and 60 degrees, respectively, and were higher than the numerical results. The interference effect from dipoles reaches maximum when they are at the top surface of Alq_3. Compared with the maximum numerical results, experimental results were higher. The results of 200-nm Alq3 are shown in Fig. 1 (b). It was found that measured light enhancement fell below the calculation, and that substantial enhancement was not gained.

The light enhancement at a certain wavelength $M(\lambda)$ is expressed as

$$M(\lambda)=\int_0^d \left\{\eta+\eta(P_s(z)-1)P_g(z)+(1-\eta)\overline{P_s}P_{ng}(z)\right\}dz \Big/ \int_0^d \eta dz \quad (1)$$

Here, z: distance from the metal, d: thickness η : radiative rate without metal, $P_g(z)$: SP generation rate, $P_s(z)$: SP scattering probability, $\overline{P_s}$: scattering probability independent of z, and $P_{ng}(z)$: energy transfer probability of the nonradiative component to SP. As z approaches zero, P_g increases, leading to generation of a higher number of SPs, N. However, on the assumption that these SPs have the same phase, P_s increases in proportion to N . Accordingly, the second term in the integral part of Eq. (1) contributes more to a positive value, which can explain the light enhancement dependence in the film thickness.

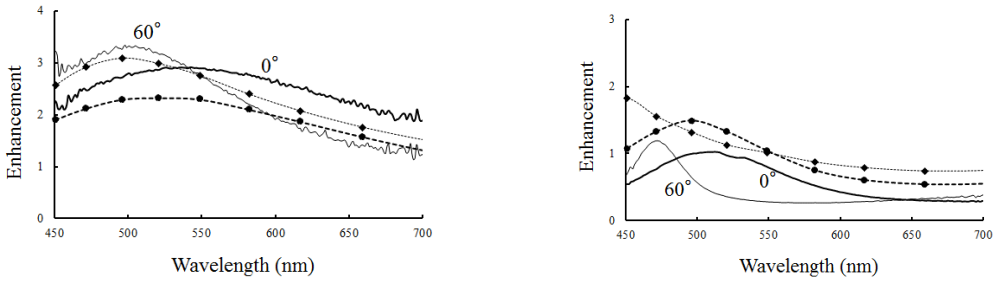

Figure 1 Experimentally observed light enhancement of Alq_3 on Ag (solid lines) and the optical interference effect (dotted lines). Circle: 0 degree and diamond: 60 degree. The thickness of Alq_3 is (a) 60 nm and (b) 200 nm.

Abstract - We report on the electromagnetic properties of a flexible dual band THz tunable metasurface able to achieve absorption coefficients and quality-factors up to 99.8% and 120, respectively. The metasurface elemental unit shape and bending capability allow for a polarization insensitive spectral response and for a resonance frequencies fine tuning. Moreover, minimum variations of non-absorbing substances refractive index up to 5×10^{-5} can be identified by using the absorber as a sensing device with detection sensitivities up to 250GHz/RIU.

Among the achievable metasurface (MS) functionalities, perfect THz absorbers emerged for their important potential applications like spectroscopic imagers, high sensitive detectors and chemical and drug sensors [1]. In particular, for these specific applications a polarization insensitive, narrow spectral bandwidth and high quality-factor (Q-factor) of the MS spectral response is essential for optimizing the device performances together with the possibility to tune the MS frequency for which perfect absorption conditions are achieved [2]. However, the main drawback for the enhancement of the MS-based device sensitivity is the low Q-factor achievable that often is unsuitable in detecting extremely small changes of the MS resonance frequency due to the presence of some specific substances close to or adsorbed on the MS. Furthermore, most of the THz absorbers reported in literature operate at fixed resonance frequencies since they are fabricated on rigid dielectric structures. In this communication, we present a novel fine frequency-tunable polarization insensitive high Q-factor dual-band THz absorber. Along the propagation direction of the electromagnetic (EM) radiation, the dual band absorber is composed from top to bottom of a 2D-array of Ag plasmonic nanoantennas (NA) elemental cells realized onto a flexible dielectric polyimide (PI) film that separates the 2D-array from an Ag ground layer covering the whole NA area. Referring to Fig.1a), the NA unit cell is composed of two concentric Ag square rings and a cylinder located at the NA geometrical center that can be realized by employing the electro-hydrodynamic jet printing technique [4]. We performed numerical simulations by using finite element method in the frequency domain to study the MS EM response in terms of the dual band resonance frequencies, the maximum achievable absorption coefficients, the frequency tunability as well as the dependence on the polarization of the impinging EM radiation. For the simulations, the 2D-array was obtained from the NA unit cell by using periodic boundary conditions along the x- and y-axes and the scattering boundary conditions along the EM wave propagation direction, i.e. the z-axis. The simulations were performed by fixing at $|E_0|$=1V/m the value of the electric field of the incident EM radiation, (x;z) the plane of incidence, and the EM properties of the metasurface have been evaluated by employing TM an TE linear polarized EM plane wave. In Fig.1b) we report the MS spectral response in the case of the TM polarization (identical results are obtained for TE polarization due to the symmetry of the NA unit cell). The absorber shows a double resonance behavior centered at f_1=1.80THz and f_2=2.26THz with absorption coefficients equal to 0.998 and 0.996, respectively. Referring to Fig.1a, the NA

geometrical parameters were chosen as L_x=100μm, L_1=85μm, L_2=50μm, d=20μm and the Ag MS film thickness was 0.2μm. The achieved Q-factors are equal to 120 and 95 for the f_1 and f_2 frequency resonances, respectively, being more than 2 times larger than those ones recently reported for a dual band MS absorber [3]. In terms of the resonance frequency bandwidth measured at full-width-half-maximum, we obtain Δf_1=15GHz and Δf_2=24GHz. Since the MS structure is flexible due to the presence of the PI layer, we investigated the possibility to tune the absorber resonances. For a variation of the NA radius-of-curvature from infinity to R=69μm of the NA unit cell, the f_2 resonance presents a blue shift of 110GHz with a 17% decrease of the Q-factor maintaining constant the absorption coefficient. Under the same conditions, the value of the f_1 resonance remain constant with an 8% and 23% decrease of the Q-factor and maximum absorption coefficient, respectively. Furthermore, we investigated the possibility of the proposed dual-band absorber MS to be used as a sensor device to measure the change of the refractive index of substances for chemical/biological applications. For this purpose, a layer of 4μm of a non-absorbing substance (i.e. an analyte) has been superimposed on top of the MS structure (i.e. adsorbed on the NA 2D-array). Fig.1c) shows the frequency shift of both f_1 and f_2 absorber resonance frequencies as a function of the variation of the refractive index of the superimposed substance. In terms of Refractive Index Unit (RIU), the resulting linear dependence allows calculating sensor detection sensitivity equal to 250GHz/RIU and 141.3GHz/RIU for f_1 and f_2 absorber resonance frequencies, respectively. Taking into account the value of Δf_1=15GHz and the resolving power Rayleigh criterion, the minimum change of the refractive index due to any kind of physical/chemical modification is equal to 5×10^{-5}.

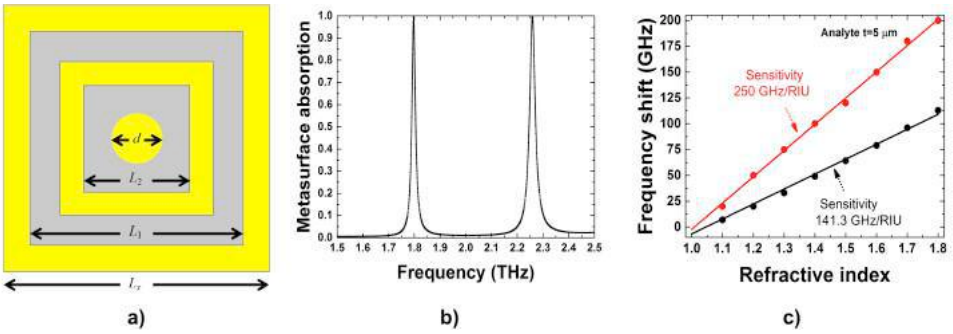

Figure 1: a) top view of the NA 2D-array metasurface unit cell; b) metasurface absorption as a function of the frequency; c) frequency shift of the f_1 (dots) and f_2 (squares) resonance frequencies as a function of the variation of the refractive index of the substance adsorbed on the MS.

Abstract-The work is devoted to the study of the novel layered heterostructures with 1D photonic crystals and magnetooptical garnet layers providing ultra-high quality factor magnetoplasmonic resonances. Such structures are specially designed to exhibit ultra-narrow resonances due to the excitation of the long-range propagating magnetoplasmon with the experimentally observed propagation distance of 50 um. Experimentally obtained FOM in such structures is up to 2200 which makes it very promising for sensing applications.

We present a novel type of magnetoplasmonic heterostructures containing one-dimentional photonic crystals and magnetooptical garnet layers. Such structures are specially designed to exhibit ultra-narrow resonances of the magnetooptical transverse Kerr effect (TMOKE) due to the excitation of the long-range propagating modes. These ultra-high quality factor resonances as well as the utilization of the magnetooptical measurements instead of the reflection ones observed in ordinary surface plasmon sensors significantly increase their sensitivity to the refractive index of the analyzed medium. Thus usage of such magnetoplasmonic heterostructures is very promising for sensing applications.

We performed the design of the magnetoplasmonic heterostructures and tuned the parameters of the structure in order to enhance the magneto-optical response via excitation of the ultalong-range propagating surface plasmon polariton mode. This structure is designed for gas sensing at the operating wavelength of 790 nm. One-dimensional photonic crystal is used to tune the impedance of the heterostructure so that the long-range propagating modes can be excited. Our sample contains 1D PC made of alternating SiO2 and Ta2O5 layers 164 nm and 119.4 nm correspondingly. PC structure is coated with a 125-nm thick ferromagnetic film of bismuth-substituted iron garnet and 8-nm thick gold film for the excitation of the SPPs.

Magnetoplasmonic sample with a thin gold film demonstrates the width of the surface plasmon resonance 0.13 deg that corresponds to the quality factor of 350. This is extremely narrow resonance for a smooth plasmonic structure with ferromagnetic since typical resonance widths in such structures are about 1 deg. Magnetooptical transversal Kerr effect related to this surface plasmon resonance has even smaller width of 0.06 deg and higher quality factor 700. This causes very high values of the structure sensitivity to the analyzed medium refractive index variation which is $1.8 \cdot 10^3$ deg/RIU.

Plasmon-Assisted Positive Photoconductance by Gold Nano-Gradient Structures

Jihye Lee[1,2], Jeong-Hyeon Kim[1,2], and Jong-Souk Yeo[1,2*]

Abstract Here, we demonstrate the electrically connected gold nano-gradient structure for investigating the positive photoconductance assisted by the plasmons. The gradient nanostructures have an optically graded colors within a visible wavelength so that the interaction of visible light and graded nanostructure shows different positive photoconductive responses depending on the coherency (coherent/incoherent) and wavelength (red, green, blue) of the incident light source. The junction of the graded nanostructure composed of carbon and gold is expected to generate hot carriers by Landau damping.

Introduction

The localized surface plasmon resonance (LSPR) occurs when the metallic nanostructure interacts with the incident light [1]. From the light-matter interaction, the conduction electrons on the surface of metallic nanostructure show the collective oscillation called surface plasmons that are defined by the geometry of the nanostructure. The excitation of surface plasmons in a nanostructure can manipulate the light so that it can be used for developing the plasmon based nanocircuit, sensing platform for bio and chemical field, and processing methods for optical information [2-4].

In order to realize the plasmon based applications, we need to understand the relationship between geometry of nanostructure and optical/electrical response depending on the characteristics of the incident light and analyze the optical-electrical transduction by the plasmon-assisted damping process. In this paper, we have fabricated the gold nano-gradient structure that is connected to the electrical contact pad with a carbon at the junction. By using this structure, we have investigated the optical and electrical responses to understand the relationship.

Results and Discussion

In figure 1 (a), the schematic of gold nano-gradient structure was shown. The types of incident light are incoherent halogen lamp and coherent laser sources. The incoherent halogen lamp has a wideband spectrum while the coherent laser sources have wavelengths of 405, 532, and 632 nm, respectively. These light sources shed light on the fabricated nanostructure as shown in Figure 1 (b). The size of the gradient nanostructure ranges from 100 nm to 600 nm. The photocurrent response from the nano-gradient structure is shown in Figure 2. The photocurrent is increased when the light source is on. Compared to the incoherent white light, the coherent sources induce different levels of photocurrent: 1.07 nA (White incoherent light), 0.78 nA (405 nm, Blue), 1.54 nA (532 nm, Green), 0.31 nA (635 nm, Red). Among them, the green light source provides a maximum photocurrent with 1.54 nA.

Conclusion

The photocurrent has shown a maximum value when the resonance condition is matched for the incident light. The excitation of hot carriers by the plasmons at

the junction of the metal and carbon is believed to affect the positive photocurrent. Further investigation and subsequent understanding of the plasmon-assisted process on the nano-gradient structure may enable the novel design of plasmon based applications.

Abstract- Gigahertz modulation of light transmitted by an extraordinary-optical-transmission (EOT) metamaterial structure is studied using optical pump-probe spectroscopy. The GHz frequency oscillations in the intensity of the transmitted light through a sample consisting of a lattice of square nano-holes in a gold film on a glass substrate are monitored experimentally. Numerical simulations of the transient deformations and strain distributions show that variations in the nano-hole area produce the dominant contribution to the GHz optical modulation.

Extraordinary optical transmission (EOT) through subwavelength-sized holes has been studied over a wide range of electromagnetic frequencies[1]. Light generally cannot go through such small apertures, but interactions with the holes allows light to be converted to surface plasmons, and to pass through more efficiently than expected on the basis of the hole area alone. This phenomenon can be used for filtering electromagnetic (EM) waves at specific wavelengths. Other potential applications are the modulation of the transmitted EM waves by electro-optic modulation (EOM) or acousto-optic modulation (AOM). Such modulations in transmission were demonstrated by combination with electronic circuits[2, 3]. Gigahertz acoustic modulation was also demonstrated: surface acoustic waves can modulate EOT in two-dimensional (2D) nano-hole arrays[4] and 1D nano-slit arrays[5], and bulk waves can modulate EOT in 1D nano-grating geometries[6]. However, quantitative analysis is lacking in the acoustic studies of 2D EOT structures. Questions remain such as how the mechanical vibrational modes excited in such structures can actually modulate the EOT. Here we report on the modulation of the transmitted intensity in a 2D EOT structure made of an array of nano-holes in a gold film on a glass substrate, and show how the GHz vibrational modes contribute to the optical modulation[7]. We conduct experiments by optical pumping and probing, and we also perform numerical simulations to elucidate the transient deformations and strain fields, which point to the hole-area modulation being the dominant effect in modulation.

The sample consists of 1 mm thick glass coated with a 40 nm gold film in which square holes (side 250 nm and pitch 710 nm) were created by electron lithography in a square lattice, as shown by the scanning electron micrograph (SEM) in the inset of Fig. 1(a). This sample shows EOT in the near-infrared region.

GHz acoustic vibrational modes in this 2D EOT structure are excited by optical pump pulses at wavelength 415 nm, and the modulation of the transmitted probe-pulse light intensity is detected at a wavelength of 770 nm. We plot in Fig. 1(a) by the dashed blue line the normalized modulus of the temporal Fourier transform (FT) of the measured transmitted intensity change. The optical pulses are delivered by two synchronized Ti:Sapphire lasers, and the orientations of the linear polarization are set perpendicular to one another and aligned along two symmetry axes of the square-hole array.

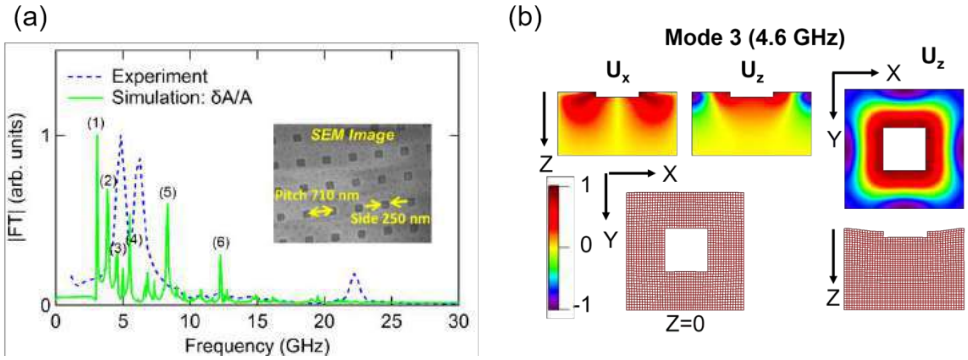

Fig 1: (a) Magnitude of the temporal FT of the experimental relative transmission intensity change (blue dashed line) and simulation of the relative hole-area modulation (green solid line). (b) Simulated deformation fields at 4.6 GHz. X and Y are in-plane coordinates, whereas Z is the out-of-plane coordinate.

We also performed numerical simulations to reveal the vibrational strain distributions in the EOT structure in order to elucidate the acoustic modulation of the transmitted light. Six vibrational modes, involving the opening and closing of the holes, could be identified from temporal Fourier transforms (FT) of the relative area change in the square-hole apertures, as shown in Fig. 1(a) by the solid green line. We show in Fig. 1(b) as an example the displacement and deformation fields for the third resonance indicated by peak (3) in Fig. 1 (a). Analysis of the average volumetric strain over the glass regions in the open holes suggests that it is the hole-modulation that provides the dominant contribution to the transmitted intensity modulation. Applications of this research include novel ultrafast acousto-optic modulators.

Steering topological surface lasers

Abstract- We demonstrated topological steering of light sources in which the phase offset to steer the beam is provided by Floquet-Bloch phase in periodic structures. It was shown that in periodic structures there exist singular states in the radiation region of the band diagram that exhibit diverging quality factor, which is useful for light source cavities. The existence of these singular states are topologically protected, and their momentum are very sensitive to any small uniform perturbations. Our experimental demonstrations open new paradigm in the implementation of light steering with applications in data communications, bio imaging and sensing.

Bound States in Continuum (BIC) introduced shown by Von Neumann and Wigner can be achieved in periodic photonic arrays above the diffraction limits where leaky out-going waves interfere destructively resulting in complete confinement of the optical mode inside the structure [1] and has been demonstrated in various passive structures [2-4]. It is possible to achieve low threshold BIC Surface Emitting Lasers (BICSEL) with small foot-prints. BIC points are topologically robust in reciprocal space, meaning that by changing some physical parameters of the cavity they can displace in the reciprocal space [5]. This topological dependence of the BIC points enables the tuning of the lasing beam direction in real space by using the same platform. Moreover, BIC points are the polarization vortex center in the reciprocal space. Basically, polarization of the surface laser operating at the BIC point is the superposition of the all neighboring polarizations making a polarization vortex in the real space.

In this work, we designed and fabricated such cavities to show tunable topological light sources that can lase with any arbitrary angle with many degrees of freedom on controlling the angle and number of the lasing beams. Fig. 1a shows the schematic of the structure, which is a PhC slab made of InGaAsP material on top of glass with PMMA resist interlayer in between and inside the holes. As depicted in the band diagram of the structure (Fig. 1b), there are three modes, with two of them double degenerate modes at Γ. All of the modes have BIC points one of which has BIC always at Γ point (symmetry protected mode) while for double degenerated modes, BIC points are off-Γ (resonantly trapped modes) and their position can be tuned by varying the radius of holes. Off-Γ BICs can move in the band diagram in such a way that they can either go toward the Γ point to annihilate or toward the Brillouin zone edges [5]. These modes can be utilized to design a PhC cavity that lases with an angle as demonstrated in the following. Fig. 2 shows the wavelength scaling by varying the radius of holes. For radii smaller than R=265nm there are one symmetry protected and two resonantly trapped BICs, while for radii larger than 265nm, the two resonantly trapped BICs annihilate and disappear. As we explained in ref. 6, the resonantly trapped mode lases first before the symmetry protected mode (band-edge mode). Therefore, below the radius of 265nm resonantly trapped modes will lase but with different pump thresholds and wavelengths while after this radius symmetry protected mode is the only mode with large quality factor and thus lases. In Fig. 2, solid points are the measurement results, which show lasing at two different wavelengths tracking BIC point along ΓX and

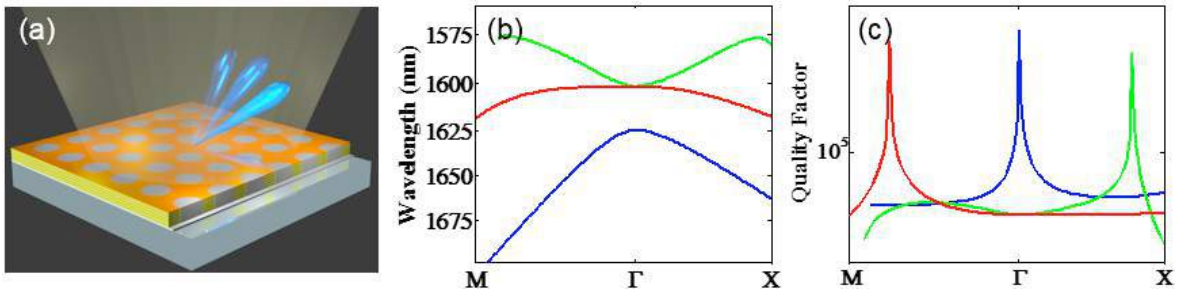

Fig. 1. a) Schematic of the laser cavity made of InGaAsP PhC slab with square lattice of holes filled by PMMA. PhC slab bonded to a glass by using PMMA interlayer and cladding is air. Thickness of the slab and the periodicity are 300 nm and 950 nm, respectively. b) Band diagram and c) quality factor of the structure shown in (a) for the radius of holes equal to 200 nm.

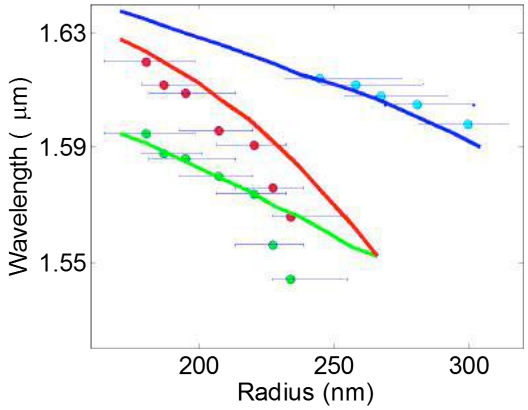

Fig. 2. Wavelength scaling of the structure shown in Fig. 1a as a function of the radius of the holes for symmetry protected and resonantly trapped modes. Solid lines are simulation results and solid points are measurement results. Horizontal lines indicating the error bars for each experimental result.

ΓM directions at smaller radii and lasing at symmetry protected mode at larger radii. We have demonstrated a new type of topological light source in periodic structures that enable steering of the lasing beam in any arbitrary directions depending on the geometrical parameters of the system. In our structure, below the radius of 265nm there are two different modes that can lase at two different lasing thresholds and wavelengths, which can easily be control by using pump power or frequency filters, while above that radius there is just the symmetry protected mode that lases. This novel topological light source opens new doors to design functional and tunable lasers.

A spectroscopic ellipsometry demonstration of ultrasharp subradiant plasmons

M. Taghinejad[1], H. Taghinejad[1], H. Moradinejad[1], A. A. Eftekhar[1], and A. Adibi[1*]
[1]School of Electrical and Computer Engineering, Georgia Institute of Technology, 778 Atlantic Drive NW, Atlanta, Georgia 30332, United States

Abstract-We numerically design and experimentally demonstrate ultra-sharp (FWHM $\approx$ 6 nm) and tunable lattice plasmon and Fano-type resonances using plasmonic nanopatch devices, where diffractive coupling of the out-of-plane electric dipoles plays a primary role. Systematic spectroscopic ellipsometry measurements reveals exotic potentials of the investigated nanopatch devices for polarization engineering and enhanced light matter interactions.

Metallic nanoresonators by leveraging the coherent oscillation of free electrons, known as the localized plasmon resonance (LPR), provide spatial resolution beyond the diffraction limit [1]. While diversity of available metals and designs allow accurate control over the spectral location of resonance in plasmonic platforms, the control over the resonance linewidth is in fact challenging. Intrinsic Ohmic loss and radiation loss are the primary effects responsible for the fast detuning and also the broad (~ 50 nm) linewidth of plasmonic resonances. A number of practical strategies for loss management in plasmonic systems have been pursued. One approach is to utilize dark subradiant plasmonic modes, featuring damped net electric-dipole that weakly radiate to far-field photons. Fano-interference is another technique to terminate radiation loss [2]. From a different perspective, lattice plasmons (LPs), owing to the simultaneous reduction of the radiative and Ohmic losses, have attracted growing attention. The LPs take advantage of in-plane dipolar coupling of the scattered light from plasmonic arrays, providing narrow resonances at wavelengths approaching inter-particle distances. This phenomenon was first reported as Wood's anomaly and was explained as the transition of grating orders from an evanescent state to a radiative state [3].

In this study, we demonstrate exceptionally narrow (FWHM $\approx$ 6 nm) lattice plasmon modes using two-dimensional nanopatch arrays (Figure 1(a)-(b)). In our approach, the z-component of the excitation electric-field (Figure 1(c)) induces out-of-plane electric-dipoles inside the nanocubes through which, the diffractive coupling of the incident light to the array becomes possible. Our angle-resolved spectroscopic ellipsometry, Figure 1(d), shows fine tuning of the LP resonance wavelength over an ~ 80 nm range, which is more than 10 times larger than the FWHM of the narrowest measured lattice mode. These modes are only achievable through TM-polarized excitations since TE-polarized light lacks out-of-plane electric-field component (Figure 1(c)). The nanopatch arrays studied here are periodic structures comprised of 30 nm-thick gold (Au) nanocubes separated from a backside Au film by an 8 nm-thick alumina (Al_2O_3) film. The interplay between the induced out-of-plane dipoles and image dipoles (formed inside the Au film) enables formation of such narrow resonances using only 30 nm-thick nanocubes. This is in sharp contrast to previous reports [4] where excitation of narrow resonances, based on out-of-plane dipoles, demands very thick (> 100 nm) metallic nanostructures.

Our utilized plasmonic nanopatch structure, owing to the large refractive index contrast at the nanopatch

edges, supports a second resonance mode (the broad resonance on the longer wavelengths) that is identified as the sub-diffraction Fabry-Pérot (FP)-like mode. In a new design, we prepare the ground for spectral proximity of the subradiant LP and the super-radiant FP modes, which leads to tunable Fano-type lineshapes through interference (Figure 2). Thanks to the polarization sensitivity of the demonstrated LP and Fano-type resonances, the proposed structure reveals great potentials for manipulation of polarization state upon reflection of light from the array. Furthermore, incorporated spacer layer into our designed device can be immediately replaced by a material of interest for various applications seeking plasmonic-enhanced light-matter interactions (e.g., plasmonic lasing and harmonic generation).

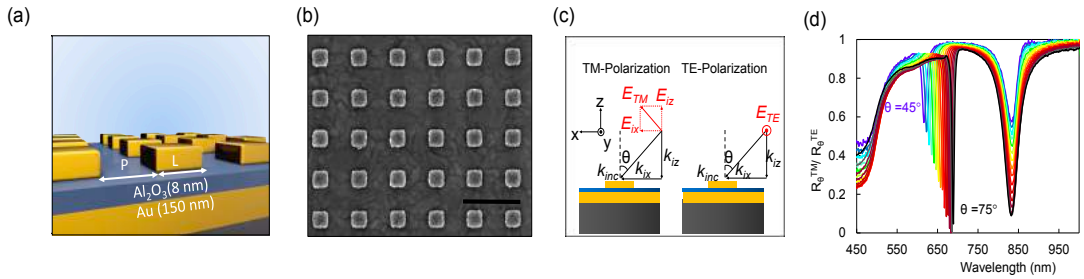

Figure 1. (a) Schematic of the plasmonic nanopatch array. (b) Representative SEM image of the fabricated two-dimensional array (L = 100 nm, P = 250 nm). (c) Designation of polarization states and electric field components of excitation light. (d) Spectroscopic ellipsometry measurements. In this panel we plot ratio of the reflection of TM-polarized light (R_θ^{TM}) to that of TE-polarized light (R_θ^{TE}) at various excitation angles (45° to 75°) with step size of 2°. The tunable and sharp resonance at the shorter wavelength and the broad resonance at longer wavelength are identified as LP and Fabry-Perot (FP) modes, respectively.

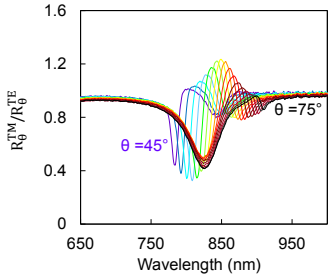

Figure 2. Demonstration of Fano-type resonance in spectroscopic ellipsometry measurements. Here, we use an array with larger period (L= 100 nm, P = 350 nm) in which the spectral vicinity of LP and FP modes allows for effective interference of the modes and generation of Fano lineshapes.

The dynamic of formation of clusters and Ag nanoparticles in colloidal system and polymer matrix

[1]Institute of Chemistry of New Materials of the NAS, Minsk, Belarus
[2] B.I. Stepanov Institute of Physics of the NAS, Minsk, Belarus
[*]corresponding author: potapov555@tut.by

Abstract- It is shown that the peak in UV-region (205-235 nm) of absorption spectrum corresponds to the scattering on clusters and nanoparticles (NPs) of Ag. For samples of sol of Ag particles at deficiency in reducing agent (0.5 % PVA) the peak at 290 nm corresponding to Ag clusters is determined. The size and dynamics of formation of clusters and Ag NPs substantially depend on such factors as UV-radiation and acoustochemical influence.

Polymer composites containing Ag NPs are of special interest for obtaining new nanostructural materials and creation of devices on their basis, thanks to the unique properties of Ag NPs.

In spite of a large number of works in this area, the dynamic of formation of clusters and Ag NPs in a colloidal system and a polymer matrix at UV-radiation and acoustochemical influence is not sufficiently studied. The purpose of present work is to determine the influence on the Ag NPs size and dynamic of their formation of such factors as UV-radiation and ultra-sound (US) treatment and also the change of the concentration of PVA – stabilizer and reducing agent for Ag particles.

Using spectroscopy in UV and visible spectral regions, atomic-force microscopy (AFM) and method of dynamic light scattering (DLS) the dynamics of Ag particles growth and their size distribution in 10 % polyvinyl alcohol (PVA) composition, PVA-film and sol are established.

Immediately after homogenization the Rayleigh scattering spectrum of PVA-composition with Ag was obtained. In our experiments we have observed the peak with λ_{max} = 233 nm caused by the scattering of UV-radiation on the clusters (~ 0.5 nm) and Ag NPs (1-10 nm). The SPR-absorption band (390-560 nm) corresponding to Ag NPs did not appear at that.

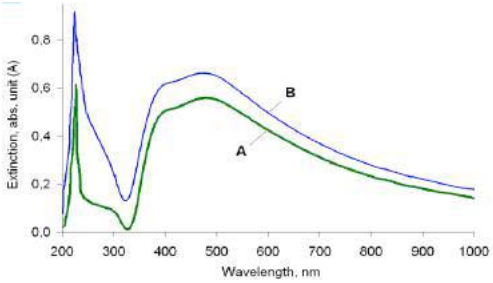

Figure 1 – Spectra of PVA-composition with Ag particles after UV-radiation.
A – UV-influence during 1 h (λ_{max} = 227 nm, A = 0.6, and λ_{max} = 470 nm, A = 0.55).
B – repeated treatment by US (during 1 h) after UV-radiation.

Acoustochemical influence causes the destruction of the clusters and Ag NPs, and the level of this destruction depends on the content of PVA in the composition. So, for example, at 10 % content of PVA under the influence of US full destruction of Ag particles takes place, and at 0.5 % – partial destruction.

After UV-radiation the formation of Ag NPs occurs and there appears deformed (asymmetric) SPR-band at

λ_{max} = 470 nm (Figure 1). The form of SPR-band indicates that the distance between NPs in PVA-composition is several tens of nanometers, i.e. electromagnetic interaction between Ag NPs becomes essential.

The additional repeated treatment by US increases SPR-absorption and, consequently, the quantity of Ag NPs. After comparison of spectra of the sample exposed to UV-radiation and the sample wherein Ag ions reduction takes place only due to PVA-matrix, it is possible to conclude that:

1) for both samples the peak of scattering and SPR-absorption band are observed;
2) SPR-absorption band (395-500 nm) is formed in the sample without UV-influence;
3) due to UV-radiation the acceleration of Ag reduction on the clusters occurs.

Dynamics of SPR-absorption growth is given in Figure 2.

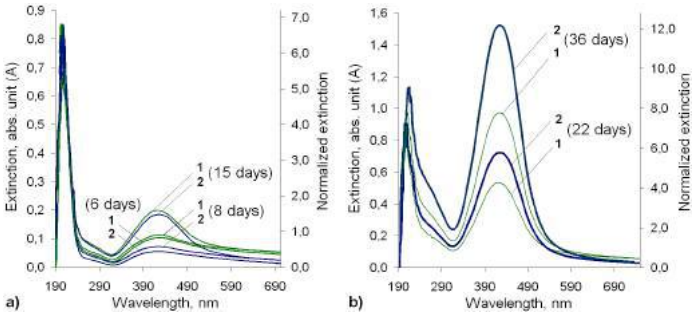

Figure 2 – Spectra of PVA-films with Ag particles after 6, 8, 15 days (a) and 22, 36 days (b). The right scale is the normalized extinction, magnification by 8 times. 1 – PVA-film with Ag after UV-US-treatment (peak of scattering with λ_{max} = 206 nm, SPR-absorption band with λ_{max} = 424 nm); 2 – PVA-film wherein the reduction of Ag^+ occurs only due to PVA-matrix.

At formation of the film Ag clusters and then NPs are intensively formed from Ag ions what is confirmed by the growth of scattering UV-peak. SPR-absorption band of PVA-film corresponding to Ag NPs with the size of 40-45 nm (λ_{max} = 424 nm) becomes symmetric, here the plasmonic absorption prevails over the scattering (Figure 2b). During first 15 days in the sample that was not subjected to UV-US-treatment the value of SPR-absorption is smaller then UV-peak, i.e. the major part of Ag is still in a form of ions (Figure 2a). But after 22 and 36 days (Figure 2b) the dynamics of growth changes, namely, the sample without treatments shows larger value of SPR-absorption. At the change of aggregate state from PVA-composition into the film the hypsochromic shift is fixed for maximum of SPR-absorption (Figures 1 and 2).

If there is not enough reducing agent (0.5 wt.% PVA), the stable sol containing the clusters and Ag NPs is obtained. The peak at 290 nm corresponds to Ag clusters. For sol sample SPR-band with maximum absorption at 490 nm corresponds to Ag NPs with average size of 80 nm. NPs size estimated by λ of SPR agrees with AFM images. According to the DLS method, the diameter of Ag NPs surrounded by ligand shell amounts to 220 nm.

Exceptional Points in Plasmonic Nanostructures

Ashok Kodigala, Thomas Lepetit, Boubacar Kanté
Department of Electrical and Computer Engineering, University of California at San Diego, La Jolla, CA 92093, USA
akodigala@eng.ucsd.edu

Abstract: We present evidence of the existence of exceptional points (EPs) in three-dimensional (3D) plasmonic nanostructures. The systems are composed of coupled plasmonic nanoresonators and can be judiciously driven to EPs by controlling symmetry-compatible modes.

Plasmonics and its applications have garnered ample attention over the years. These applications range from chemical and biological sensors to enhanced photovoltaics [1-2]. We design 3D plasmonic structures with exceptional point (EP) singularities. Exceptional Points (EPs) are singularities of open systems where at least two complex eigenmodes coalesce [3]. They manifest themselves by the simultaneous degeneracy of both resonant frequencies and linewidths. These points are highly sensitive to external perturbations as even a tiny variation will lift the degeneracy and cause splitting of both resonant frequencies and linewidths. These results make it possible to envision a highly sensitive molecular sensor.

A plasmonic system based on multiple coupled plasmonic bars, depicted in Figure 1(a), is considered. The dimensions of an individual gold bar are chosen such that the dipolar resonance falls in the optical domain at a wavelength of 1.55 μm. Placing these gold bars in close proximity hybridizes their individual plasmon modes into multiple system modes with different symmetries as shown in Figure 1(b) [4-6]. Here, the instantaneous charge profiles of each mode are depicted for a plane wave excitation with the electric field along the length of the bars. The spectral locations of these hybridized plasmon modes can be tuned by spatially shifting one bar in relation to the other two. Essentially, we break the symmetry of the overall shift-bar system by shifting one of the bars. Here, we chose to shift the middle bar by an amount 'dx'.

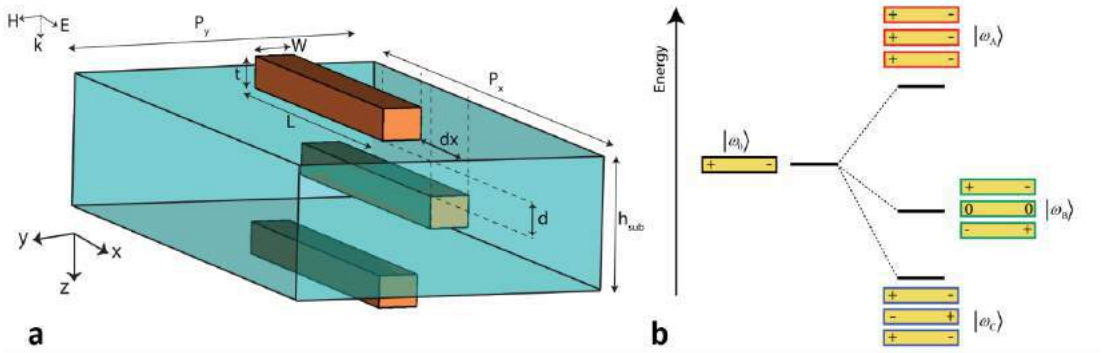

Figure 1: (a) Unit cell setup of plasmonic gold bars with a dielectric (SiO2) spacer given in blue with dimensions: L=450 nm, W=50 nm, t=40 nm, Py=400 nm, Px=800 nm, hsub, dx (variable). The gold bars are described using the Drude model with a plasma frequency (ω_p=1.367x10^{16} rad/sec) and collision frequency (ω_c=6.478x10^{13} rad/sec) based on values from Ref. [5]. (b) Energy-level diagram describing the plasmon hybridization in the shift-bar system with three modes: ω_A, ω_B, ω_C where $\omega_A > \omega_B > \omega_C$ for dx=0. ω_0 is the resonances of an individual bar.

Initially at no shift, mode A, ω_A, has charge in all the bars oscillating in-phase and mode C, ω_C, has charge in all bars oscillating out-of-phase while mode B, ω_B, has no field in the middle bar as seen in Figure 1(b). As such, mode A resides at a higher energy (higher frequency) due to all repelling forces and mode C resides at a lower energy (lower frequency) as a result of repelling forces.

We now examine the effect of shifting the middle bar in the x-direction on all three modes of the plasmonic system. As the middle bar is progressively displaced, the repelling forces associated with mode A weaken to become attractive. Similarly, the attractive forces of mode C weaken to become repulsive. Lastly, the coulomb forces associated with mode B remain constant with shift as there is no field present in the bar. This behavior is observable from the resonances of the system as seen in the figure below.

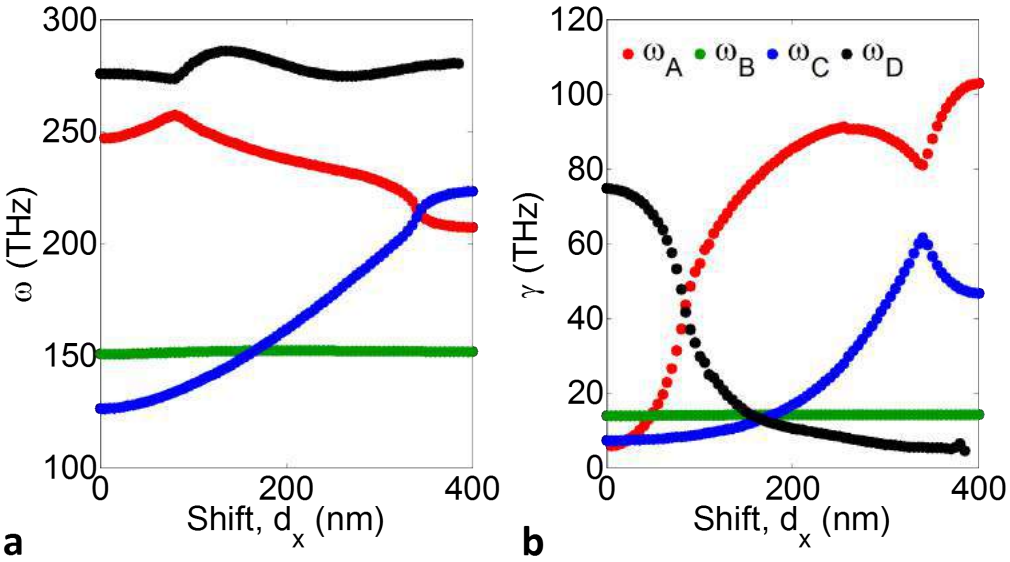

Figure 2: Resonance information in the form of complex poles extracted from scattering parameters and plotted as a function of shift dx (middle bar) (a) Resonance frequency of modes A, B, C and higher order mode D plotted as a function of shift 'dx' and their corresponding (b) linewidths. There is observable coupling between neighboring modes that share a symmetry, i.e., mode A with C at dx = 350 nm and mode A with D at dx = 80 nm. Mode B (green) is unperturbed by both the shift and neighboring modes due to its symmetry. Coupling of modes A (red) and C (blue) leads to an EP singularity where the two modes coalesce.

We see that mode A (red) moves to lower frequencies with shift and mode C (blue) moves to higher frequencies with shift, whereas mode B (green) remains unperturbed [6]. Modes of similar symmetry couple, that is, mode A couples with C at dx=350 nm and mode A with D at dx=80 nm. With additional parameter tuning, the coupling between mode A and C lead to an EP singularity where the two modes coalesce to have the same complex resonance (resonance frequency and linewidth) and eigenvectors. An EP can also be realized in systems with more plasmonic resonators.

We have demonstrated the existence of exceptional points in a three-dimensional system of coupled plasmonic nanoresonators at optical wavelengths (near-IR). Furthermore, the general approach proposed in designing EPs can be used to construct EPs of higher order in physical systems where more than two modes coalesce.

Enhancing the infrared absorption of hybrid organic–inorganic perovskites using a high-*Q* metasurfaces

Govind Dayal[1,2] and Ranjan Singh[1,2,*]

[1]Division of Physics and Applied Physics, School of Physical and Mathematical Sciences, Nanyang Technological University, 21 Nanyang Link, Singapore 637371

[2]Center for Disruptive Photonic Technologies, Division of Physics and Applied Physics, School of Physical and Mathematical Sciences, Nanyang Technological University, 21 Nanyang Link, Singapore 637371

We report on design, fabrication, and characterization of high-Q metasurfaces and their multispectral response at near infrared frequencies. The metasurfaces perforated with an array of overlapping annular and rectangular apertures support fundamental and higher order plasmonic resonances which result in high-Q response at mid-infrared frequencies. We show that spectral response of the metasurface can be tuned to a great amount by judicially engineering the hybridization of plasmon resonance in metasurfaces. We then perform the surface enhance infrared spectroscopy of PMMA and solution-processed hybrid organic–inorganic perovskites (HOIPs) with the formula CH3NH3PbI3 using high-Q metamaterial cavity. We show that infrared absorption of extremely weak vibrational modes can be enhanced using well designed high-Q resonances.

Differentiating surface waves and waveguide modes guided by interfaces with one-dimensional photonic crystals

Muhammad Faryad

Department of Physics, Lahore University of Management Sciences
Lahore 54792, Pakistan.
muhammad.faryad@lums.edu.pk

Abstract— One-dimensional photonic crystals are made of multi-layers of different dielectric materials with periodic arrangement. Such photonic crystals support surface waves at their interfaces as well as waveguide modes guided by individual constituent layers. This study examines the differences and similarities between the two types of modes. The differentiation is necessary to fully exploit the promise of photonic crystals in integrated optics.

1. SUMMARY

The interface of a one-dimensional photonic crystal (PC) and a homogeneous material supports surface waves [1, 2, 3], as shown schematically in Fig. 1. If the homogenous material is a metal, surface waves are called surface-plasmon-polariton (SPP) waves [2, 3, 4]. The surface waves are, by definition, independent of the thickness of the partnering materials on both sides of the guiding interface, beyond the critical thickness required to localize the the surface waves. In addition to the surface waves, the waveguide modes can also be guided by the planar layers in a PC, as is schematically also shown in Fig. 1. This figure shows one such waveguide, which is the most important one with respect to the surface waves that are also guided by the same metallic interface.

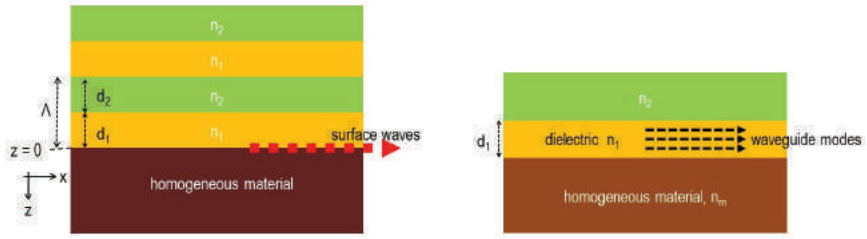

Figure 1: (Left) Schematic geometry of the metal/PC interface showing the guiding of the surface waves. (Right) Schematic geometry of the asymmetrical waveguide formed by the first layer adjacent to the homogeneous material.

The most important feature of the SPP waves guided by an interface of a metal and a one-dimensional PC is the multiplicity of the surface waves, i.e., more than SPP waves of both the *p*- and *s*-polarization states with different phase speeds, spatial profiles, and degree of localization to the metal/PC interface can be excited. This has been shown theoretically [3] and experimentally [4].

Why do we get multiple SPP waves with metal/PC interface? This work was undertaken to address this question. The hypothesis is that the waveguide effect gives rise to multiple SPP waves. As representative results, the real and imaginary parts o f the relative wavenumbers κ/k_0 of the multiple SPP waves that can be guided by the metal/PC interface are given in Fig. 2. For comparison with one set of the waveguide modes, the real and imaginary parts of the relative wavenumbers β/k_0 of the waveguide modes supported by the first layer adjacent to the metal are given in Fig. 3.

A comparison of the results in Figs. 2 and 3 shows that, except for $p1$ branch of SPP waves, all SPP-wave branches have their counterpart in the waveguide modes. Each SPP-wave branch

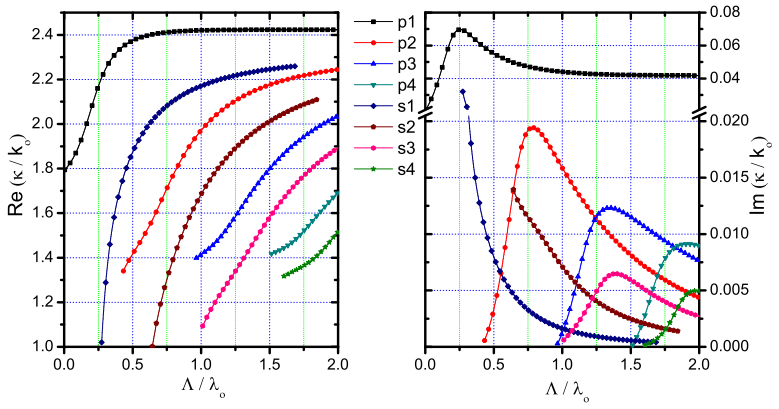

Figure 2: **SPP waves:** (left) Real and (right) imaginary of parts of the relative wavenumbers κ/k_0 of SPP waves as a function of the period $\Lambda = 2d_1 = 2d_2$ of the PC shown in Fig. 1.

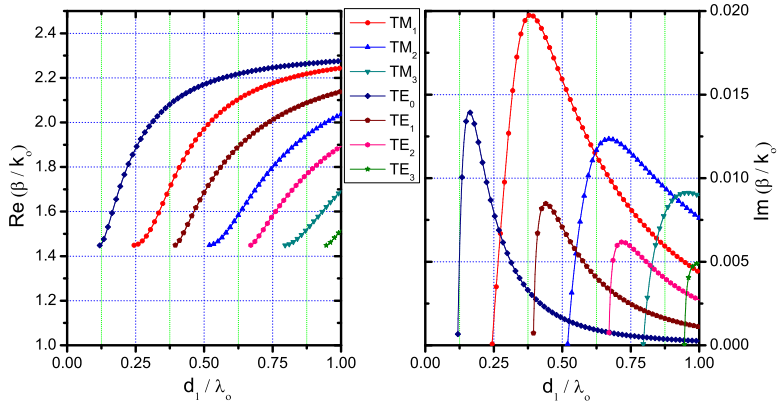

Figure 3: **Waveguide modes:** (left) Real and (right) imaginary of parts of the relative wavenumbers β/k_0 of the waveguide modes as a function of the thickness d_1 of the dielectric waveguide shown in Fig. 1.

is different from the counterpart waveguide branch for small values of d_1; however, it approaches the waveguide branch as d_1 increases. This shows that waveguide modes play a role in generating multiple SPP waves guided by the metal/PC interface. This will be further elucidated by comparing the field profiles of the SPP waves and the waveguide modes. Furthermore, this phenomenon will be explored for Tamm waves as well that guided by an interface of a PC with a homogeneous dielectric material.

Abstract— By applying power conservation law to absorption cross section, allowable scattering coefficients for any passive electromagnetic scatterers are shown in a phase diagram regardless of geometry, structures, material dispersion and extrinsic operating frequency. This phase diagram not only provides a complete information for energy assignments through radiation loss (scattering cross section) and dissipation loss (absorption cross section), but also offers a clear understanding of all possible extrinsic states. Based on this diagram, we propose a systematic method to design field-controllable devices at subwavelength scales.

In the last decades, passive receivers or scatterers with exotic phenomena have been extensively studied in various wave subjects, from electrodynamic waves, acoustic waves, to quantum matter waves. In particular, invisible cloaking, coherent perfect absorbers, and compact resonant scatterers are revealed with non-trivial scattering solutions [1, 2, 3, 4]. It is undoubted that the concepts behind these structures are relied on our understanding of scattering phenomena. In this work, we propose a phase diagram to revisit these fundamental light scattering processes, with a systematic approach to design functional scatterers.

When incident power is absorbed by passive objects, it would be non-zero in absorption cross section, i.e., $\sigma^{abs} > 0$. With this condition and applying the electromagnetic multi-pole expansions to sources-free Maxwell equation in a surrounding environment, the absorption cross section can be compactly written in an infinite series connected with complex scattering coefficients $C_n^{(TE,TM)}$,

$$\sigma_n^{abs(TE,TM)} \equiv -\frac{(2n+1)\lambda^2}{2\pi}(Re\{C_n^{(TE,TM)}\} + |C_n^{(TE,TM)}|^2) \geq 0. \tag{1}$$

Here, TE and TM represent transverse electric and transverse magnetic modes, respectively. By introducing a phasor representation for scattering coefficients $C_n^{(TE,TM)} = |C_n^{(TE,TM)}| \exp[i\theta_n^{(TE,TM)}]$, one can introduce a phase diagram for passive scatterers, defined by amplitude square and phase of scattering coefficients for each channels. Then, with the inequality shown in Eq. (1), we reveal all allowable scattering solutions $C_n^{(TE,TM)}$ in the phase diagram, i.e., the colored region illustrated in Fig. 1(a).

The finding here is to provide a complete energy information for each channels of TE and TM modes. It shows the maximum value of absorption power is bounded for each channels, corresponding to cancellation of outgoing radiation, i.e., coherent perfect absorption [4]. Another interesting result to be seen from the phase diagram is that, along the constant absorption power contour, the scattering objects could have different scattering signals. This is a useful result to manipulate a subwavelength device with a low scattering field but without sacrificing any energy absorption. In order to further control light responses based on this phase diagram, we introduce two auxiliary parameters: $\alpha_n^{(TE,TM)}$ and $\beta_n^{(TE,TM)}$, into the scattering coefficients $C_n^{(TE,TM)} = -[1 + i(\alpha_n^{(TE,TM)} + i\beta_n^{(TE,TM)})]^{-1}$, as shown in Fig. 1(b).

As the incident wavelength is much larger than optical length of scattering objects, the electrostatic approximation can always provide a good model to describe its radiation. In this scenario, the corresponding scattering coefficients for two-layered structures in a shape of sphere can be found in the analytical form:

$$\alpha_1^{(TM)} + i\beta_1^{(TM)} = \frac{3\lambda^3}{2(2\pi a)^3}\frac{2\gamma^3(1-\epsilon_s)(\epsilon_c-\epsilon_s) - (2+\epsilon_s)(\epsilon_c+2\epsilon_s)}{\gamma^3(\epsilon_s-\epsilon_c)(2\epsilon_s+1) + (1-\epsilon_s)(\epsilon_c+2\epsilon_s)}. \tag{2}$$

Here, λ is the operating wavelength, a is the size of our system, γ is the ratio of the core radius to the size of system, ϵ_s is shell permittivity, and ϵ_c is core permittivity. Once the trajectory is chosen

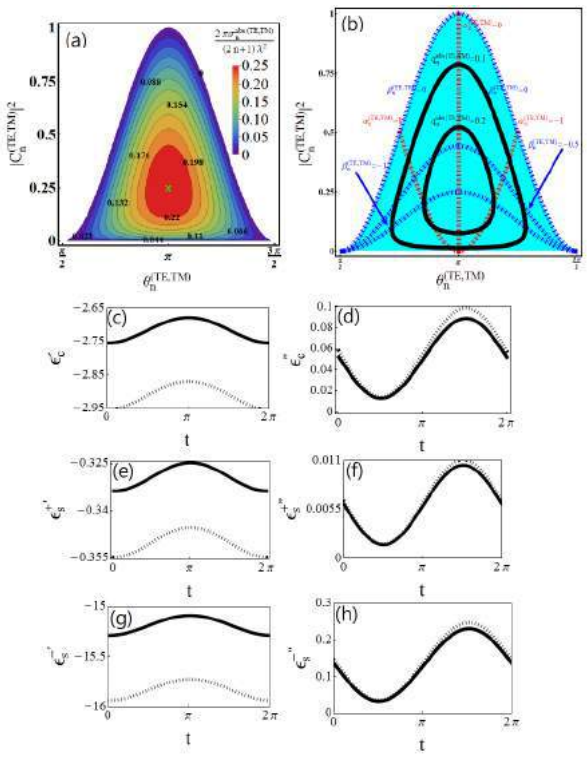

Figure 1: (a) The phase diagram for passive scatterers. The normalized absorption cross section is bounded within $[0, 0.25]$. (b) Trajectories illustrated by two auxiliary parameters $\alpha_n^{(TE,TM)}$ and $\beta_n^{(TE,TM)}$. Here, the black-curves represent constant absorption powers. (c-h) The corresponding dielectric constants to satisfy a given radiation response [5]. Solid curves are obtained from analytical solutions. Dashed curves are obtained from numerical calculation of exact Mie theory. Parameters used are: (c-d), $\epsilon_s = 3.12$, $a = \lambda/24$ and $\gamma = 0.9$; (e-h), $\epsilon_c = 5$, $a = \lambda/24$ and $\gamma = 0.9$.

from the colored region in our phase diagram, the corresponding material parameters, ϵ_s and ϵ_c, can be easily traced back through Eq. (2), which support the required scattering responses, see Fig. 1 (c-h) [5]. Based on phase diagram, our proposed architecture provides a compact way to design devices with required field responses. Obviously, the phase diagram would largely simplify the complicated light scattering phenomena.

In summary, we introduce a phase diagram as a compact tool to link the scattering and absorption powers for each channel. With the supported trajectories in the phase diagram, we reveal a systematic way to find out a variety of solutions in the composited materials to possess the same absorption power.

Silver nanoparticles with many sharp apexes and edges as efficient nanoresonators for shell-isolated nanoparticle-enhanced Raman spectroscopy.

K. Kołątaj[1*], J.Krajczewski[1], and A. Kudelski[1]
[1]University of Warsaw, Poland
[*]corresponding author: kkolataj@chem.uw.edu.pl

Abstract- One of the tools which is used for investigations of various interfaces, especially in the *in situ* conditions, is shell-isolated nanoparticle-enhanced Raman spectroscopy – SHINERS. In this contribution we tested decahedral and prismatic silver nanoparticles containing a large number of sharp apexes and edges as nanoresonators in SERS and SHINERS measurements. We found that the SERS enhancement factors obtained in the experiments with such anisotropic nanoparticles are *ca.* one order of magnitude larger than in similar experiments with spherical nanostructures.

SHINERS measurements were introduced by Tian et al. in 2010 as the new approach to analyze various surfaces[1]. In this method Raman spectrum was measured from an investigated substrate covered with gold nanopartciles protected by a thin layer of silica or alumina. Gold nanoparticles act as electromagnetic nanoresonators, significantly enhancing electric field of the incident electromagnetic radiation and hence leading to large increase of the Raman signal from studied surface. The inert shell separates metal cores from direct contact with probed molecules and keeps them from agglomeration. Therefore, such systems might find more analytical applications, also for living cells.

In this work, we report the synthesis of decahedral and prismatic silver nanoparticles with silica layer which are very new type of SHINERS nanoresonators with many sharp apexes and edges. We also show their application for Raman studies of some molecules and yeast cells.

To synthesize decahedral and prismatic silver nanoparticles we used methods developed by Kitaev et al. and Mirkin et al. respectively [2,3]. Obtained nanoparticles had mainly decahedral or prismatic shape with average size of 43 and 49 nm respectively. To create silica layer on obtained nanoresonators we used method developed by Mirkin et al. [3].

To compare decahedral and prismatic nanoparticles with spherical nanoresonators we carried out Raman measurements for monolayers of 4–mercaptobenzoic acid (PMBA) deposited on Pt and covered with various nanoresonators (see Fig. 1). As can be seen from Figure 1, nanoparticles with sharp edges enhance Raman signal about one order of magnitude more effectively than spherical nanoresonators.

Decahedral-Ag@SiO_2 nanoparticles have been tested in SHINERS measurements of monolayers of PMBA on Pt and in measurements of model biological samples. Figure 2 shows Raman spectra of *Saccharomyces boulardii* (yeast) cells before and after deposition of decahedral-Ag@SiO_2 nanoparticles. As can be seen in this Figure, in the Raman spectrum recorded with the decahedral-Ag@SiO_2 nanoparticles many Raman bands (e.g., at 1135, 1315, 1346, 1456, 1611, 1665 cm^{-1}) can be clearly identified, whereas in a case of the Raman spectrum recorded without nanoresonators it is very hard to distinguish these bands from the noise.

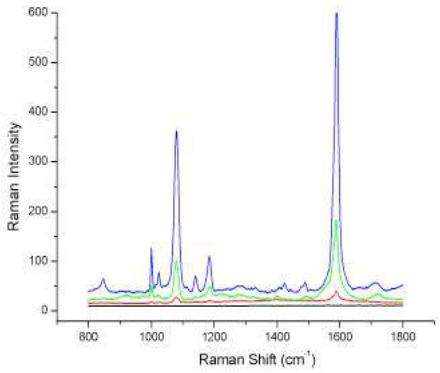

Figure 1. *Raman spectra of monolayer of 4-mercaptobenzoic acid on the platinum surface before deposition of silver nanoparticles (black line) and covered with the spherical (red curve), decahedral (green curve) and prismatic nanoparticles (blue line).*

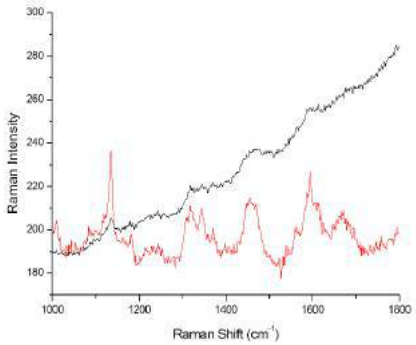

Figure 2. *Raman spectra of Saccharomyces boulardii cells without nanoparticles (black curve) and after addition of decahedral-Ag@SiO_2 nanoparticles (red curve).*

Abstract - The interaction of slow surface plasmon polariton waves of far-infrared regime with an electric current induced in the graphene deposited on the boundary between a semiconductor film and dielectric substrate is investigated. It is shown that under the phase matching condition, when phase velocity of a surface plasmon polaritons approaches the drift velocity of charge carriers in graphene, a surface wave can be substantially enhanced by the drift current in graphene.

A surface plasmon polariton in planar structures is an electromagnetic excitation that propagates along the surface of conducting and dielectric media. In contrast to optical beams propagating in three dimensions, surface plasmon polariton is a surface electromagnetic wave, whose electromagnetic field decays exponentially with increasing distance from the interface into each medium. However, ohmic losses are inherent to all plasmonic structures so that further development of integrated plasmonics requires implementation of efficient loss compensation techniques and amplification of surface plasmon polariton waves.

In this work we propose a surface plasmon polariton amplification mechanism due to energy transfer from an electron drift current wave propagating in graphene into a far-infrared slow surface electromagnetic wave propagating along a semiconductor-dielectric boundary in waveguide geometry. A necessary condition of the interaction of these waves is phase matching condition, when the phase velocity of the surface wave approaches the drift velocity of charge carriers in graphene. The current in graphene can be considered to be localized at the interface of the media, which also provides an effective interaction of drift current and a surface wave. It is shown that in the spectral region of the surface plasmon polariton slowing-down its amplification coefficient can reach values substantially exceeding the ohmic loss coefficient of the surface wave in the structure (shown by the color area in Fig.). Moreover, the amplification coefficient can be varied with the applied voltage through the change of the drift velocity.

Abstract - The evolution of intensive surface plasmon polariton waves in a metal film-dielectric substrate structure is investigated taking into account absorption properties of metal. The transformation of slightly modulated plasmon polariton wave into a sequence of surface pulses due to modulation instability effect in a structure with amplification is demonstrated.

In this work, the model of modulation instability (MI) of an intensive surface plasmon polariton (SPP) wave in a thin metal film with Kerr nonlinearity is developed. The main feature of this model is that some spatial harmonic perturbations of the SPP wave can be unstable due to the nonlinear optical properties of metal film. Under the influence of MI, the initially weak perturbations grow quickly in time leading to spatial redistribution and longitudinal localization of the SPP energy on the subwavelength scale. However, losses in metal play an important role in plasmonic processes and can lead to reducing of nonlinear effects manifestation. Results of our numerical simulation confirm the necessity for loss compensation and amplification of SPP waves in structure.

The dielectric substrate is considered to be active, which provides enough gain to compensate for the losses in the metal. For this case it is shown that during a time interval of a few picoseconds the modulated SPP wave is transformed into a train of pulses due to nonlinear effects. In the case of the film thickness of 10 nm the pulsation frequency equals 0.2 THz, the duration of each pulse is less than 0.5 ps (Fig. 1). One can see that the time period of SPP wave evolution is picoseconds, and at certain moments the local intensity increases several times in comparison with the initial SPP wave (10^{-2} W/m^2).

This work was supported by the Ministry of Education and Science of the Russian Federation (Project 14.Z50.31.0015, State Contracts 3.3889.2017, 3.5698.2017/П220), RFBR (Project 17-02-01382).

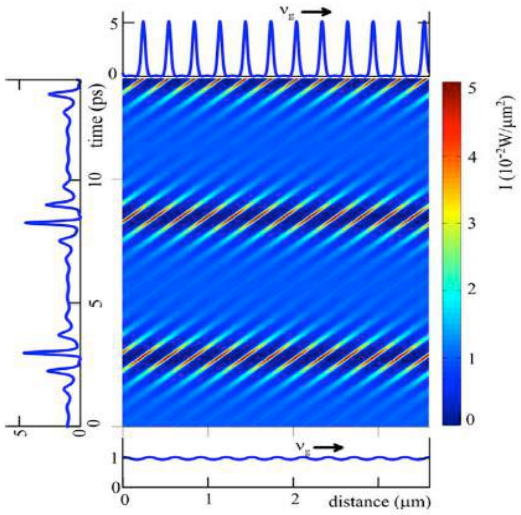

Fig. 1. Evolution of the SPP wave intensity in silver film of thickness 10 nm under condition of loss compensation; the initial wave (at $t = 0$), modulated along x-coordinate (in bottom), time dynamics of the wave intensity at $x = 0$ (left), spatial distribution of the SPP intensity (top) at $t = 14 ps$. The period of the spatial modulation approximately corresponds to the maximum of the modulation instability gain.

Nonlinear Optical Responses under Weak Excitation Regime from Embedded Quantum Dots in Semiconductors Covered by Plasmonic Metasurfaces

Masanobu Iwanaga*, **Takaaki Mano**, **and Naoki Ikeda**

National Institute for Materials Science (NIMS), 1-1 Namiki, Tsukuba 305-0044, Japan

Abstract— We fabricated an optimized plasmonic metasurface on bulk semiconductor of GaAs to improve extraction efficiency of photoluminescence (PL) emitted from embedded quantum dots. We found that the PL intensity is approximately square to the excitation power even under weak excitation conditions. The metal-semiconductor system is an essentially nonlinear system, suggesting the potential for high-performance plasmon-merged semiconductor devices.

Plasmonic resonances have been expected to realize significantly enhancing effects for various materials for a few decades. Still, the definite success has been limited to a small number of cases such as enhancements for optical signals (i.e., fluorescence and Raman scattering) from molecules placed properly on plasmonic metasurfaces [1–6] and thresholdless plasmonic nanolasers [7].

We have explored metal-semiconductor systems, in which plasmonic metasurfaces were designed on bulk II-VI semiconductors including quantum dots (QDs) in order to improve extraction of the photoluminescence (PL). Figure 1(a) illustrates a plasmonic metasurface on bulk GaAs. The metasurface is fabricated on the top and comprises a single layer of square hole array. The thickness of Au was 35 nm. As an adhesion layer, Ti of 1 nm thickness was inserted between the Au and GaAs.

Figure 1(b) shows a typical measured PL spectrum at room temperature through the metasurface. The periodicity was set to 250 nm in order to tune the resonance to the peak of PL spectrum. The plasmonic resonance appears as reflectance (R) dip at 910 nm. The PL spectrum is shown with a red solid curve and the R spectra at the normal incidence is shown with a black dashed curve. The PL comes from InAs QDs embedded in GaAs at depth of 50 nm from the outmost surface, as indicated by red dotted lines in Fig. 1(a). Note that a scattered laser line appeared at 1064 nm, which was double to the incident wavelength of 532 nm. The incidence was emitted by a single-mode continuous-wave laser.

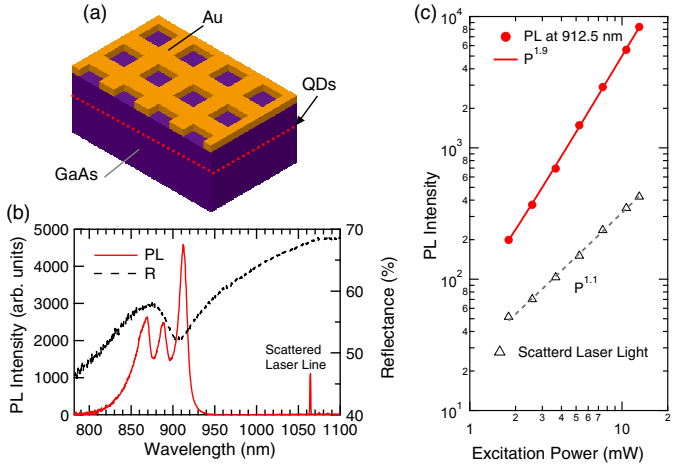

Figure 1: (a) Schematic of on-top Au plasmonic metasurface covering on bulk GaAs, in which QDs are grown at 50-nm depth, indicated by red dotted line. (b) Measured PL and R spectra, shown with red and black dashed curves, respectively. (c) Dependence of the PL intensity at 912.5 nm on the mW-order excitation power.

Figure 1(c) shows excitation-power dependence of the PL peak at 912.5 nm (red dots) and the scattered laser line (gray open triangles). The excitation power was varied in mW order and quite weak. However, the PL-peak intensity is proportional to $P^{1.9}$ (P: excitation power) and approximately square of P. In contrast, the scattered laser line exhibits almost linear response. Thus, we experimentally found unconventional superlinear optical responses from the QDs even under weak excitation. We will discuss the mechanism considering plasmonic hot-electron contributions to the PL processes.

In conclusion, we experimentally found that the metal-semiconductor merged systems incorporating the plasmonic metasurfaces form nonlinear systems even under the weak excitation regime. This result implies that well-designed metal-semiconductor systems substantially improve electronic processes in optoelectronic semiconductors, opening a new route to attain plasmon-assisted high-performance semiconductor devices.

Abstract- Artificial subwavelength structures exhibiting multiple resonances in the visible range, known as color filters, are widely used in color printing beyond diffraction limit and color displays. Here, we propose a new reflective color filter structure comprising of a triangle periodic array of cross-shaped aluminum nanorods with various angles of rotation symmetry. Flexible tunability of color in wide color gamut is demonstrated on the device by changing the incident polarization.

Metamaterials for color generation has recently drawn great of interest for sub-wavelength printing and new generation display due to the ability to overcome wavelength diffraction limit and reduce complexity of multiple color printing processes [1]. Plasmonic resonances on metallic nanostructures are normally used to realize color filters such as plasmonic transmission color filters, including additive color filters and subtractive color filters. More recently, reflection color filters are promising due to its potential applications and advantages of angular insensitivity and energy saving [2]. However, reflection type of plasmonic color filter have shown color gamut not enough to illustrate vivid red, blue, and green color. Recently, a number of approaches have been explored to find out new plasmonic nanostructure for improving color performance [3-4]. Here, we propose a new approach to achieve wide color distribution based on new tunable reflection type nanostructure. The device consists of a Al_2O_3 dielectric layer sandwiched by a triangular periodic array of cross-shaped aluminum nanorods at the top layer and a bottom reflector layer as depicted in Fig. 1a. The color can be actively controlled by rotating the incident polarization or rotating the cross-shaped nanorod unit as shown in Fig. 1b. By changing angle of incident polarization and nanorods, together with the lattice period and length of nanorods, we can achieve wide color gamut at CIE 1931 diagram as demonstrated in Fig. 1c, which is wider than the one recently reported in [5].

In summary, we propose a new design of plasmonic color filter, fabricate and demonstrate its color tunability according to the incident polarization and angle of rotation symmetry of each cross-shaped nanorod.

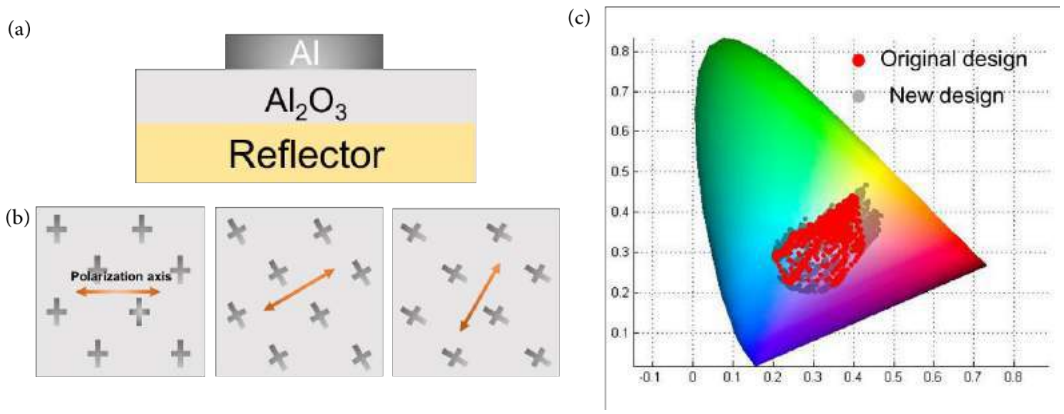

Figure 1. (a) Cross section of the proposed nanostructure. (b) Top view of the nanostructure with incident light axis. (c) CIE 1931 color space of structure published in [6] and in our new design [6].

Abstract-Loss compensation by optical gain in semiconductor media is a promising solution to the problem of high intrinsic losses in nanoscale plasmonic structures. However, any realization of the surface plasmon amplification scheme is unavoidably associated with the heat generation problem. The stronger the pump, the higher heat generation. Here, we estimate the lower bound to the heat generation rate, suggest possible thermal management solutions and discuss limits of plasmonic circuitry.

Plasmonics offers outstanding opportunities for light manipulation at the subwavelength scale, which enables the realization of densely integrated optical circuits for on-chip communication (Fig. 1a). However, due to strong absorption in metal, optical signals in plasmonic structures suffer from strong attenuation. There is a well-known tradeoff between the propagation distance and mode confinement for plasmonic waveguide structures [1]. The use of a gain medium allows to go beyond this general law and greatly increase the propagation distance in deep-subwavelength plasmonic structures with strong field confinement. Loss compensation can be implemented by placing an optically [2] or electrically [3,4] pumped gain medium near the metal surface and ensuring a high overlap with the electric field of the SPP mode (Fig. 1b). The SPP power dissipated due to the propagation losses is resupplied by stimulated emission in the gain medium. However, only a part of the pump energy, transmitted to the gain medium, is transformed into SPP signal, while the rest is radiated to free space and into plasmonic modes, or, which is worse, is converted into heat. Absorption of SPP in metal also contributes to heat generation (Fig. 1c). High heat generation power increases the temperature of the chip, which reduces the energy efficiency of the pumping scheme and can potentially destroy the device.

In this work, we discuss a lower bound to the heat generation rate associated with the amplification scheme, which can guarantee lossless SPP guiding [5]. Due to the high optical gain required for loss compensation in plasmonic nanostructures with strong mode confinement, we limit our consideration to the semiconductor gain medium, which is believed to be the best choice for such devices [6]. The contributions to the heat generation rate can be separated into two groups. The first group is associated with the imperfections of the compensation scheme, while the second is inherent to any plasmonic structure with gain. This second group includes heating due to nonradiative recombination in the inversely populated semiconductor and SPP absorption in metal, which cannot be reduced by improving the amplification scheme. We evaluate the minimum possible heating power produced by plasmonic components with gain and its dependence on the operating light wavelength. These results are then used to find limitations on the maximum integration density of plasmonic components and on other characteristics of plasmonic circuits.

Abstract- In the contribution the plasmon resonances of mid-IR antennas fabricated on an absorbing silicon-rich oxinitride substrate and their utilization for spatially localized absorption enhancement of electromagnetic radiation in this substrate will be discussed. The conclusions of this contribution are also applicable for other spectral regions where the materials exhibit strong absorption resonances, for instance in the visible.

It has been demonstrated that interesting phenomena occur if the antennas interact through their near fields with nearby dielectrics possessing absorption peaks or bands at specific wavelengths. This is known from a series of works dealing for instance with intuitive models based on coupled molecular and plasmonic resonators predicting new effects such as the transition between electromagnetically induced transparency (EIT) and enhanced absorption [1].

We will report on the surface plasmon resonances of mid-infrared Au antennas deposited on an absorbing silicon-rich oxinitride (SRON) layer [2], and on their utilization for enhancement of a spatially localized absorption of IR radiation in SRON. The antenna resonances were determined from far-field IR reflection spectra measured over a broad mid-IR range. Due to a strong coupling of localized surface plasmons with vibration modes (optical phonons) in SRON these spectra generally show up Rabi splitting which results in two hybrid branches of resonance wavelengths scaling nonlinearly with the antenna arm length (Fig. 1 left). The corresponding electric field distribution is shown in Fig. 1 right. To maximize spatially localized energy absorption in SRON, a compromise wavelength between that one related to optimum antenna resonances and the SRON absorption wavelengths must be chosen. We stress that the principles of this method can be utilized in other dielectric or semiconductor materials strongly absorbing in the mid-IR range, and, more generally, in other spectral regions, including the visible (e.g. due to excitons). Hence, in addition to the spatially localized heating the principles can be exploited in optimization of the efficiency of IR and light detectors, solar cells, biosensors and other applications.

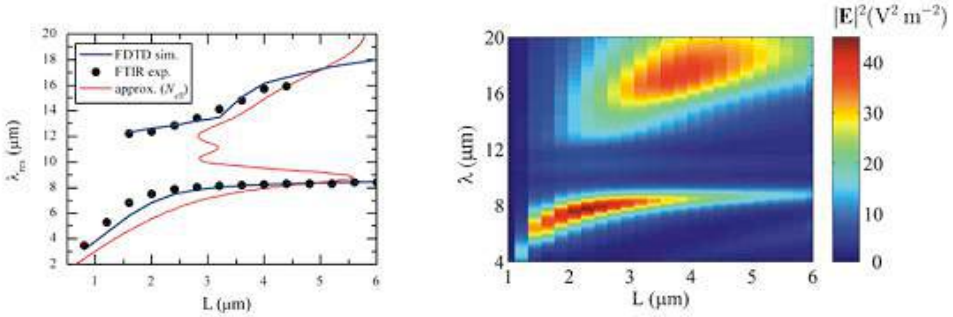

Figure 1: Left: Resonance wavelengths vs. antenna arm lengths (L). The red curve is yielded by the analytical formula $\lambda_{res} = n_{SRON}(\lambda_{res})2L$. Right: The simulated spectra of the square of electric field ($|E|^2$) (V^2m^{-2}) averaged over a domain (with dimensions 1.2 μm x 1 μm x 110 nm) in SRON beneath the antenna gap for different antenna arm lengths.

Plasmofluidic assembly of nanometallic structures: from single-molecule SERS to dynamic lithography

Partha Pratim Patra, Junsuk Rho
Department of Mechanical Engineering, POSTECH, South Korea
ppptra@gmail.com

Sub-wavelength control and manipulation of light is one of the most desirable issues in science and technology. To destine this, surface plasmon polariton (SPP) plays a significant role and to harness SPP, the nanometallic architectures have unprecedented ability to concentrate and transport light. The sophisticated and versatile applications of SPPs mostly rely on the geometry and the arrangement of the nanostructures. Thus innovative 'preparation and assembly' of nanometallic architectures is crucial. Especially, by assembling the nanostructures in a controlled way, one can deploy the plasmon-coupling for subtle modulation of light wave. Recently, the assembly of nanostructures has opened up a promising field of research which is directly linked to many other important subjects, e.g. biophotonic sensing, metamaterials, optical nanoscopy, thermoplasmonics, nonlinear plasmonics, photovoltaics, catalysis etc.

Herein we present how to harness plasmofluidic field (plasmonic field in fluid) to create efficient electromagnetic hot-spots by assembling colloidal nanoparticles to detect single-molecule SERS signals[1]. Also we shall discuss how the extension of this technique can lead to a preamble of reconfigurable dynamic lithography of plasmonic nanostructures at metal-fluid interface[2].

An in situ strategy to synthesis of plasmonic gold NPs by using plasmonic molybdenum oxide

M. Hosseini[1], **M. Ranjbar**[1*]

Isfahan University of Technology, Isfahan, Iran
[*]corresponding author: ranjbar@cc.iut.ac.ir

Abstract- The reduction of $HAuCl_4$ by molybdenum oxide nanoparticles synthesized via a simple electrochemical anodizing of molybdenum is investigated. By mixing colloidal plasmonic molybdenum oxide with $HAuCl_4$ aqueous solution, the mixed turned to a red-wine color with pronounce SPR properties. By using different analysis involving, X-ray diffraction (XRD), transmission electron microscope (TEM), X-ray photoelectron spectroscopy (XPS), furrier transformed infrared (FTIR) spectroscopy, cyclic voltammetry, and UV-Vis spectroscopy the colloidal nanoparticles of Au/MoO_x be characterized.

Gold and molybdenum oxide belong to material category with plasmonic behavior especially when they are prepared in nanoscale dimensions like colloidal suspensions. Plasmonic nanoparticles show pronounced interactions with visible light caused by collective excitations of conduction electrons [1]. The unique property of localized surface plasmon (LSPR) of nanoparticles is the mystery of its novel development in many applications such as optical sensing [2], photocatalytic [3] and solar energy devices [4].

To obtain composites of gold-metal oxide different synthesis technique are employed such as co-precipitation or deposition-precipitation of gold salt and support metal precursors in the presence of some stabilizing materials and reducing agents [4]. In more cases, removal of these stabilizers and ligand substances can be achieved using thermal and oxidative approaches, while it causes unpleasant changes in the size, shape and crystality of nanoparticles. Comparing with thermal decomposition of gold salt [5], reducing noble metal on a semiconductor substrates directly without any foreign reducing agents and stabilizing molecules, can lead to nanostructures with considerably enhanced activity [6]. This paper reports the reduction of $HAuCl_4$ by blue molybdenum oxide nanosheets, synthesized via a facile electrochemical anodizing of molybdenum. Mixing the colloidal blue molybdenum oxide with $HAuCl_4$ aqueous solution in various molar ratio causes reduction of gold salt into gold nanoparticles. To preparing different MoO_x:$HAuCl_4$ ratios (10:1, 20:1, 30:1 and 40:1), various amount of colloidal blue molybdenum oxide were added drop by drop into 20ml of $HAuCl_4$ aqueous solution. We characterized samples by different conventional techniques including UV–Vis spectrometry, XRD, TEM, XPS, FTIR and cyclic voltammetry.

Fig.1 shows the optical absorption spectra of the initial blue molybdenum oxide suspension and the $HAuCl_4$ solution. The former one displays an optical absorption band in the range of 400–1100 nm. This absorption band is the known characteristic plasmonic peak of molybdenum oxide containing oxygen deficiency [7]. After addition of $HAuCl_4$ solution into the blue molybdenum oxide, the existing blue color gradually disappears due to oxidation of molybdenum oxide and at the same time, the suspension transforms into a pink color due to formation of gold NPs. Optical absorption spectra revealed that localized surface plasmon (LSPR) resonance peak of gold arises after mixing and, depending on Mo:Au ratio, the absorption peak of blue MoO_x decline. At

the same time, optical band gap of molybdenum oxide increases by Au concentration indicating oxidation of blue MoO_x. Moreover, a significant shift in the location of one or two absorption peaks of molybdenum oxide was observed which is attributed to the plasmonic behavior. For most of samples, a red shift for gold LSPR was also observed when blue molybdenum oxide concentration is high due to its upper refraction index comparing with that of MoO_3. XPS, FTIR and cyclic voltametery showed that Mo oxidation state in blue molybdenum oxide colloids is mainly Mo^{5+} and mixing with gold salt leads to formation of Mo^{6+} states.

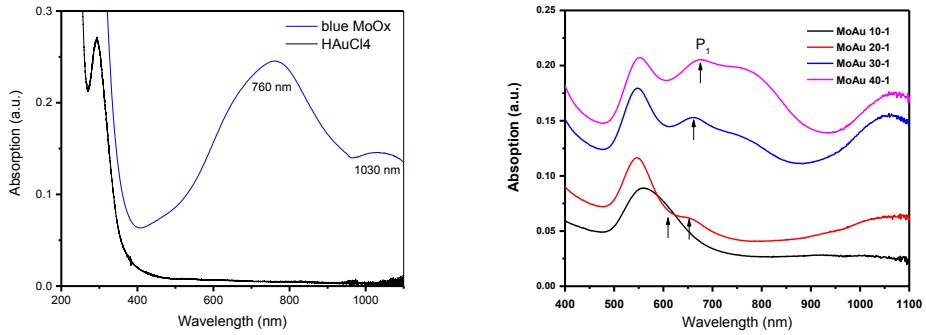

Figure 1: The optical absorption spectra of the initial blue MoOx suspension, the $HAuCl_4$ solution and different concentrations of Mo:Au ratio.

Abstract

A near-zero refractive index design based on hyperbolic metamaterials operating in the visible regime is proposed. The structure is composed of a metal-dielectric multilayer, where the dielectric constants are opposite in order to tune the design for a specific wavelength and purpose. The near zero refractive index is designed to be within the visible range.

1. Introduction

Hyperbolic metamaterials (HMM) [1,2] have been implemented in the design and investigation of wave propagation behavior. They are anisotropic media created from structures including multilayer stacks, nanorods and hyperlenses. A similar anisotropic structure has achieved negative refraction in the ultraviolet region [3] using different design methods. Theoretically, similar negative refractive media, and even collimators, could be created systematically using a HMM approach. A considerable challenge arises in bringing HMMs to the visible range. Optical metamaterials have been fabricated using common materials, such as TiO_2 and Ag [4], but with very low transmission. The goal becomes finding materials with special properties that improve transmission and reduce loss from reflection and absorption through careful consideration of desired optical properties and tradeoffs.

2. Research methods

Having epsilon near zero can influence the refractive of the structure to index near zero behavior [5]. The assumptions made in obtaining near zero index in the optical regime is that permeability is unity and a permittivity of zero, or epsilon near zero (ENZ), will carry the most weight in affecting the refractive index of the entire structure.

$$n = \sqrt{\varepsilon\,\mu} \qquad (1)$$

2.1. Proposed potential materials

Designing a metamaterial stack involves using two alternately layered materials with dielectric constants of opposite signs. An ideal pair would have their dielectric functions change at a similar rate across a large band of wavelengths. Available materials in the visible range do not share this quality and must be designed for a narrow bandwidth.

A plasmonic material should be chosen based on its complex dielectric constant. The real part should have a negative value that remains fairly close to zero depending on the wavelength. A few noble metals that are commonly used as conductors have potential. With an increasing wavelength, however, their dielectric constant may drop too low to be effective. This factor limits how far the metamaterial can go from the ultraviolet range into the visible range.

The imaginary part, or loss, of the dielectric constant should be even closer to zero than its real part. Some noble metals and transparent conducting oxides (TCO) have low dielectric loss, but TCOs maintain a positive real dielectric constant in the visible range disqualifying them as plasmonic materials. Compared to other metals, silver has a low dielectric loss. Despite its high dielectric constant, it is the best candidate for a plasmonic material.

A third option for plasmonic materials would be to use nitrides such as HfN, ZrN and TiN [6,7]. Studies into these materials show their real dielectric constant becomes negative halfway through the visible range from green to red. They may act as possible substitutes for noble metals at higher wavelengths, but available nitrides also have high dielectric loss. If this value is too high, they won't produce metamaterial properties. Individual research would be required to understand changes to the dielectric constant of nitrides based on multiple variables presented during different deposition methods.

The real dielectric constant of the dielectric material should be positive and start at a value slightly higher than the magnitude of the dielectric constant of the plasmonic material at the chosen wavelength. This ensures that the HMM remains a Type I HMM and allows the wave to propagate through like an insulator [8]. Similar to plasmonic materials, dielectric materials should have a loss that is very close to zero. Most losses of suitable dielectrics will have values in the micro range.

There is a point where the Type I HMM becomes a Type II HMM as the wavelength increases [2], characterizing HMMs as band pass filters. This crossover occurs when the real dielectric constants of both the plasmonic and dielectric materials are equal, ignoring sign. As a Type II, the metamaterial takes on metallic properties, reflecting a larger amount of light.

2.2. Structure design

With silver having the lowest dielectric loss of metals for optical applications, it is chosen as the plasmonic material. This is confirmed from plotting the reflectance, transmittance and absorptance of four metals with the same thickness of 50 nm in Fig. 1 at an incident angle of 0°.

The alternating layers create a structure with anisotropic properties. Effect Medium Theory is used to obtain the components of permittivity in anisotropic medium [8]. Parallel permittivity is used for x and y components or the ordinary components in a uniaxial crystal and perpendicular permittivity for the z component or the extraordinary component.

$$\varepsilon_{\parallel} = \frac{\varepsilon_1^d L_d + \varepsilon_1^m L_m}{L_d + L_m} \tag{2}$$

$$\varepsilon_{\perp} = \frac{\varepsilon_1^d \varepsilon_1^m (L_d + L_m)}{L_d \varepsilon_1^m + L_m \varepsilon_1^d} \tag{3}$$

Equation (2) provides the fill fraction of plasmonic material by setting epsilon parallel equal to zero and one of the thicknesses as a constant in nanometers and solving for the other thickness. The fill fraction is the ratio of the thickness of a layer of plasmonic material compared to the total thickness of one pair of different layers. It is also taken as the sum of thicknesses of all plasmonic layers per total thickness of the stack.

Using a generalized version of Snell's law for anisotropy, the refractive is found using Equation (4),

$$n = \sqrt{\varepsilon_{\parallel} \varepsilon_{\perp}} \tag{4}$$

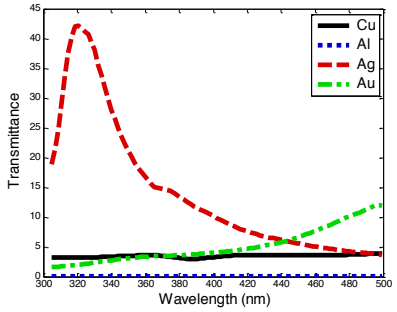
where n is the refractive index of the stack [1,2,8,9]. Instead, a set of equations to solve for the angle of refraction θ for the extraordinary angle of incidence [10],

$$\theta_e = \arcsin\left[n_i \sin(\theta_i) \sqrt{\frac{n_o^2 \cos^2\phi + n_e^2 \phi}{n_o^2 n_e^2 - (n_i \sin\theta_i)^2 (n_e^2 - n_o^2)\sin^2\phi}} \right] \tag{5}$$

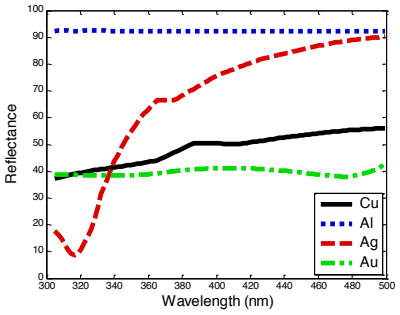
$$\theta_{kp} = \sin\phi \cos\theta_e \tag{6}$$

$$\tan\theta = \frac{n_o^2}{n_e^2} \tan\theta_{kp} \tag{7}$$

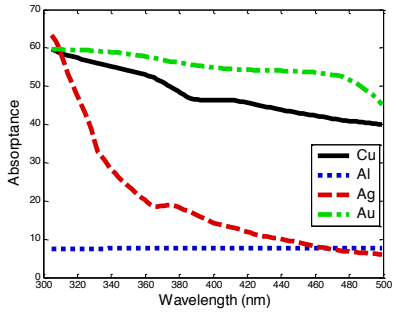
where θ_e is the extraordinary angle of refraction, n_i is the refractive index of the outside medium, θ_i is the incident angle, n_o and n_e are the ordinary and extraordinary indices of refraction, the angle between the y axis and the optical axis is ϕ, and θ_{kp} is the angle between the optical axis and the wave vector at the extraordinary angle. It is later shown that the value of n_o has a significant role in achieving index near zero if the dielectric losses of both the plasmonic and dielectric materials are low.



(a)



(b)



(c)

Figure 1: (a) Transmittance, (b) reflectance and (c) absorptance for 50nm thick metals.

2.3. Results

Comparing Equation (2) and (3), only the epsilon parallel equation has a zero, while epsilon perpendicular has a pole. This can be seen in Fig. 2 (a) where the zero occurs around 58% silver and in Fig. 2 (b) where the pole occurs around 42% silver. The region between the pole and zero where epsilon parallel real is positive and epsilon perpendicular real is negative produces a Type I metamaterial [2]. The fill fraction where we want to produce an ENZ is at zero.

The refractive index of the stack is plotted using equation (4) in Fig. 3. The area between 42% and 58% silver has a refractive index close to zero. According to the results, the best percentage of silver would be slightly above 50%. Taking into account the extinction coefficient, a better percentage would be closer to 58% to reduce the amount of loss. To confirm this, the angle of refraction is calculated with equations (5), (6) and (7) for an incident angle of 20° and plotted in Fig. 4. which shows an angle approaching 0° around 42% and 48%, and an angle below 1° in between.

The transmittance, reflectance and absorptance of three pairs of silver and dielectric material is shown in Fig. 5 with the thickness of silver around 15 nm. 50% transmittance is approximated for a 50 nm thick layer at 405 nm.

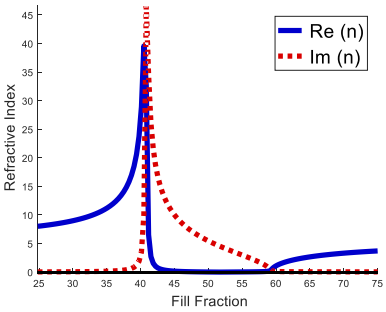

Figure 3: Refractive index.

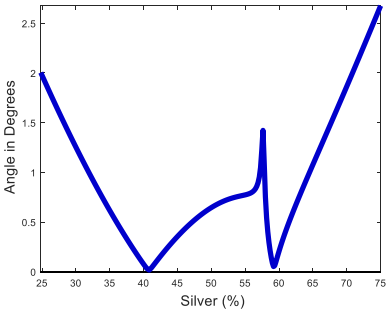

Figure 4: Angle of refraction for an incident angle of 20°.

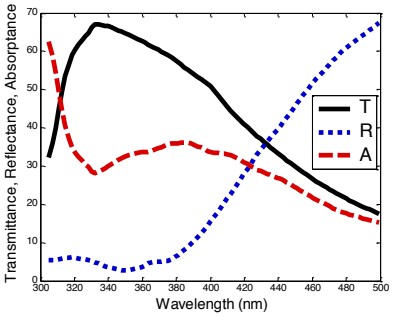

Figure 5: Transmittance, reflectance and absorptance for three pairs of silver/dielectric.

3. Discussion

The final design is a multilayer stack deposited on a thin glass substrate using a magnetron sputtering system with thicknesses set to percentages obtained from the data above. There are three points of interests from the results: 42%, 51% and 48% approximately.

The first percentage corresponds to the pole obtained from the effective medium theory, but has high dielectric loss. 51% is a common solution to achieve both epsilon near zero and epsilon near pole (ENP), but the wavelength is set to a narrow band based on the material characteristics. The key variable in achieving an angle of refraction close to zero is the value of ordinary refractive index in equation (7) which requires an epsilon parallel close to zero. Choosing 48% silver would be the best option for 405 nm. This fill fraction may be changed for different wavelength.

In this paper, permeability is assumed to be unity in the optical regime, however, diamagnetic responses within layers will lower its value [11]. Reaching zero would require an infinite number of layers, but certain materials have a penetration depth which will limit this and the total thickness of the stack. Fig. 6 shows a reduced transmittance down to 20% for the stack doubled to 6 pairs of silver and dielectric material. Decreasing the thicknesses of individual layers to increase the number of layers could increase the transmittance, but it might have an adverse effect on the refractive index of the individual layers. These thicknesses should be chosen based on the magnetron capabilities and the effects on the dielectric constant of the dielectric material.

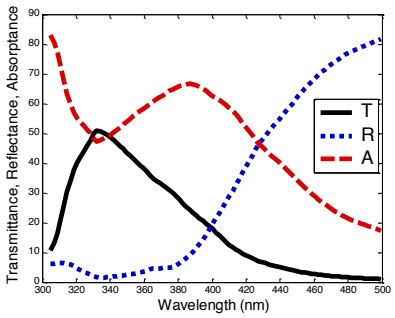

Figure 6: Transmittance, reflectance and absorptance for six pairs of silver/dielectric.

4. Conclusion

Using effective medium theory in combination with low loss materials can produce an epsilon-near-zero metamaterial stack in the visible range. An alternative to silver with both lower dielectric constant and loss is needed to include the higher wavelengths. It may be further altered to form structures such as gratings to increase transmittance and control and possibly form negative index materials. The simplicity of the structure increases the ease of manufacturing and its practical use in larger fabrications.

Abstract

Irregularities in metamaterials are usually perceived to have detrimental impacts. Here, we demonstrate that positional irregularities also open up an innovative way to control the properties of interface waves between two layers of materials.

1. Introduction

Nanowire metamaterials have attracted significant attention due to their innovative impact on both fundamental physics and practical applications. Particularly the discovery that hyperbolic metamaterial functionality can be achieved by structures with very simple geometry, such as nanorod arrays [1] and metal-dielectric multilayers [2, 3], really sparked the scientific interest during the past few years. It was proposed, that one-dimensional metallic gratings representing a simple metasurface with practically realistic geometries, are capable of tailoring the dispersion, and thus the propagation characteristics of surface plasmons in an exceptional manner [4]. Here we study the influence of irregularity on the propagation of surface waves at the interface between two different materials.

2. Dispersive relations and properties of the irregular metamaterials

The structure of the metamaterial is shown in Fig.1, where parameters d and S represent the diameter of the metallic nanowire. All the involved media are nonmagnetic, so the magnetic permeability of every medium is the same as that of vacuum. In our numerical calculation, we use a metallic or semiconductor nanowire metamaterial structure as an example to explore the dispersive features of surface plasmon polaritons, where $\varepsilon_{m,s}^{M}(\omega) = \varepsilon_{\infty} - \dfrac{\omega_p^2}{\omega^2 + i\delta\omega}$. By means of effective medium approximation it is possible to evaluate the effective permittivities of the nanowire metamaterial which are described by the following equations:

$$\varepsilon_{\perp}^{M} = \varepsilon_{d}^{M}\left[\frac{\varepsilon_{m,s}^{M}(1+\rho)+\varepsilon_{d}^{M}(1-\rho)}{\varepsilon_{m,s}^{M}(1-\rho)+\varepsilon_{d}^{M}(1+\rho)}\right] \quad (1)$$

$$\varepsilon_{\parallel}^{M} = \varepsilon_{m,s}^{M}\rho^{M} + \varepsilon_{d}^{M}(1-\rho) \quad (2)$$

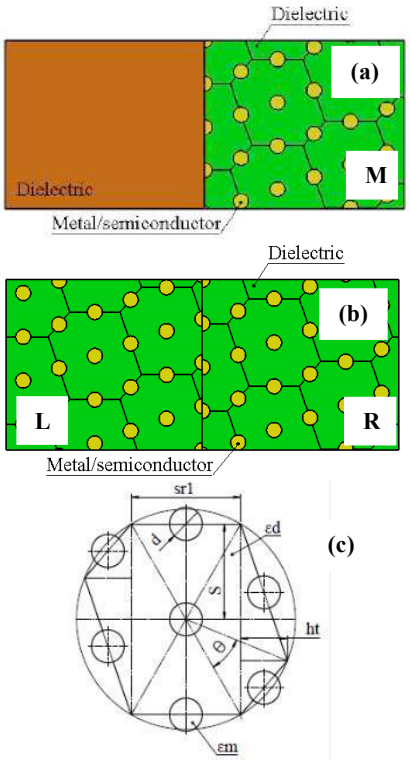

Fig. 1. Fragment of the nanowire metamaterial bounded by either the isotropic medium (dielectric) (a) or ansotropic medium (metamaterial) (b) along with the metmaterial unit cell (c).

Here, subindex M refers to the metamaterial under consideration. Moreover, ρ is the metal fill fraction ratio which is defined as:

$$\rho = \frac{nanowire\ area}{unit\ cell\ area} \quad (3)$$

A possible way to calculate the metal fill fraction (ρ) is to obtain values for pore diameter (d) and spacing (S) and apply the following equation with ht and $sr1$ being the geometrical parameters of the hexagon in case of irregularly positioned metamaterial (Fig. 1).

It is worthwhile mentioning, that

$$ht = \sqrt{2S^2 + \frac{sr1^2}{2} - 2\left(S^2 + \frac{sr1^2}{4}\right)\cos\theta} \times \sin\left(arc\tan\left(\frac{2S}{sr1}\right) - \frac{\theta}{2}\right) \quad (4)$$

with θ being the irregularity angle (Fig. 1).

Under made assumptions, it is possible to derive the dispersion relation for the surface modes localized at the interface between two media with the left one being either isotropic or anisotropic. In case of the metamaterial bounded with the dielectric we evaluate the tangential components of the electric and magnetic fields at the interface and obtain a single surface mode with the propagation constant [5]

$$\beta = k\left(-\frac{\varepsilon_d^M \varepsilon_d a\left(\varepsilon_d - \varepsilon_{m,s}^M \rho + \varepsilon_d^M\left(\rho - 1\right)\right)}{b\left(\varepsilon_d^2 + \frac{\varepsilon_d^M\left(\varepsilon_{m,s}^M \rho - \varepsilon_d^M\left(\rho - 1\right)\right)a}{b}\right)}\right)^{1/2}, \quad (5)$$

Where k is an absolute value of wavevector in vacuum and β is the component of the wavevector parallel to the interface and $a = \varepsilon_d^M\left(\rho - 1\right) - \varepsilon_{m,s}^M\left(\rho + 1\right)$, $b = \varepsilon_d^M\left(\rho + 1\right) - \varepsilon_{m,s}^M\left(\rho - 1\right)$.

To analyze the properties of the surface waves at the interface between two nanowire metamaterials, i.e. anisotropic media, we evaluate the tangential components of the electric and magnetic fields at the interface and obtain a single surface mode with the propagation constant, β. It is interesting to notice that in case of $\varepsilon_m^L = \varepsilon_m^R$ and $\varepsilon_d^L = \varepsilon_d^R$, the obtained result coincides with the dispersion of the surface wave as follows:

$$\beta = k\left(\frac{\varepsilon_d^L\left(\varepsilon_d^L + \varepsilon_m^L - \varepsilon_d^L\rho_L + \varepsilon_m^L\rho_L\right)\left(\varepsilon_d^L + \varepsilon_m^L - \varepsilon_d^L\rho_R \quad \varepsilon_m^L\rho_R\right)}{\sqrt{4\varepsilon_d^L\varepsilon_m^L - \left(\varepsilon_d^L\right)^2\rho_L - \left(\varepsilon_d^L\right)^2\rho_R + \left(\varepsilon_m^L\right)^2\rho_L + \left(\varepsilon_m^L\right)^2\rho_R + 3\left(\varepsilon_d^L\right)^2 + \left(\varepsilon_m^L\right)^2 - \left(\varepsilon_d^L\right)^2\rho_L\rho_R - \left(\varepsilon_m^L\right)^2\rho_L\rho_R \quad 2\varepsilon_d^L\varepsilon_m^L\rho_L\rho_R}}\right) \quad (6)$$

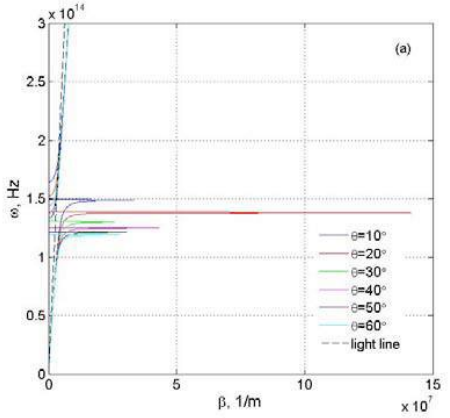
Herein, the sub-indices L and R refer to the left and right metamaterial under consideration, respectively.

3. Discussion

In this section, we investigate SPs supported by the metal and semiconductor nanowire metamaterials presented in Fig. 1. In order to obtain a concise insight into the effect of the losses of the metal nanowires on the modes characteristics, we first consider the lossless case. Then, we revise the results by including the losses in the calculations. The parameters of silver are obtained by fitting this dielectric function to a particular frequency range of bulk dielectric data [6]. It is found [7] that for silver, the values of $\varepsilon_\infty = 5$, $\omega_p = 9.5eV$, $\delta = 0.0987eV$ give a reasonable fit to the bulk dielectric data. It is interesting to notice that heavily doped silicon (n>2.2×10^{19} cm^{-3}) has been shown to exhibit metallic properties at terahertz frequencies [8, 9] and has the potential to replace metals in such applications [10]. The case of a heavy-doped Si is considered, assuming that the doping level is N=5×10^{19} cm^{-3} [11]. Figs. 2-4 show the dispersion curves of the irregular nanowire metamaterial. Although the graphs possess the similar outline with that of traditional metal-SPP, the dispersion curves for the irregular nanowires have some particularities that deserve further considerations.

A. Lossless case

In case the losses are ignored, the plot of Eq. 4, 6 leads to the band structure that can be divided into allowed and forbidden regions. Panels 2 (a), (b) are plotted for different angle θ, i. e. for θ = 10 - 60°. The panel (a) shows the dispersion of the nanowire metamaterial that is bounded with dielectric (ε=4) and the panel (b) – with metamaterial.



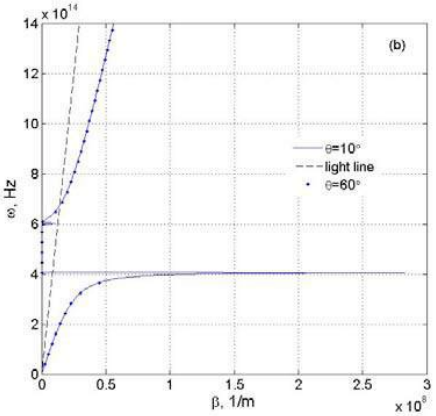


Fig. 2. The dispersion of SPs supported by the lossless metallic nanowire metamaterial bounded by dielectric (a) and metamaterial (b). The black dashed line show the light line.

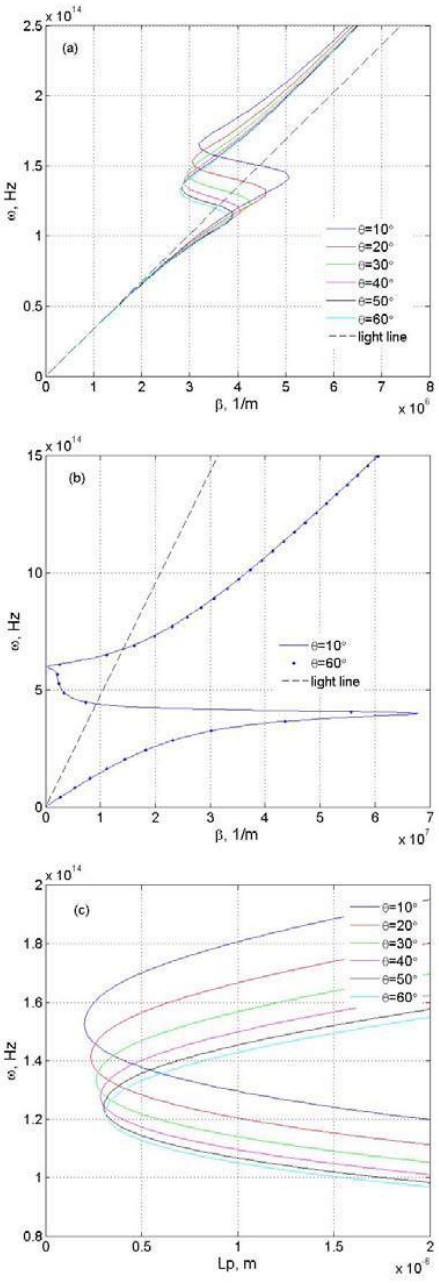
The allowed modes appear in a wide range of frequency for the specific values of the wavevector β as presented in panel 2 (a), (b). When the metamaterial is bounded with the dielectric, the allowed band shrinks as it is depicted in panel 2 (a). As it is seen from panels 2 (a), (b), by increasing the angle θ, the SPs supported by the system shifted to lower frequencies; the allowed bands shrink to the narrower regions. It should be mentioned that bands deviate significantly from the light line, and this departure is greater in case of the metamaterial bounded with metamaterial. We remark that such dispersion curves exhibited similar behaviors of SPPs propagating along the ordered nanowire metamaterial interface. The asymptotic frequency is tuned by the value of θ, and the maximum value of tuning reaches to 1.6 GHz, if θ=10° and the metamaterial is bound with the dielectric. In the case of the irregular metamaterial, the amendment of θ is equivalent to change in ρ, resulting in the change of asymptotic frequency. For comparison, the dispersion relation of the ordered nanowire metamaterial (θ=60°) is also calculated, as shown in the cyan line in Figs. 2 (a), (b). We observe that the asymptotic frequency of the ordered structure (the cyan line) is lower than that of the irregular structure.

B. Lossy case

Up to now, we have completely ignored the effect of the losses, coming from Re(ε), in our analysis. In the case Im(ε) is involved in the calculations, the wavenumber takes the complex values, i. e. $\beta = \beta' + i\beta''$, and therefore the wavenumber would be complex within the whole frequency region. Panels (a) and (b) of Fig. 3 show the dispersion diagrams and (c) and (d) the propagation length of the surface waves for both cases. While there are visible changes in dispersion curves, the most notable feature is the drastic enhancement of the propagation length as the angle θ is increased.



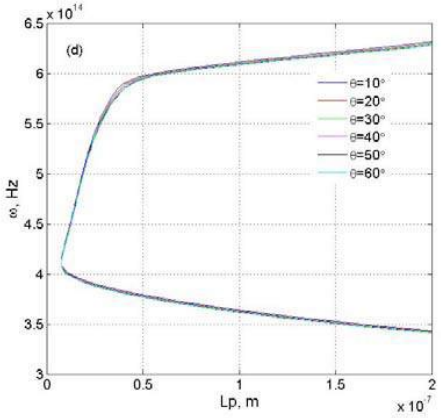


Fig. 3. The dispersion of SPs supported by the lossy metallic nanowire metamaterial bounded by dielectric (a) and metamaterial (b) along with the propagation lengths for different cases (panel (c) – dielectric; panel (b) - metamaterial); the black dashed line shows the light line.

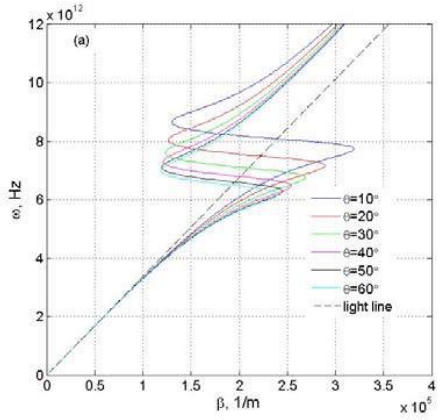
As it is seen from panels (c), (d) of Fig. 3, L_p values of the SPs for θ=60° are considerably smaller than those of θ=10°. This means that when real losses are included, the nanowire metamaterial supports the SPs that are not as efficient as SPs of the irregular metamaterial. By efficient SPs we mean modes with large L_p. From these panels, it can be observed that by decreasing the angle θ from 60 to 10°, the frequency range in which the SPs are supported can be extended. Moreover, the propagation characteristics can also be improved.

Since our goal is to obtain the nanowire metamaterial with the capability of supporting SPs with longer propagation length, for the results presented in Fig. 3 we have replaced metal with the semiconductor. Figure 4 shows dispersion of the SPs in case of the semiconductor nanowire metamaterial.



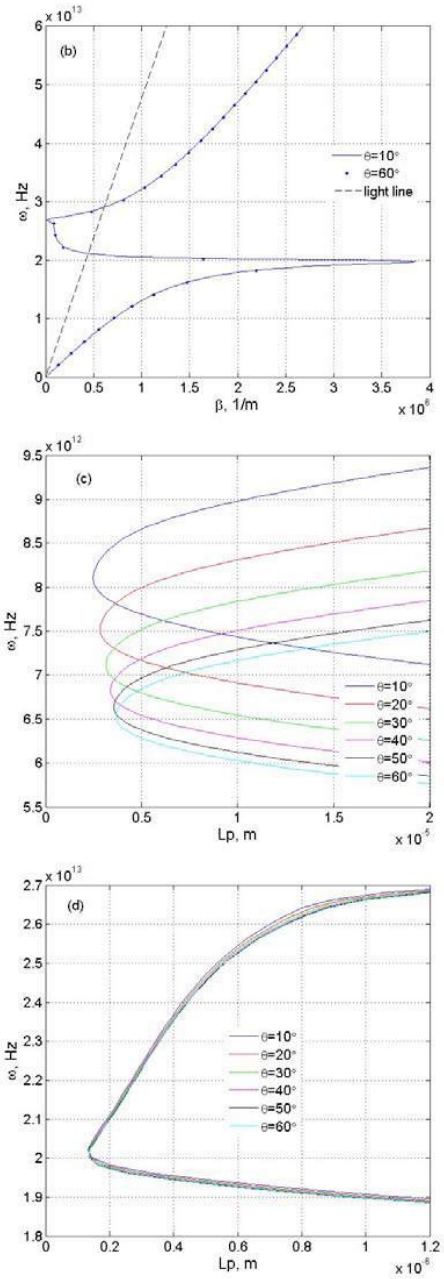


Fig. 4. The dispersion of SPs supported by the lossy semiconductor nanowire metamaterial bounded by dielectric (a) and metamaterial (b) along with the propagation lengths for different cases (panel (c) – dielectric; panel (d) - metamaterial); the black dashed line show the light line.

It can be concluded that the semiconductor nanowire metamaterials support SPs with the longer propagation length. It is clear that the propagation length of semiconductor-SPPs is around 10 times longer than that of metal-SPP. Thus, the propagation loss of semiconductor-SPPs is much lower than that of metal-SPPs. Consequently,

in some circumstances, using the irregular semiconductor nanowire metamaterial structures would result in longer propagation length. And by adjusting the level of irregularity (angle θ), the properties of SPP mode could be tuned.

4. Conclusions

The SPP guided by the irregular nanowire metamaterial was studied theoretically. The dispersion relation of the SPP was derived treating the metamaterial as an anisotropic material by the effective medium theory. It is revealed that semiconductor-SPPs have narrower frequency range than metal. As far as we are concerned, the oscillation of free electrons at the metal surface results with the surface plasmon. Naturally, the decrease of the number of free electrons would lead to the reduction of frequency range. The calculation results also revealed that the semiconductor-SPPs have larger propagation length compared with metal-SPPs. Therefore, at some specific frequency, semiconductors could be more favorable than metal in transmitting signals. Moreover, it should be noticed, that there is a room of possibilities to increase the propagation length of the modes up to two orders by replacing the metallic nanowires with the semiconductor ones. These irregular nanowire metamaterial structures are appropriate for feasibly designing irregular metamaterial, which are beneficial to guiding and sensing applications.

Abstract

The possibility is established and the conditions are found for localization of plasmon-polaritons (PPs) near the boundaries of hyperbolic metamaterials (HMs) of both the I and II types with arbitrary orientation of the optical axis. It is grounded that such surface PP has the transverse spin momentum which depends on the wavelength of the exiting wave, the orientation of the optical axis of the hyperbolic metamaterial, and dielectric properties of bordered media.

1. Introduction

It is known that propagating circularly polarized light beam possesses the longitudinal spin angular momentum (SAM) the direction of which coincides with the wave vector [1]. Meanwhile, each photon transfers the angular momentum $\pm\hbar$ depending on the sign of circular polarization. For linear polarized propagating wave the longitudinal spin angular momentum is absent [1-3].

In the general case the angular momentum carried by the monochromatic light beam represents a superposition of SAM and orbital angular momentum (OAM) related to the optical phase profile of the beam in the plane orthogonal to the propagation direction. Vortex (Laguerre-Gaussian, Bessel-Gaussian) beams with the amplitude of electric vector $E(\rho,\varphi)=E_o(\rho)\exp(im\varphi)$ (ρ,φ are the cylinder coordinates, m is the azimuthal phase index, or topological charge) are examples of the fields possessing OAM. For these vortex beams each photon carries OAM that equals to $m\circ$. When vortex beams interact with microobjects the transfer of spin and orbital momenta to the particles takes place that permits to control them.

Recently it was shown that the spin momentum of evanescent waves (including ones with linear polarization) appears to be nonzero and perpendicular to the wave vector that principally differs these waves from propagating ones [4,5]. Thus, the transverse SAM arises, the origin of which is caused by the rotation of the electric vector of the evanescent wave in the propagation plane. The features of transverse SAM are investigated for evanescent waves at the boundary of isotropic media. But optical anisotropy can essentially influence the conditions of existence of surface waves and transverse spin related to them.

In Ref. [6] the possibility is shown of the presence of transverse spin momentum for plasmon-polariton fields excited at the boundary of the II type hyperbolic metamaterial (HMM) with optical axis perpendicular to this boundary. In this paper we investigate the influence of HMM optical axis orientation on the conditions of existence of surface plasmon-polaritons with transverse spin momentum at the metamaterial interface. As an example, we consider HMM created from multilayered metal-dielectric structures.

2. Surface plasmon-polariton at the boundary of isotropic medium and hyperbolic metamaterial with arbitrary oriented optical axis

2.1. Features of plasmon-polaritons at the boundary of isotropic medium and hyperbolic metamaterial with arbitrary oriented optical axis

Let us consider a metamaterial formed from layered-periodic metal-dielectric medium. In the effective medium theory when the thickness of each layer is sufficiently small, i.e. $|k_d d_d|<<1, |k_m d_m|<<1$ where k_d, k_m are the wave numbers of dielectric and metallic layers, respectively, this multilayered structure can be considered as anisotropic effective medium with the permittivity tensor represented in the form:

$$\varepsilon = diag\{\varepsilon_\perp, \varepsilon_\perp, \varepsilon_\parallel\} = \varepsilon_\perp + \delta \mathbf{c} \otimes \mathbf{c}, \qquad (1)$$

where $\delta = \varepsilon_\parallel - \varepsilon_\perp$, $\varepsilon_\parallel$ and $\varepsilon_\perp$ are the longitudinal (along the Z' axis) and transverse (in the plane orthogonal to Z') main permittivities, $\mathbf{c}$ is the unit vector along the HMM optical axis, and the symbol $\otimes$ denotes the dyadic product of the vectors ($\mathbf{c}\otimes\mathbf{c} = c_i c_k$). The main permittivities of this structure are determined by the following relations:

$$\varepsilon_\perp = (1-f)\varepsilon_d + f\varepsilon_m, \varepsilon_\parallel^{-1} = [(1-f)/\varepsilon_d + f/\varepsilon_m]. \quad (2)$$

Here ε_d and ε_m are the permittivities of dielectric and metallic layer, respectively, f is the filling factor (the volume part of metal in the unit cell). The permittivity of metal ε_m is described by the modified Drude formula:

$$\varepsilon_m(\omega) = \varepsilon_\infty - \omega_p^2/(\omega^2 + i\omega\Gamma) = \\ = \varepsilon_\infty - \omega_p^2/(\omega^2 + \Gamma^2) + i\omega_p^2\Gamma/[\omega(\omega^2 + \Gamma^2)]. \quad (3)$$

Here ω_p is the volume plasma frequency, ε_∞ is the sum of the interband contributions, $\Gamma = V_F/l$ is the damping constant, V_F is the Fermi velocity, l is the electron mean free path in bulk metal. For silver we have $\varepsilon_\infty = 5$, $\omega_p = 14\cdot10^{15}s^{-1}$, $\Gamma = 32\cdot10^{12}s^{-1}$, $V_F = 1.4\cdot10^6 ms^{-1}$[7]. For simplicity of our consideration we suppose that in Eq. (2) $\mathrm{Im}(\varepsilon_l)\approx0$, $\mathrm{Im}(\varepsilon_l)\approx0$. As calculation shows [8] this assumption is correct for spectral regions where parameters $\varepsilon_\perp$ and $\varepsilon_\parallel^{-1}$ significantly differ from zero.

Let the HMM border with the isotropic medium with permittivity ε_1. Meanwhile, the angle between the optical axis of the metamaterial and the normal to the HMM boundary (Z axis) is θ (Fig.1).

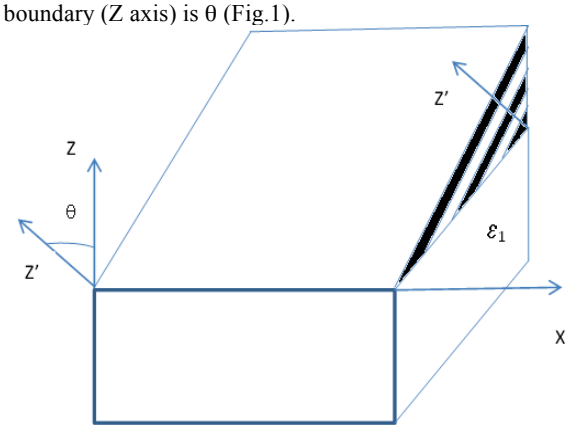

Figure 1: The scheme of the considered structure. The Z′ axis is parallel to the $\mathbf{c}$ vector.

Now we consider *p*-polarized surface waves propagating along the *X* axis in the plane separated the isotropic dielectric with permittivity ε_1 and hyperbolic metamaterial. We'll use the coordinate system *XYZ* (see Fig.1) in which the effective permittivity tensor ε', characterizing the hyperbolic metamaterial, is represented in the form:

$$\varepsilon' = U\varepsilon\widetilde{U}. \quad (4)$$

Here U is the transformation matrix which permits to transfer from the coordinate system related to the HMM main dielectric axes to the system of coordinate XYZ:

$$U = \begin{pmatrix} \cos\theta & 0 & -\sin\theta \\ 0 & 1 & 0 \\ \sin\theta & 0 & \cos\theta \end{pmatrix}, \quad (5)$$

the symbol "tilde" denotes the transposition. As follows from Eqs.(4) and (1)

$$\varepsilon' = U\varepsilon\widetilde{U}.\varepsilon_{xx}\mathbf{e}_x\otimes\mathbf{e}_x + \varepsilon_\perp\mathbf{e}_y\otimes\mathbf{e}_y + \varepsilon_{zz}\mathbf{e}_z\otimes\mathbf{e}_z + \\ + \varepsilon_{xz}(\mathbf{e}_x\otimes\mathbf{e}_z + \mathbf{e}_z\otimes\mathbf{e}_x). \quad (6)$$

Here

$$\varepsilon_{xx} = \varepsilon_\perp\cos^2\theta + \varepsilon_\parallel\sin^2\theta, \\ \varepsilon_{zz} = \varepsilon_\perp\sin^2\theta + \varepsilon_\parallel\cos^2\theta, \quad (7) \\ \varepsilon_{xz} = (\varepsilon_\parallel - \varepsilon_\perp)\sin\theta\cos\theta,$$

$\mathbf{e}_x$, $\mathbf{e}_y$, and $\mathbf{e}_z$ are the unit vectors of the used coordinate system.

Let us represent the vectors of the field inside the dielectric (*d*) and metamaterial (*m*) in the form

$$\mathbf{F} = \begin{cases} \mathbf{F}^d\exp(\kappa_d z + iqx - i\omega t), & z<0 \\ \mathbf{F}^m\exp(-\kappa_m z + iqx - i\omega t), & z>0 \end{cases}, \quad (8)$$

where $\mathbf{F}$ denotes the electric $\mathbf{E} = (E_x, 0, E_z)$ or magnetic $\mathbf{H} = (0, H_y, 0)$ vector, $\kappa_{d,m} > 0$ and q are the decay constant and longitudinal wave number of the surface plasmon-polariton, respectively, $\kappa_d^2 = q^2 - k_0^2\varepsilon_1$, $k_0 = \omega/c$, ω is the cyclic frequency of electromagnetic wave, c is the light velocity in vacuum. Taking into account Eq. (8) from the Maxwell equations one can obtain the relations for electric and magnetic vectors inside the dielectric and metamaterial:

$$\mathbf{E}^d = -\frac{A_0}{\varepsilon_1}(i\frac{\kappa_d}{k_0}\mathbf{e}_x + \frac{q}{k_0}\mathbf{e}_z)e^{iqx+\kappa_d z}, \\ \mathbf{H}^d = A_0\mathbf{e}_y e^{iqx+\kappa_d z}. \quad (9)$$

$$\mathbf{E}^m = \frac{A_0}{sk_0}[(i\kappa_m\varepsilon_{zz} + q\varepsilon_{xz})\mathbf{e}_x - \\ (q\varepsilon_{xx} + i\kappa_m\varepsilon_{xz})\mathbf{e}_z]e^{iqx-\kappa_m z}, \\ \mathbf{H}^m = A_0\mathbf{e}_y e^{iqx-\kappa_m z}. \quad (10)$$

Here $s = \varepsilon_{xx}\varepsilon_{zz} - \varepsilon_{xz}^2$, A_0 is the amplitude, and the phase factor $\exp -i\omega t$ is omitted. Substituting Eq. (10) into the Maxwell equation $rot\mathbf{E} = -(1/c)\partial\mathbf{H}/\partial t$ we find:

$$\kappa_m^2 = aq^2 - bk_0^2 + 2iqd\kappa_m, \quad (11)$$

where $a = \varepsilon_{xx}/\varepsilon_{zz}, b = s/\varepsilon_{zz}, d = \varepsilon_{xz}/\varepsilon_{zz}$. For small and large (close to 90°) values of the θ angle the parameter ε_{xz} (and hence, the d parameter) is small. Owing to this the decay constant κ_m is represented in the form:

$$\kappa_m = \kappa_{mo} + i\kappa_{m1}. \quad (12)$$

It should be noted that $|\kappa_{mo}| >> |\kappa_{m1}|$. Then, squaring Eq. (12) and comparing the result with Eq. (11), we obtain:

$$\kappa_m = \kappa_{mo} + idq = \sqrt{aq^2 - bk_0^2} + idq. \qquad (13)$$

It follows from Eq. (13) that the decay constant is complex. Thereby, the plasmon-polariton has a nonzero propagation constant along the normal to the metamaterial boundary. It means that its phase velocity is directed under the γ angle towards the HMM border:

$$tg\gamma = -d. \qquad (14)$$

As follows from Eq. (14), both for the I type HMM ($\varepsilon_\perp > 0, \varepsilon_{||} < 0$) and the II type HMM ($\varepsilon_\perp < 0, \varepsilon_{||} > 0$) one can realize two different cases of the phase velocity orientation of plasmon-polariton: 1) the phase velocity is directed from the boundary inside the metamaterial, and 2) the phase velocity is directed towards the boundary. The case 1) takes place for the I type HMM at $\gamma > 0$ (positive value of the θ angle relates to the optical axis which is disposed between the Z and X axes of the chosen coordinate system), and for the II type HMM at $\gamma < 0$. The case 2) takes place for the I (or II) type HMM at $\gamma < 0$ (or $\gamma > 0$, respectively). If $\gamma \triangleq 0$ or $\gamma \triangleq \pi/2$ the transverse component of the wave vector of plasmon-polariton disappears, and the equation for the longitudinal wave number of the plasmon-polariton is represented as

$$q = k_0 \sqrt{\frac{\varepsilon_1 \varepsilon_{zz} (\varepsilon_{xx} - \varepsilon_1)}{\varepsilon_{xx}\varepsilon_{zz} - \varepsilon_1^2}} = k_0 \sqrt{\varepsilon_{eff}} \qquad (15)$$

2.2. The condition of the plasmon-polariton localization at the boundary of hyperbolic metamaterial

Now we'll analyze the possibility of localization of the electromagnetic wave on the interface of isotropic medium and hyperbolic metamaterial. Due to the exponentially decaying of the amplitude of this field when moving off the boundary, the wave number *q* has to be larger than modules of wave vectors of the waves propagating inside the dielectric and metamaterial. Thereby,

$$\varepsilon_{eff} > 0,\ \varepsilon_{eff} > \varepsilon_1,\ \kappa_m > 0. \qquad (16)$$

From inequalities (16) the conditions of localization of plasmon-polariton at the boundary of hyperbolic metamaterial follow: $\varepsilon_{zz} > \varepsilon_1$, $\varepsilon_{xx} < 0$. For the hyperbolic metamaterial of the I type these conditions are fulfilled at

$$\sin^2\theta > Y_1 = \sin^2\Theta_1 = \frac{\varepsilon_\perp}{|\varepsilon_{||}| + \varepsilon_\perp}, \qquad (17)$$

$$\sin^2\theta > Y_2 = \sin^2\Theta_2 = \frac{|\varepsilon_{||}| + \varepsilon_1}{|\varepsilon_{||}| + \varepsilon_\perp}. \qquad (18)$$

From Eqs.(17), and (18) it follows the condition of existence of localized plasmon-polaritons at the boundary of the hyperbolic metamaterial of the I type and isotropic dielectric:

$$|\theta| > \theta_1 = \max\{|\Theta_1|, |\Theta_2|\},\quad \Theta_{1,2} = \arcsin\sqrt{Y_{1,2}}. \qquad (19)$$

Similarly, for the hyperbolic metamaterial of the II type the excited plasmon-polariton is localized if the following conditions are fulfilled:

$$\sin^2\theta < Y_3 = \sin^2\Theta_3 = \frac{|\varepsilon_\perp|}{\varepsilon_{||} + |\varepsilon_\perp|}, \qquad (20)$$

$$\sin^2\theta < Y_4 = \sin^2\Theta_4 = \frac{\varepsilon_{||} - \varepsilon_1}{\varepsilon_{||} + |\varepsilon_\perp|}. \qquad (21)$$

From Eqs. (20), and (21) one can obtain the general condition for existence of localized plasmon-polaritons at the boundary of the metamaterial of the II type and isotropic dielectric:

$$|\theta| < \theta_2 = \min\{|\Theta_3|, |\Theta_4|\},\quad \Theta_{3,4} = \arcsin\sqrt{Y_{3,4}}. \qquad (22)$$

Obtained Eqs. (19), and (22) are determined the conditions of localization of surface plasmon-polaritons at the interface of isotropic medium and hyperbolic metamaterial.

2.3. Localized plasmon-polaritons at the boundary of multilayered metal-dielectric nanostructure Ti_3O_5/Ag

As an example we consider the hyperbolic metamaterial created on the basis of the layered-periodic structure Ti_3O_5/Ag the unit cell of which is formed by the nanolayers of silver (Ag) and isotropic dielectric Ti_3O_5.

In Fig.2, 3 the spectral dependences of effective permittivities $\varepsilon_\perp$ and $\varepsilon_{||}$ are represented for hyperbolic metamaterial on the basis of the metal-dielectric layered structure Ti_3O_5/Ag. For calculation here and below we suggested that the thickness of the metal layer was 20 nm, and the filling factor was *f*=0.3. As is seen from Figs.2,3, in the spectral region $320\ nm < \lambda < 390\ nm$ this structure displays the properties of the I type HMM, and for the wavelength $600\ nm < \lambda$ it can be considered as the II type HMM.

Now we support that all layers are deposited on the substrate (for example, fused quartz with dielectric permittivity ε_1=2.1), and the periodicity axis (the optical axis) of the structure is oriented at a certain angle θ to the normal to its border. As is illustrated in Fig.4, for this case the condition (19) is fulfilled for large values of θ. It should be noted that if the parameter $|\varepsilon_{||}|$ increases the value of the angle $\theta_1 = \max\{\Theta_1, \Theta_2\}$ becomes larger.

For hyperbolic metamaterial of the II type created on the basis of metal-dielectric layered structure Ti_3O_5/Ag the condition (22) is fulfilled at small values of the θ angle, i.e. when the optical axis is close to the normal to the HMM

boundary. Meanwhile, the parameter θ_2 increases if $|\varepsilon_\perp|$ becomes larger.

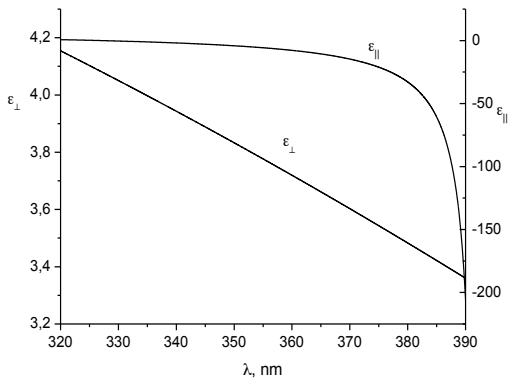

Figure 2: The spectral dependences of main dielectric permittivities of the I type HMM on the base of Ti_3O_5/Ag structure.

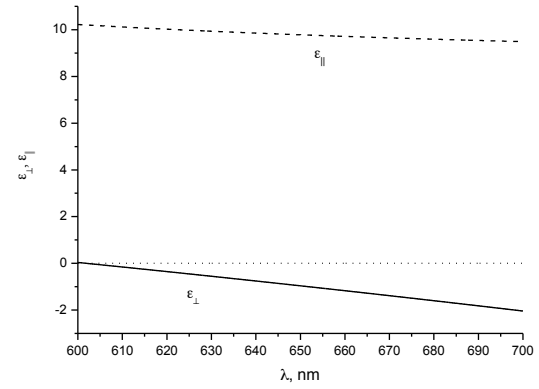

Figure 3: The spectral dependences of main dielectric permittivities of the II type HMM on the basis of Ti_3O_5/Ag structure.

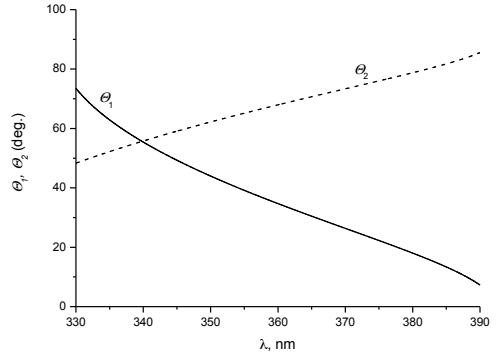

Figure 4: The spectral dependences of the angles $\Theta_{1,2}$=arcsin $(Y_{1,2})^{1/2}$ for the I type HMM on the base of Ti_3O_5/Ag structure.

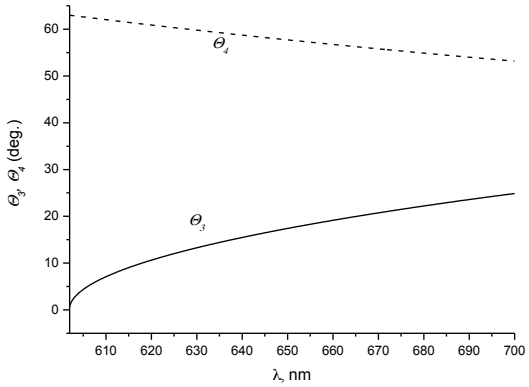

Figure 5: The spectral dependences of the angles $\Theta_{3,4}$=arcsin $(Y_{3,4})^{1/2}$ for the II type HMM on the basis of Ti_3O_5/Ag structure.

3. Transverse spin angular momentum of surface plasmon-polariton

As follows from Eqs. (9), and (10), the electric vector of plasmon-polariton, localized inside the dielectric, is deposited in the propagation plane (*X,Z*) and has both real and imaginary components $\mathbf{k}^d = q\mathbf{e}_x + i\kappa_d\mathbf{e}_z$. Owing to this the phase difference $-\pi/2$ between the components E_x^d and E_z^d appears. This causes the rotation of the electric vector in the propagation plane *(XZ)* and emergence of the transverse component S_y of spin angular momentum [4,5]:

$$\mathbf{S} = \frac{1}{16\pi\omega}\mathrm{Im}\left[\mu^{-1}(\mathbf{E}^*\mathbf{E}) + \varepsilon^{-1}(\mathbf{H}^*\mathbf{H})\right] \quad (23)$$

Then, as follows from Eqs. (23), and (9), the transverse component of SAM is represented in the form:

$$S_y = \frac{|A_0|^2}{8\pi\omega\varepsilon_1^2}\frac{\kappa_d q}{k_0^2}e^{2\kappa_d z}(z<0). \quad (24)$$

Taking into consideration the following relations

$$|A_0|^2 = 8\pi\varepsilon_1 k_0^2 W/q^2,\ W = (\varepsilon_1\mathbf{E}\mathbf{E}^* + \mathbf{H}\mathbf{H}^*)/(16\pi),$$

from Eq. (24) one can obtain:

$$S_y = \frac{W}{\omega\varepsilon_1}\frac{\kappa_d}{q}e^{-2\kappa_d z}. \quad (25)$$

Eq. (25) is applicable for calculation of transverse spin angular momentum carrying by the spatially localized surface wave into a transparent dielectric. In the immediate vicinity of the interface between media, the expression (25) is simplified:

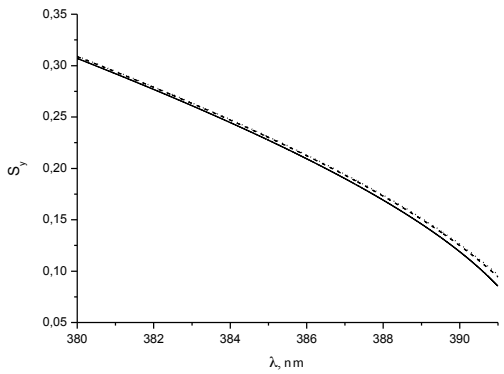
$$S_y = \frac{2\kappa_d q}{q^2 + \kappa_d^2}. \qquad (26)$$

Eq. (26) is convenient to use for calculating the amplitude of the transverse component *Sy* of the spin as a function of the wavelength of the surface plasmon-polariton at the interface between the hyperbolic metamaterial and the dielectric and, in particular, with a liquid or water containing microparticles. In this case, the parameter *Sy* determines the torque momentum acting in the direction of the *Y*-axis on particles near the surface of the metamaterial.

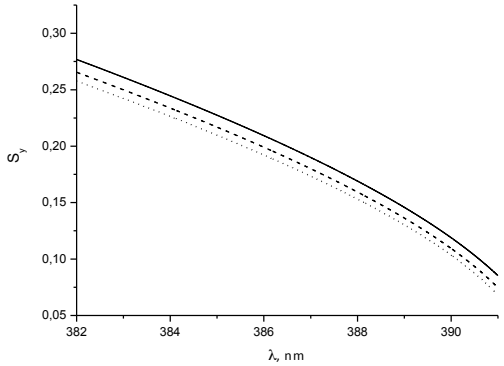
In Figs.6,7 the spectral dependences of expected value of transverse spin (in $\hbar$ units) for plasmon-polariton localized at the boundary of layered-periodic medium Ti_3O_5/Ag and dielectric (water, glyserine, glass). It is seen that the expected value of transverse spin S_y changes with variation of the wavelength. This indicates the possibility of controlling the transverse spin moment and, consequently, the force acting on the microparticles placed in the dielectric near its boundary with the metamaterial, by changing the length of the light wave exciting the surface plasmon-polariton.

However, as is seen in Figs.6,7, dependences $S_y(\lambda)$ are deferent for the spectral regions where considered metal-dielectric structure possesses the properties of HMM of the I and II types. These differences display in the following. If the wavelength increases from the short-wavelength region (where the structure possesses the properties of the I type HMM) up to the wavelength for which $\varepsilon_{\|}^{-1} \to 0$, the expected S_y value decreases (Fig.6). If the wavelength decreases from the long-wavelength region (where the structure possesses the properties of the II type HMM) up to λ for which $\varepsilon_{\perp} \to 0$, the expected value S_y of transverse spin momentum increases (Fig.7).

Moreover, the expected value of transverse spin appears to be dependent on the orientation of the optical axis and permittivity of the medium bordered with the metamaterial. But these dependences are different for spectral regions related to the I and II types of HMMs. In the first case (the I type HMM) the curvature of the $S_y(\lambda)$ curve decreases with increasing the angle θ (Fig.6a). Besides, in this spectral region the S_y value decreases if the permittivity ε_1 increases (Fig.6b). In the second case (the II type HMM) with increasing the angle θ the expected value S_y of transverse spin also increases (Fig.7a), and with increasing ε_1 the curvature of the $S_y(\lambda)$ curve decreases (Fig.7b).



a



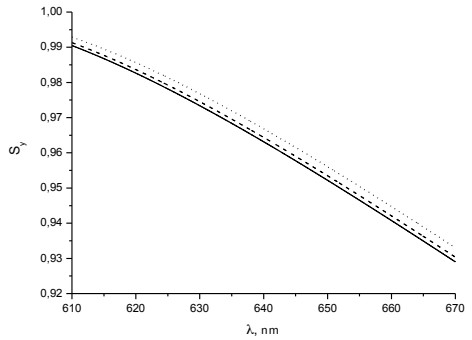
b

Figure 6: The spectral dependence of the expected value of transverse spin (in ħ units) for the localized wave formed at the interface of the metal-dielectric multilayered medium Ti_3O_5/Ag and dielectric: a) water; b) water (solid line), glyserine (dashed line), optical glass BAF 10 (dotted line). The optical axis is oriented at the angle of: a) θ=87.8° (solid line), 89° (dashed line), 90° (dotted line); b) 87.8°.

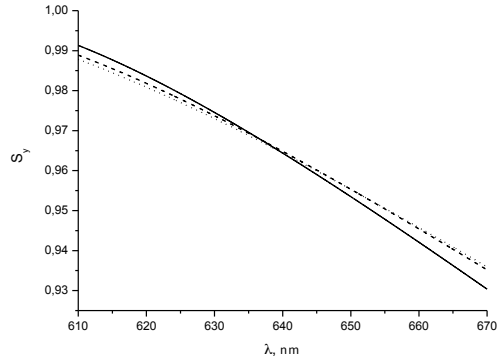
4. Conclusions

Thus, in this paper we investigated the features of plasmon-polaritons excited at the interface of the hyperbolic metamaterial and dielectric for the case when the optical axis is oriented under the angle towards the boundary. The expressions are obtained for the complex electric and magnetic vectors as well as for the decay constants of the fields on both sides of the interface. It is shown that the propagation constant of plasmon-polariton has the component oriented perpendicular to the boundary inside the metamaterial. Hence, the surface wave has a radiative component propagating inside the HMM under a certain angle to its border. It is established that for hyperbolic metamaterials of different types (the I and II) changing the orientation of the optical axis one can realize the conditions

when the phase velocity of plasmon-polariton is directed from the boundary inside the metamaterial or towards the boundary.



a



b

Figure 7: The spectral dependence of the expected value of transverse spin (in ħ units) for the localized wave formed at the boundary of the metal-dielectric multilayered medium Ti_3O_5/Ag and dielectric: a) water; b) water (solid line), glyserine (dashed lline), optical glass BAF 10 (dotted line). Optical axis is oriented under the angle: a) $\theta=1^o$ (solid line), 3^o (dashed line), 5^o (dotted line); b) 3^o.

The possibility is shown and the conditions are determined for localization of plasmon-polariton at the boundary of hyperbolic metamaterial of both the I and II types.

It is grounded that surface plasmon-polariton, localized near the interface of isotropic dielectric and hyperbolic metamaterial, possesses the transverse spin angular momentum, the expected value of which depends on the wavelength of exciting radiation, the orientation of the optical axis of HMM, and permittivity of bordered medium.

For illustration of obtained results we carries out a numerical modeling of optical properties of hyperbolic metamaterial formed on the basis of layered-periodic metal-dielectric medium.

Abstract

A novel structure of the symmetrical semi-circular cavity MIM (metal-insulator-metal) waveguide filter based on the aperture coupled method is proposed. The transmission spectrum of the filter is obtained by using the finite element method (FEM). Using the adjustable characteristics of this filter, the transmission characteristics of the three communication windows (850nm, 1310nm, 1550nm) at optical telecommunication regime can be controlled. The excellent performance of this filter can be applied in the micro-nano optical devices, especially in optical fiber communication.

1. Introduction

Surface Plasmon Polaritons (SPPs) are waves that propagate along the surface of a conductor and a dielectric due to the interaction between the free electrons of the conductor and the incident electromagnetic field [1]. SPPs have promising application on the devices in highly integrated optical circuits because they overcome the conventional diffraction limit and can manipulate light on sub-wavelength scales [2,3]. Among various SPPs based waveguides, metal-insulator-metal (MIM) structure has attracted tremendous interests of the researchers in recent years, because of its potential applications to manipulate and control light in nanoscale[4].

At present, the SPPs based on the MIM structure functional optical devices have made great breakthrough in theoretical and experimental research, such as Bragg reflector[5], splitter[6], interferometer[7], filter[8] and so on, where the filter technology is critically important in the development of micro-nano integrated optical devices, especially in optical communication equipments. Therefore, the study of MIM structure filter is fruitful and different resonant cavity structure filters based on SPPs are proposed. Such as, rectangular resonator[9], rectangular ring resonator[10], nano-disk[11], ring cavity[12], trapezoid cavity[13] , etc. These filters are all based on the evanescent coupling method. Their function is single and the bandwidth of their passband or stopband is relatively narrow. However, wide bandwidth filters can play special roles in some cases. Besides, since the decay length of the field in the metal layer is typically around 20nm, very small gaps ($<$ 20nm) are required to achieve any noticeable coupling. Furthermore, the evanescent coupling is both inefficient and challenging to realize even with state-of-the-art electron beam or ion beam lithography. Compared with the evanescent coupling, aperture coupling can improve coupling efficiency and the coupling strength can be controlled by varying the aperture width and depth[14,15].

In this paper, a new type of symmetric semi-circular cavity MIM waveguide structure filter is constructed based on the aperture coupled method. And the semi-circular cavity can be reduced by half of the size compared to the disk or ring at the same radius. The finite element method (FEM) is used to simulate and analyze the transmission characteristics of the filter. Through the analysis of the structure parameters, the influence of the structure parameters on the transmission characteristics is obtained. And by using the relation between the structure parameters and the transmission characteristics, the optimized structure and the simulation results are achieved. Finally, a single-function filter (band-pass filter) is obtained by improving the filter structure (the left and right semi-circular cavities are changed to disk).

2. Structure and method

As shown in Figure 1, the MIM structure filter is composed of three semi-circular cavities connected with the band waveguide through the rectangular apertures. The structure parameters r, A, d, D, L and W represent the radius of the semi-circular cavity, the width of the rectangular aperture, the gap between the bottom of the semicircular cavity and the waveguide, the distance between the centers of two semi-circular cavities, the distance between the point P/Q and the semi-circular cavity, the waveguide width, respectively. The parameter d is set to 50nm to eliminate evanescent coupling between the semi-circular cavity and the band waveguide [14]. The parameters L and W are fixed to 300nm and 50nm. The tunable structure parameters A, r and D are initialized to 40nm, 100nm and 200nm, respectively.Two power monitors are, respectively, set at the points of P and Q to detect the incident and the transmission fields for calculating the incident power of P_{in} and the transmitted power of P_{out}. The transmission coefficient is defined as $T = P_{out}/P_{in}$[16].

In this paper, the transmission characteristics of this filter can be obtained by COMSOL Multiphysics 5.0 based on the FEM method. The insulator is set as air ($\varepsilon_{r(air)}$= 1)

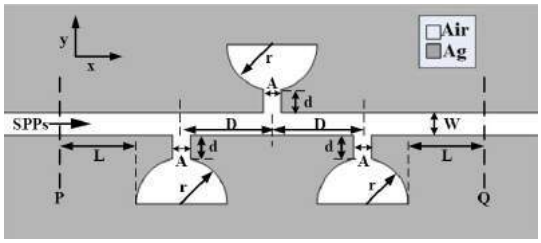

Figure 1: The schematic diagram of the symmetric three semi-circular cavities MIM waveguide filter structure.

and the metal is silver (Ag). The dielectric constant ε_m of silver can be calculated by the standard Drude model,

$$\varepsilon_m = \varepsilon_\infty - \omega_p^2/(\omega^2 - \mathrm{i}\omega\gamma). \quad (1)$$

Here, ε_∞ is the dielectric constant at infinite frequency, γ and ω_p are the electron collision frequency and bulk plasma frequency, respectively. The parameters for silver can be set as ε_∞=3.7, ω_p=9.1eV, and γ=0.018eV [17]. The boundary condition is chosen as the scattering boundary condition [13].

3. Transmission characteristic

Figure 2 shows the transmission spectrum of the filter, in which the tunable structure parameters A, r and D are set as the initial value (A=40nm, r =100nm, D=200nm). As shown in Figure 2, the filter can be treated as multi-functional filter. The first optics communication window of the telecommunication regime is located in its passband and the second and the third windows are in its stopband. The transmission spectrum of this filter appears depression in the passband at the shortwave, but the transmittance of the passband is high and nearly more than 70%. While the transmittance of its stopband is close to 0 and the stopband has the characteristic of flat-bottom. Besides, the falling and the rising edge of this filter are very steep.

4. Analysis of the structure parameters

In order to fully study the transmission characteristics of this filter, the influences caused by the change of the structure parameters A, r and D on the transmission spectrum is analyzed one by one. It is shown in Figure 2 that the passband of the filter at the short-wave has a depression. However, what we expect are the characteristics of the flat-top of the passband and the flat-bottom of the stopband. So, next, we will focus on studying the change trend of the depression of the passband at the shortwave and the bandwidth of the passband and the stopband with the change of the tunable structure parameters.

4.1. Influence of the structure parameter r on the transmission characteristics

When maintaining the structure parameters A and D the initial value unchanged(A=40nm, D=200nm), the transmission spectrum of the structure filter appears obvious red shift with the increase of r, as shown in Figure 3. And with the increase of r, the depression at the shortwave is getting more and more shallow. The bandwidth of the passband increases slowly, but the stopband's increases rapidly. The passband at the long-wave appears a fast drop.

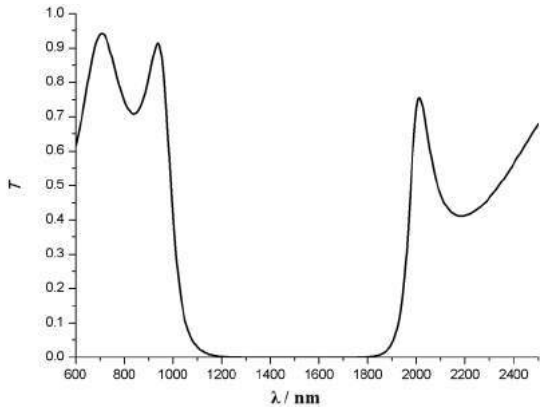

Figure 2: The transmission spectrum of the filter that we proposed with its initial structure parameters (A=40nm, r =100nm, D=200nm).

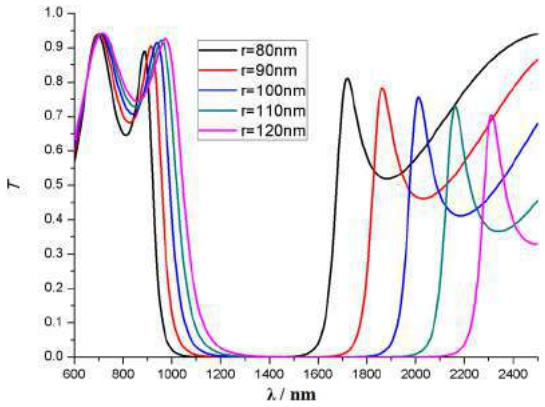

Figure 3: The transmission spectrum of this filter with the increase of r (A=40nm, D=200nm).

4.2. Influence of the structure parameter D on the transmission characteristics

When only changing D and keeping the parameter r and A the initial value the same (r=100nm, A=40nm), the transmission spectrum of the filter appears slight red shift with the increase of D, as shown in Figure 4. And with the increase of D, the depression at the short-wave is getting deeper and deeper; the bandwidth of the passband at the short-wave and the stopband are almost unchanged; the drop degree of the passband at the long-wave slows down.

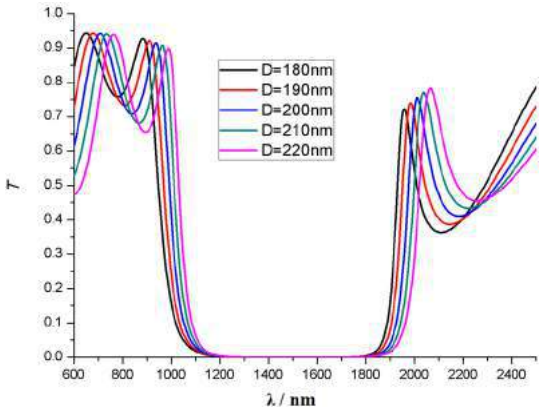

Figure 4: The transmission spectrum of this filter with the increase of D (r=100nm, A=40nm).

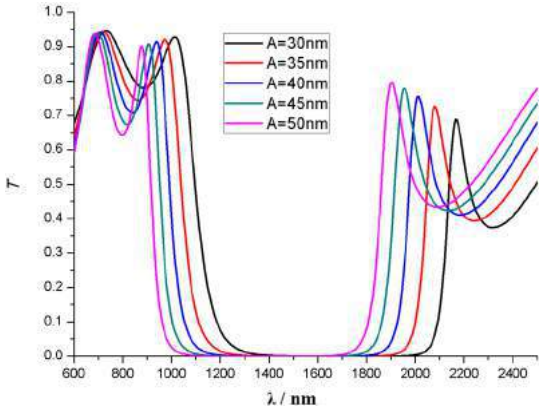

Figure 5: The transmission spectrum of this filter with the increase of A (r=100nm, D=200nm).

4.3. Influence of the structure parameter A on the transmission characteristics

When only changing A and keeping the parameters r and D the initial value unchanged (r=100nm, D=200nm), the transmission spectrum of the filter appears obvious blue shift, as shown in Figure 5. With the increase of A, the depression of the passband at the short-wave is getting deeper and deeper. The bandwidth of the passband at the short-wave decreases and the stopband's almost keeps unchanged; The drop degree of the passband at the long-wave grows up.

Finally, the effects of the structure parameters r, D, and A on the transmission characteristics of the filter are explained. First, the semi-circular cavity and the rectangular aperture can be treated as a "magnetic container". Here, the effective index of the rectangular aperture can be larger than the effective index of the semi-circular cavity and air. So, the waves will flow into "magnetic container" due to the higher effective index of the rectangular aperture, when the

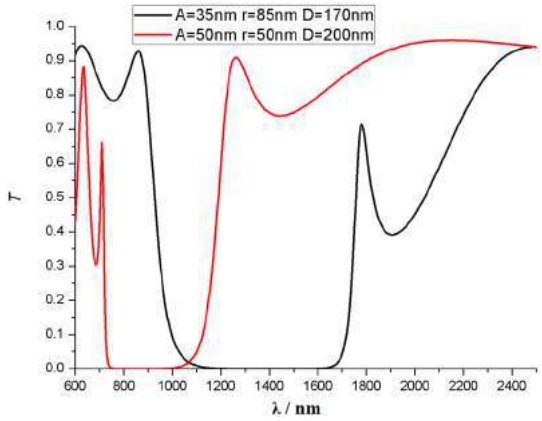

Figure 6: The transmission spectra of the optimized structures.

SPPs waves propagate along the waveguide. And the effect of "magnetic container" causes that the SPPs waves experience a longer propagation length compared with the bare resonator [18, 19]. With the increase of the structure parameters r and D, the red shift of the transmission spectrum is due to the increase of the effective propagation length of the SPPs waves in the MIM filter. Since the parameter r is the parameter of the semi-circular cavity and parameter D is the distance between centers of the three semicircular cavities, so, when increasing r and D to the same degree, the increase of the effective propagation length caused by the semi-circular cavity area with the increase of r will be much greater than that caused by the parameter D. And this is the reason why the red shift of Figure 3 is more visible than that in the Figure 4. At last, we explain the influence of the parameter A on the transmission spectrum. At the same incident wavelength, the effective refractive index of this structure decreases with the increase of the structure parameter A and the resonant wavelength becomes longer with the increase of the effective refractive index of this system [19]. Consequently, with the increase of the structure parameter A, the resonant wavelength of the system moves to the short-wave and the transmission spectrum appears blue shift.

5. Optimization of the structure parameters and the simulation results

First of all, this filter is designed to be used in the telecommunication regime and to control the three optical communication windows on and off. From Section 4, we can learn the different effects of parameters r, D, A on the transmission spectrum. The parameters r, D and A have an effect on the depression of the passband at short-wave. Besides, the parameter r and A have a great influence on the bandwidth of the passband and stopband, while the parameter D has little effect on it. In view of these rules, the tunable parameters can be optimized to get the optimized results,

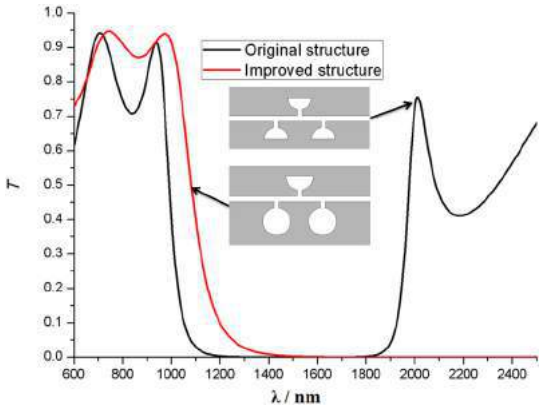

Figure 7: Comparison of transmission spectrum of the improved MIM structure and the original structure filter.

as shown in Figure 6. When the tunable parameters r, D and A are set as 35nm, 85nm and 170nm, respectively, the transmission spectrum of this optimized structure is shown as the black curve. Here, the first optical communication window (850nm) is at the passband of this optimized structure at the short-wave and the center position of the stopband is in the vicinity of 1400nm, which is a good balance between the second and the third optical communication windows. With the decrease of r or the increase of A, the transmission spectrum of this filter is greatly shifted to the direction of the short-wave. And taking advantage of this nature, the tunable parameters are set as A = 50 nm, r = 50 nm and D = 200 nm to obtain another optimized structure shown in the red curve. The first optical communication window is located in its stopband and the second and third optical communication windows are in its passband. Thus, the optimized results are achieved and the control of the three optical communication windows is realized, too.

6. Single functional filter

When keeping the initial tunable structure parameters unchanged (A = 40 nm, r = 100nm, D = 200nm), the left and right semi-circular cavities of the original filter structure are changed to the disk to form an improved MIM structure. As shown in Figure 7, compared with the transmission spectrum of the original structure filter, the transmittance of the improved filter no longer grows up at the wavelength greater than 1800 nm. The transmittance of its passband is higher and the depression of it is very shallow. So, it can be used as a single-functional (band-pass) filter.

7. Conclusions

In summary, a symmetrical semi-circular cavity MIM waveguide structure filter based on SPPs is proposed and studied. This filter has the characteristics of multi-function, tunable and wide bandwidth, etc. By adjusting the structure parameters, the transmission characteristics of the three communication windows (850nm, 1310nm, 1550nm) at optical telecommunication regime can be controlled and the optimized structures and its corresponding transmission spectra can be obtained. Finally, a single-functional (band-pass) filter is achieved with the improved MIM structure. This series filters will have potential engineering application values in micro-nano optics integrated devices, especially in optical fiber communication.

Combinational Analysis of 2D metamaterials using AFM-IR and s-SNOM

Eoghan Dillon[1*], and Hyuk Woo Jun[2]

Abstract: This talk will focus on techniques and instrumentation for measuring chemical and optical properties of 2D materials with nanometer scale spatial resolution. Conventional infrared spectroscopy is one of the most widely used tools for chemical analysis, but optical diffraction limits its spatial resolution to the scale of many microns. Atomic force microscopy (AFM) enjoys excellent spatial resolution, but has historically lacked the ability to perform robust chemical analysis. This presentation will discuss two techniques (1) AFM-based infrared spectroscopy and (2) scattering scanning near field optical microscopy (s-SNOM). Both of these techniques overcome the diffraction limit, providing the ability to measure and map chemical and optical properties with nanometer scale spatial resolution. As complementary techniques, AFM-IR and s-SNOM together provide an unrivaled capability to perform nanoscale chemical analysis on a diverse range of organic, inorganic, photonic and electronic materials. This talk will focus on the applications of both AFM-IR and s-SNOM to the characterization of a variety of 2D materials, including, nanoantenna arrays and 2D metasurfaces. The applications of nanoantennas are very diverse, ranging from sensing to energy conversion. The ability to measure and tune the resonance structures of these antennas is of vital importance to the construction of accurate and reliable devices. s-SNOM can be readily used as a tool to image the antenna resonance nodes when illuminated at the correct wavelength. In addition to the ability to collect high resolution images of optical phenomenon, the nanoIR2-s provides the capability to spectrally probe nanoscale surface features. This work will show the s-SNOM spectra collected on bar antennas, with the antenna resonance can be clearly resolved, in good agreement with theoretical predictions. AFM-IR and s-SNOM have been used in combination to investigate the role of chirality in the origins of circular dichroism in 2D nanoscale materials. Fully two-dimensional (2D) metamaterials, also known as metasurfaces, comprised of planar-chiral plasmonic metamolecules that are just nanometres thick, have been shown to exhibit chiral dichroism in transmission (CDT).Theoretical calculations indicate that this surprising effect relies on finite non-radiative (Ohmic) losses of the metasurface. Until now this surprising theoretical prediction has never been experimentally verified because of the challenge of measuring non-radiative loss on the nanoscale. s-SNOM is used to map the optical energy distribution when the structures are exposed to RCP and LCP IR radiation while AFM-IR was then used to detect the drastically different Ohmic heating observed under RCP and LCP radiation. For the first time it has been conclusively established the circular dichroism observed in 2D metasurfaces is attributed to handedness dependent Ohmic heating.

Enormous Nonresonant THz Field Enhancement with Nanoslits

Om Krishna Suwal and Dai-Sik Kim

Centre for Atom Scale Electromagnetism, Department of Physics and Astronomy, Seoul National University, Seoul 08826, Republic of Korea.

*Corresponding author: dsk@phya.snu.ac.kr

Abstract- Transmission of Terahertz (THz) electromagnetic wave through a substrate is encumbered because of scattering, multiple reflections, absorption, and Fabry–Perot effects when the wave interacts with the substrate. To exclude the undesired interaction of electromagnetic wave with substrates, we investigated THz transmission through a substrate-free nanoslits. We experimentally realized a nonresonant electromagnetic field enhancement by a factor of almost 10^4 in substrate-free 5-nm gold nanoslits. Our nanoslits yielded over 90% normalized electric field transmission in the low-frequency THz region; the slit width was 5 nm, and the gap coverage ratio was 10^{-4} of the entire membrane, 0.42 mm^2. This large field enhancement was attributed to gap plasmons generated by the THz wave, which squeezes the charge cross-section, thus enabling highly dense oscillating charges and strong THz field transmission from the nanoslits.

Previously, we have demonstrated enhancement factors of nearly three orders of magnitude with a 70-nm-wide slit[1]. We assumed that a major obstacle is the substrate, which decreases the transmission and creates undesirable interactions between the gap and the substrate. Here, we demonstrate the experimental realization of nearly four orders of field enhancement by using gold nanoslits on a Si_3N_4 membrane[2]. Our nanoslits had a 5-nm gap that extended up to the entire membrane, with a length of 0.65 mm that was sufficient to surpass the cut-off THz frequency. This structure enabled us to achieve near-maximum field enhancement in the THz region. We observed a straight 1/f-dependent field enhancement factor, as shown in Fig. where f is the frequency. In our case, the gap width was a million times smaller than the wavelength; however, the length of the slit was of the same order as the wavelength. Our experimental results indicates the field enhancement increased by approximately 15 fold at 0.14 THz when Si substrate was removed out from the same nanogap sample (Fig.). Some irregularities in transmission curve was also observed because of the grating modes when the slit array diffracted the incident radiation into the sample plane. We explained the results by poor coupling of THz wave among the evanescent modes because of higher refractive index of substrate.

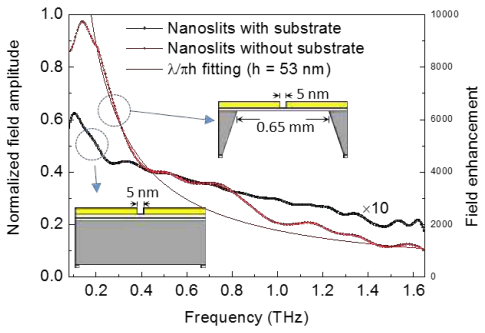

Figure: Normalized field amplitude before and after substrate etched out. The normalization was done with Si substrate and free space for before and after substrate. 1/f fitting seems to be well fitted for the measurement without

Anomalous extinction in lossless index-matched terahertz nanogaps

Abstract- Metamaterials are capable of allowing incident wave to neither transmit nor reflect, leading to a perfect absorption. This phenomenon is usually explained in terms of simultaneous manipulation of electric permittivity and magnetic permeability to be impedance-matched to free space[1]. The energy absorption is conceived to occur inside the supporting dielectrics where the electric field amplitude is large, yet systematic study on the actual energy flow has barely been made.

In this work we observe anomalously large extinction of terahertz waves interacting with sub-30nm nanogap arrays even without any absorbing materials within. Simple, exclusive geometry of our nanogap enables analytic study on the origin of the observed phenomena[2]. We find that destructive interference of the diffracted field from the gap and reflected field from metal leads to a giant reflection dip at the resonance, suggesting that absorption might not be the cause of the observed extinction. Nonlinear transmission measurements and calculations indicate that index-matching effect of silicon substrate leads to higher field enhancement at the gap, in which case the extinction further increases to above 60%. Our study provides new insight into how to analyse transmission and reflection signals from nanostructures, and will therefore be of great interest in absorption enhancement or dielectric sensing applications.

Abstract

This work presents the spectral properties of Fano resonances generated in nonlinear photonic structures with emphasis on optical switching/bistability. The simple photonic structures such as slab waveguide gratings and coupled slab waveguide gratings in which Fano resonances with various quality and asymmetric factors are designed and their characteristics analyzed with a finite-difference time-domain method. We demonstrate the switching/bistable behaviors of the structure at Fano resonance which provides a significant switching intensity reduction compared to the established Lorentzian resonant structures.

1. Introduction

Various applications of Fano resonance, which rely on its high quality factor due to its sharp and asymmetric profile, have been proposed such as filters, modulators, sensors, broadband reflectors, and lasers [1]. In general, the Fano resonant lineshape in the photonic system is given:

$$R(\varepsilon) = F\frac{(\varepsilon+q)^2}{1+\varepsilon^2} \quad (1)$$

where $\varepsilon = 2\frac{\omega-\omega_o}{\Gamma}$, q is an asymmetric factor, ω_o is a resonant frequency, F is a constant factor which describes the degree of asymmetry, and Γ is a resonant linewidth at half-maximum. The Q-factor is defined by the resonant frequency over the resonant linewidth at half-maximum. The Eq. (1) has been widely used to express the spectrum response of Fano lineshape. It suggests that there are exactly one minimum and one maximum in the Fano lineshape. Fig. 1(a) shows the Fano profiles according to the Eq. (1) for several q-factors. The F-factor is chosen for maximum amplitude of lineshape to unity. The lineshapes for special q-factors are shown in the inset. As $|q|\rightarrow\infty$, the transition to the continuum is too weak, so that the lineshape is entirely determined by the transition through the discrete state only with the standard Lorentzian. As q = 0, it describes a symmetric dip, called the inverted Lorentzian lineshapes. Other cases of q-factors are also shown in Fig. 1 (a), as q-factor changes, the degree and asymmetry of lineshape change and the actual resonant frequency may lie somewhere between the peak (maximum response) and the dip (minimum response) of the asymmetric lineshape. For q = 1, the resonant frequency locates exactly at half of the distance between the peak and dip. In addition, when q-factor changes sign, the reversible of Fano lineshape is also plotted. As a consequence, both changing of amplitude and sign of q- factor hold significant implications for the promising photonic device applications such as sensitive optical filters, lasers, biosensors,

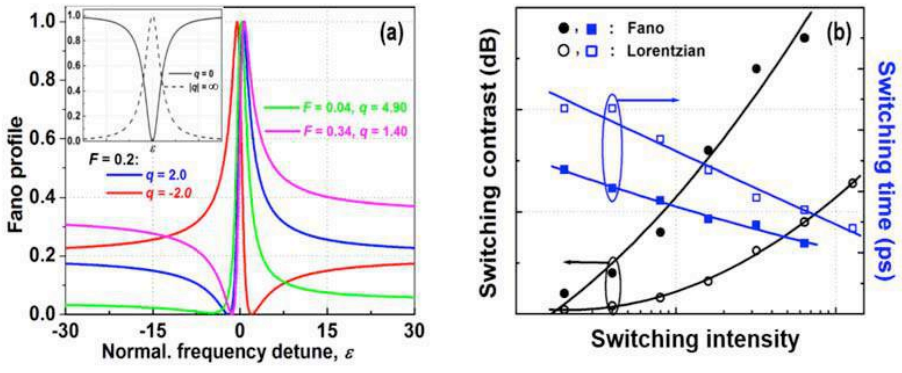

Fig.1. (a) Fano profiles with the formula $F*(\varepsilon + q)^2/(\varepsilon^2 + 1)$ for various values of the asymmetry factor q. The special cases are shown in the inset (Lorentzian lineshapes). (b) Illustration of switching parameters, e.g. switching contrast and switching time vs. switching intensity, based on Fano (solid circle and square dots) and Lorentzian (hollow circle and square shapes) lineshapes with the same of Q-factor and frequency detuning from the resonant peak [1]. The lines are the guides to the eye.

and also switching/bistability.

Recently, Fano resonance has been explored in our works of slab waveguide gratings and optical switching/bistability characteristics based on Fano resonance may provide more bistable switching efficiency than that based on Lorentzian resonance in nonlinear slab waveguide gratings [2,3]. With a given *Q*-factor, asymmetric profiles can provide sharper features than Lorentzian and hence allow more efficient input intensity. Based on the achieved results, Fig. 1(b) shows the illustration of switching parameters, e.g. switching contrast and switching time vs. switching intensity, based on Fano and Lorentzian lineshapes with the same of *Q*-factor and frequency detuning from the resonant peak [4]. In the following sections, we present two examples of Fano resonances in the grating and coupled grating structures and its applications for bistability/switching.

2. Bistability in the nonlinear slab grating with narrow slits

Fano resonances can be simply obtained by using a grating structure with narrow slits as depicted in Fig. 2(a). In this case, a grating structure whose guiding layer is chalcogenide glass (As_2S_3, n = 2.38) with a thickness of 220 nm on a thick glass substrate (n = 1.5). The grating slit aperture (*w*) is formed by a rectangular corrugation in As_2S_3 waveguiding layer with the depth and periodicity (Λ) of 220 nm and 860 nm, respectively. A normally incident wave with transverse electric (TE) polarization is used. Fig. 2(b) shows the calculated linear reflection spectra for three gratings with various slit widths of *w* = 15 nm, *w* = 30 nm, and *w* = 45 nm. Ultra narrow slit (~12 nm) can be fabricated [5], but it is at the border of current electron-beam lithography. In our optimized Fano resonance-based grating design, *Q*-factor of 14,861 can be achieved with the slit width *w* of 15 nm and the resonant peak at 1563.1 nm. As the slit width *w* increases, the resonant wavelength shifts to short wavelength and the *Q*-factor of Fano resonance decreases dramatically. For instance, with the slit width *w* of 45 nm, the resonant wavelength and *Q*-factor are 1516.0 nm and 630, respectively. It means that as the slit width increases, the waveguide mode gets much leaky and hence the linewidth becomes broader leading to a decrease of *Q*-factor. The inset of Fig. 2(b) shows the electric field distributions of the resonances known as TE_0 modes.

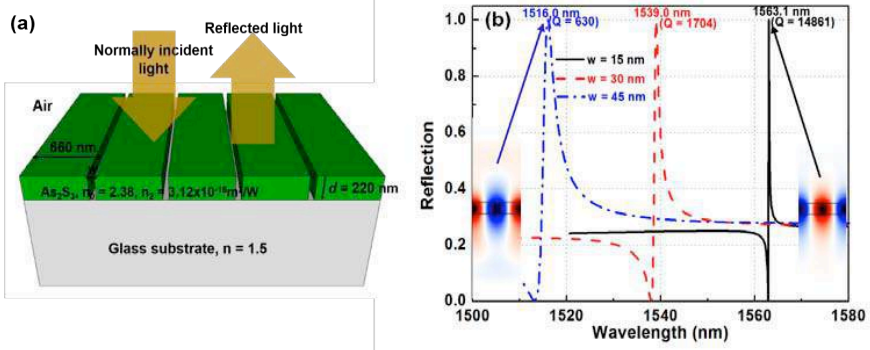

Fig. 2. (a) Sketch of nonlinear grating structure with narrow slits under normally incident light. (b) Reflection spectra for various slit widths (*w*). The insets in (b) show the field distributions at resonances.

In order to see all-optical bistable switching behaviors in nonlinear grating structure with narrow slits, we excite an incident CW source with suitable operating wavelength on the surface of the structure. In general, the operating wavelength is chosen approximately at the center of the all-optical bistability region. In our calculations of all-optical bistable switching for nonlinear grating structure with narrow slits, we choose the operating wavelengths at 50% and 1/e reflection, which locate in the bistability region. In nonlinear calculations, the third-order nonlinear coefficient of As_2S_3 is $n_2 = 3.12\text{x}10^{-18}$ m^2/W [6]. Fig. 3 shows a dependence of reflection on the incident flux intensity of the all-optical bistable switching in the nonlinear grating structure with various narrow slits of (a) *w* = 15 nm, (b) *w* = 30 nm, and (c) *w* = 45 nm, respectively, for the operating wavelength at 50% reflection. It can be seen that the all-optical bistable switching behaviors are formed in all designs. The calculation technique to achieve the bistability behavior was discussed in [2]. In fact, the all-optical bistable switching behaviors have two switching points at the increasing (S_1) and decreasing (S_2) input intensities. The present of S_1 and S_2 in these cases are due to the very short distance between the depths and peaks of linear reflection spectra. The switching times are not mentioned in this work. The incident intensity for switching can be estimated as the input intensity for which the reflection decreases abruptly in the blue and red curves. For example, in Figs. 3(a-c), the estimated switching intensities are 5.6 MW/cm^2, 366.1 MW/cm^2, and 2548.8 MW/cm^2 (at point S_1) and 2.0 MW/cm^2, 181.1 MW/cm^2, and 1306.4 MW/cm^2 (at point S_2) and *Q*-factors of 14861, 1704, and 630 for the slit widths *w* = 15 nm, 30 nm, and 45 nm, respectively. Fig. 3(d) shows the all-optical bistable switching behavior for the slit width *w* of 15 nm with the operating wavelength at 1/e reflection. As seen in Fig. 3(d), the estimated switching intensities are about 25.2 MW/cm^2 at point S_1 and 3.8

MW/cm^2 at point S_2. Compared to the result in Fig. 3(a), it can be seen that the more different the operating wavelength from the resonant wavelength, the higher the switching intensity and the broader the bandwidth of bistability region will be. Because, the detuning of the operating wavelength corresponds to the broad bandwidth and thus the high amount of the resonance shift is required to change the state. In addition, as long as the input intensity exceeds a certain value, the low-reflection state in the bistability region can be maintained. For example, for the slit width w of 15 nm, the bistability regions (between S_1 and S_2) are from 5.6 MW/cm^2 to 2.0 MW/cm^2 and from 25.2 MW/cm^2 to 3.8 MW/cm^2 for the operating wavelengths at 50% and 1/e of reflection, respectively. The all-optical bistable switching behaviors of other slit widths are also shown the same tendency.

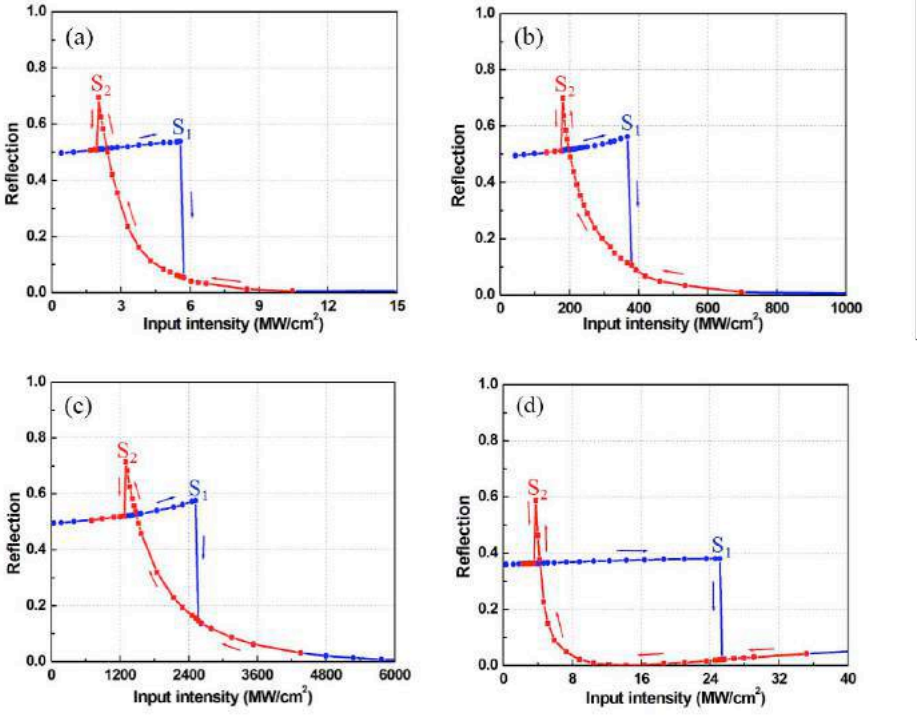

Fig. 3. All-optical bistable switching in the nonlinear grating structure depicted in Fig. 2(a) with the operating wavelength at 50% reflection. (a) w = 15 nm, (b) w = 30 nm, (c) w = 45 nm, (d) operating wavelengths at 1/e reflections for w = 15 nm.

3. Optical bistability in coupled slab waveguide gratings

As presented above, bistability/switching behaviors can be obtained based on Fano resonances in nonlinear slab grating with very narrow slits. The switching intensity depends on Q-factor and the shape of Fano resonances. In general, the dependence of switching intensity and Q-factor is $1/Q^2$. To achieve high Q-factor, the slit width w must be decreased. Due to fabrication limitation, it is a big challenge to reduce the slit width w smaller than 12 nm. High Q-factor, however, can be achieved if two coupled identical slab waveguide gratings facing each other with a gap-distance of d and horizontal shifted-alignment of s is shown in Fig. 4. Each slab waveguide grating supports the Fano resonance, where key structural parameters are defined as the guiding layer with a thickness (h) of 220 nm on a thick glass substrate. Since the Q-factors of Fano resonances in coupled slab waveguide gratings are very sensitive to the gap-distance d and horizontal shifted-alignment s, we treat the Fano resonances in both cases of changing the gap-distance d and horizontal shifted-alignment s as follows:

3.1. Perfect alignment

In the case of perfect alignment (s = 0) of two identical slab waveguide gratings, the coupling strength (determines Q-factor) and resonant wavelength of the system can be easily tuned by changing the gap-distance d. When two slab waveguide gratings are coupled, there are two resonant wavelengths that we called first (F1) and second (F2) Fano resonances. Because of our interest focusing on the F2 shape, Fig. 5(a) shows the reflection spectra at F2 for various the gap-distances d. The gap-distance d is optimized to have the peak (maximum reflection) and depth (minimum reflection) at the resonance close to 1 and 0, respectively. The gap-distance d is important, because the photons can tunnel between them, and then the scattering effect will happen, hence the peak and depth will be not perfect unity and zero in some cases due to scattering loss [7]. This mechanism, therefore, no longer requires the long gap-distance d to achieve high reflectivity and sensitivity. For

the grating width w = 30 nm, the gap-distance d ($d \leq$ 300 nm) is found close to an optimal value. In other words, for a gap-distance d as small as 300 nm, the Fano resonances with high sensitivity can be still existed. As increasing the gap-distance d, the F2's resonant peak shifts to the short wavelength and its Q-factor increases. The resonant peaks, estimated Q-factors, q-factors, and F factors for F2 resonances of the perfect alignment coupled two slab waveguide gratings for various gap-distances d are shown in Table 1. With the gap-distance 50 nm $\leq d \leq$ 300 nm, the resonant wavelengths are in the 1552.2 nm - 1684.9 nm range. The Q-factor increases as the gap-distance d increases due to the long distance of Fabry-Perrot (FB) resonator formed between two slab waveguide gratings [7]. High FP resonator's Q-factor makes the leaky mode from the outside hard to couple into the resonator. It means that as the gap-distance d increases, the Fabry-Perrot mode gets little leaky and hence the linewidth becomes narrower leading to an increase of Q-factor. The Q-factors are 2104, 2543, 3759, and 8522 for the gap-distance d of 50 nm, 100 nm, 170 nm, and 300 nm, respectively. Further importance, as gap-distance d increases, the asymmetric factor q decreases and the reflectivity of side-bands (*RSB*) increases due to the strongly transition to the continuum. Hence, q-factor becomes a function of the R*SB* and Q-factor, $q \rightarrow q$(*RSB*,Q-factor). Our concentration focuses on the positive asymmetric factor q as small as possible. The exact definition for q-factor is not easy to find in the arbitrary photonic systems.

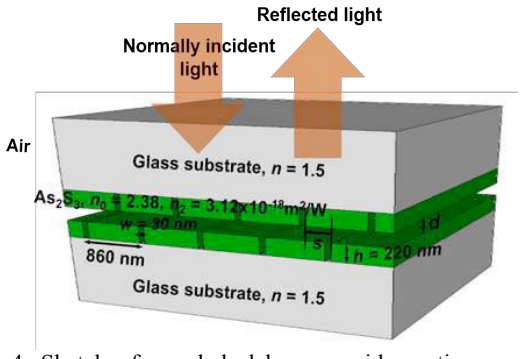

Fig. 4. Sketch of coupled slab waveguide gratings under normally incident light. The gap-distance d and horizontal shifted-alignment s are tuned for exciting Fano resonances.

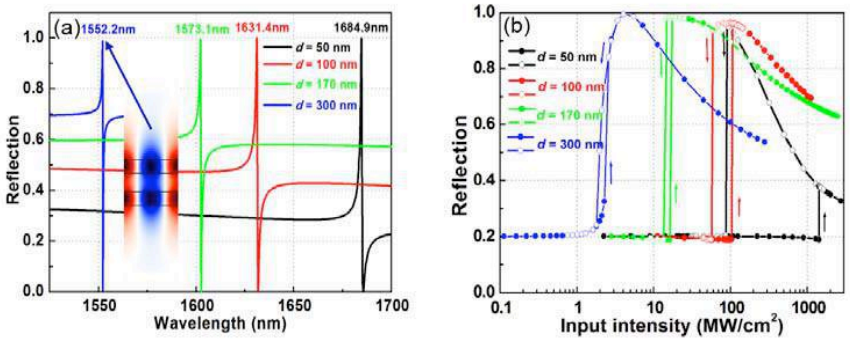

Fig. 5. (a) Reflection spectra of the coupled slab waveguide gratings depicted in Fig. 4 with s = 0. The calculations are done for TE polarized light where electric-field is along to the As_2S_3 strips. The inset shows field distribution at F2 resonance. (b) Bistability curves of the coupled gratings for various gap-distances d of 50 nm, 100 nm, 170 nm, and 300 nm, respectively, with operating wavelength at 20% reflection.

Table 1. Resonant peaks and Q-factors of the coupled slab waveguide gratings for various gap-distances d.

Gap-distance d (nm)	50	100	170	300
Resonant peak (nm)	1684.9	1631.4	1573.1	1552.2
Q-factor	2,104	2,543	3,759	8,522
q-factor	1.696	1.110	0.835	0.655
Switching intensity (MW/cm^2)	1427.1	104.1	16.2	2.2

Fig. 5(b) shows the calculated bistable behaviors of the perfect alignment coupled slab waveguide gratings for the gap-distance d of 50 nm, 100 nm, 170 nm, and 300 nm. Bistable behaviors are clearly observed. In each bistable curve, the incident intensity for switching can be estimated as the input intensity for which the reflection increases abruptly in the dotted solid curve. The estimated switching intensities are 1427.1 MW/cm^2, 104.1 MW/cm^2, 16.2 MW/cm^2, and 2.2 MW/cm^2 corresponding to the quality factors Q = 2104, 2543, 3759, and 8522, and asymmetric factor q = 1.699, 1.110, 0.835, and 0.655 for the gap-distances d = 50 nm, 100 nm, 170 nm, and 300 nm, respectively. In contrast to the Lorentzian resonance, these Fano-based results do not follow the $1/Q^2$ dependence rule of the switching intensity [8-11]. The switching intensity is also influenced by the asymmetric factor q. The asymmetric factor q relates to the Q-factor and the reflectivity of the side-bands. For example, the Q-factors and switching intensities are (2104, 1427.1 MW/cm^2), (2543, 104.1 MW/cm^2), and (8522 and 2.2 MW/cm^2) for the gap-distances d of 50 nm, 100 nm, and 300 nm, respectively. While the Q-factors increase gradually, the switching intensities dramatically decrease due to a reduction of asymmetric factors q. The Q-factor increases 4.0 times but the switching intensity decreases 648.7 times.

We next consider the operating wavelength influence on the switching intensity. We keep the gap-distance d of 300 nm, the optical bistable behaviors for operating wavelengths at 20%, 40%, and 60% reflections corresponding to the shifted-wavelength ($\Delta\lambda$) of 0.088 nm, 0.222 nm, and 0.833 nm from the depth. As seen in Fig. 6, the switching intensities are 2.2 MW/cm^2, 9.7 MW/cm^2, and 140.5 MW/cm^2 for the operating wavelengths at 20%, 40%, and 60% reflections, corresponding to the operating wavelengths of 1552.319 nm, 1552.453 nm, and 1553.064 nm, respectively. It is seen that as we change the operating wavelength ($\Delta\lambda$ = 0.745 nm) from 20% to 60% reflections, the switching intensity increases from 2.2 MW/cm^2 to 140.5 MW/cm^2 (increasing 63.9 times).

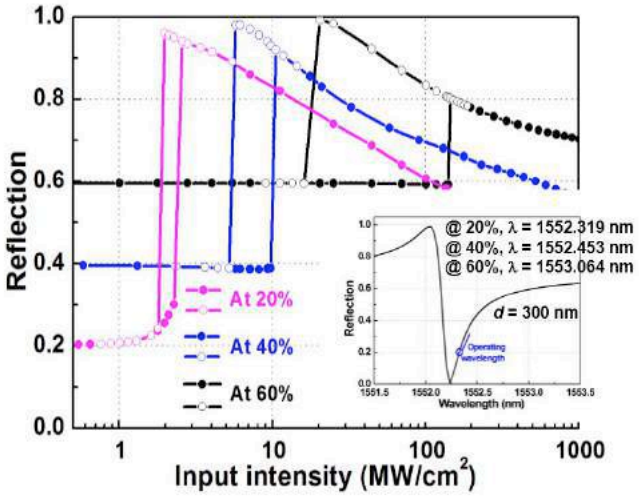

Fig. 6. Bistability behaviors for the gap-distance d = 300 nm. The switching intensities are 2.2 MW/cm^2, 9.7 MW/cm^2, and 140.5 MW/cm^2 for the operating wavelengths at 20%, 40%, and 60% reflections, respectively.

3.2. Horizontal shifted-alignment

Next, we consider coupled slab waveguide gratings with horizontal shifted-alignment. Various shifted-alignment coefficients s are examined while the gap-distance d of 300 nm is fixed as an optimal value to achieve the Fano resonance with high sensitivity and high Q-factor. Our calculated linear reflection spectra for the gratings with various horizontal shifted-alignments s = 100 nm, 150 nm, and 430 nm as shown in Fig. 7 (a). For comparison purpose, the linear reflection spectrum of coupled slab waveguide gratings with perfect alignment is also plotted. The horizontal shifted-alignment s is supposed to mainly change the phase retardation between two slab waveguide gratings. If horizontal shifted-alignment s is 430 nm (half-period), the reflection spectrum is reversed to the case of perfect alignment. So it may cause a phase retardation change of π. The deviations from either of the coupled slab waveguide gratings lead to high Q-factors' states [12].

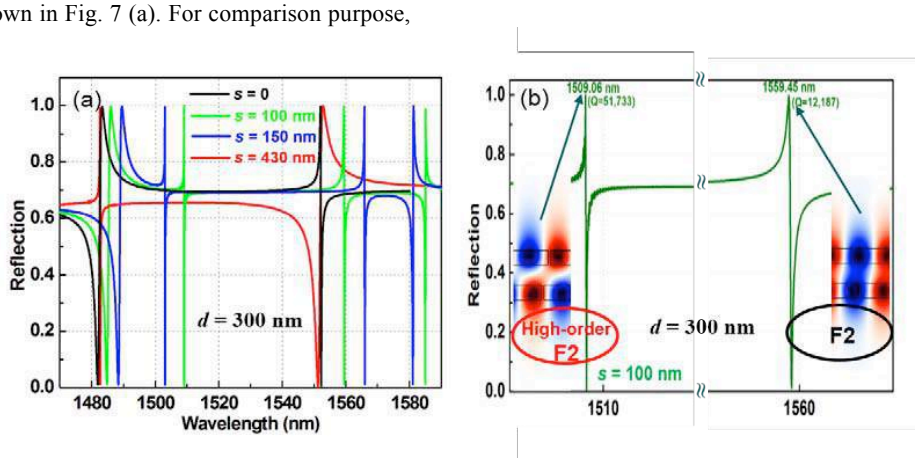

Fig. 7. (a) Full reflection spectra of the coupled slab waveguide grating for various horizontal shifted-alignments and (b) the enlarged F2 regions for horizontal shifted-alignments s of 100 nm. The gap-distance d is fixed at 300 nm.

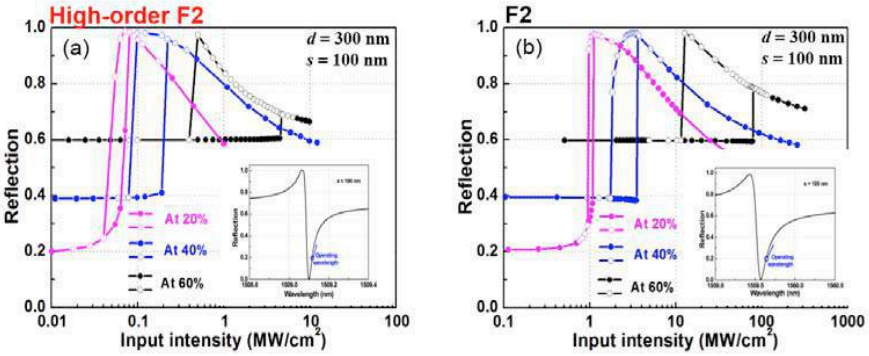

Fig. 8. The bistability behaviors of high-order F2 (a) and F2 (b) resonances for various operating wavelengths of the coupled slab waveguide gratings for the horizontal shifted-alignment *s* of 100 nm.

Table 2. The resonant peaks, *Q*-factors and switching intensities for the horizontal shifted-alignment *s* = 100 nm of the coupled slab waveguide gratings for high-order F2 and F2 Fano resonances.

		High-order F2	F2
Resonant peak (nm)		1509.06	1559.45
Q-factor		51,733	12,187
Switching intensity (MW/cm^2)	20%	0.06	1.08
	40%	0.19	3.43
	60%	4.43	79.97

In our case, we consider the horizontal shifted-alignment *s* of 100 nm and 150 nm and the reflection spectra are plotted in Fig. 7 (a). There are four resonant peaks in each reflection spectrum of horizontal shifted-alignment *s* of 100 nm and 150 nm. The reflectivity of side-bands for all cases of perfect and horizontal shifted-alignment does not change. The reflectivity of side-bands is fixed at around 70%. There exist two Fano resonant F2 shapes, as shown in Fig. 7(b). The F2 and high-order F2 of Fano resonances are located at the longer and shorter wavelengths, respectively. The field distributions and *Q*-factors at resonances are shown in the insets of Fig. 7(b). As the results, the mirror symmetry of the system is broken and brings mainly change in the phase retardation between slab waveguide gratings. It results the higher *Q*-factors. Comparing the field distributions of the perfect alignment (inset of Fig. 5(a)) and the horizontal shifted-alignment cases (insets of Fig. 7(b)), we note that the horizontal shifted-alignment allows the excitation of the state of high-order F2 with a different local modal profile of F2. As seen in Fig. 7(b), the *Q*-factor of high-order F2 resonance is higher than that of F2 resonance. The *Q*-factors for F2 and high-order F2 are 12,187 and 51,733 for the horizontal shifted-alignment *s* = 100 nm. The inset of Fig. 7(b) shows the electric field distributions at F2 and high-order F2 resonances. Table 2 summarizes the resonant peaks, Q-factors and switching intensities for the horizontal shifted-alignment s = 100 nm of the coupled slab waveguide gratings for high-order F2 and F2 Fano resonances.

The optical bistable behaviors for various operating wavelengths of the high-order F2 and F2 resonances in the case of the horizontal shifted-alignment *s* = 100 nm are shown in Figs. 8 (a) and 8(b), respectively. As seen in Fig. 8(a), the high-order F2 case, the switching intensities are 0.06 MW/cm^2, 0.19 MW/cm^2, and 4.43 MW/cm^2 for operating wavelengths at 20%, 40%, and 60% reflections. It is approximately two orders increasing of switching intensity when operating wavelength changes from 20% to 60%. In Fig. 8(b), for the F2 case, 1.08 MW/cm^2, 3.43 MW/cm^2, and 79.97 MW/cm^2 for operating wavelengths at 20%, 40%, and 60% reflections are shown. From Figs. 8(a) and 8(b), the high-order F2 and F2 resonances based the horizontal shifted-aligment, for the operating wavelength at certain reflection. For example, the operating wavelength at 20% refection, *Q*-factors and switching intensities are (12,187 and 1.08 MW/cm^2) and (51,733 and 0.06 MW/cm^2) for the F2 and high-order F2 resonances, respectively. At the F2 resonance, the *Q*-factor is 4.24 times smaller and the switching intensity is 18.0 times higher than those at high-order F2 resonances. In case of operating wavelength at 60% refection, the switching intensity at the F2 resonance is 79.97 MW/cm^2. It is 18.95 times higher than that at the high-order F2 resonances corresponding to the switching intensity of 4.43 MW/cm^2. The other horizontal shifted-alignment *s* are also treated and not shown here, show the same tendency.

Since the *Q*-factors and switching intensities accordingly of the coupled nonlinear gratings are dependent on the horizontal shifted-alignment. In this work, we do not pay much attention on the optimization to achieve the highest *Q*-factor and lowest switching intensity. We instead focus on demonstrating the possibility to significant enhance the *Q*-factor and reduce the switching intensity by using the horizontal shifted-alignment. Based on the enhancement of *Q*-factor and reduce switching intensity accordingly by the horizontal shifted-alignment, the system will undoubtedly facilitate the development of new optical bistable devices towards high efficiency of switching intensity.

4. Conclusion

In conclusion, the Fano resonances have been explored in nonlinear photonic structures such as slab waveguide grating and coupled slab waveguide gratings. The optical

switching/bistability characteristics based on Fano resonance provide more bistable switching efficiency than that based on Lorentzian resonance in nonlinear slab waveguide gratings. We believe that our design and numerical investigation have been a useful guideline for the implementation of Fano resonant configurations for optical devices.

Abstract

There are recent efforts toward the integration of plasmonic nanostructures with graphene, such as to enhance its light-matter interaction which can result in novel optoelectronic technologies. The present work describes numerical efforts to optimize a plasmonic dimer geometry and materials, which results in strongly enhanced electromagnetic near fields that can be coupled with a graphene layer. We used FEM and DDA simulations to understand the details of the coupling mechanism, and also investigate the effect of directionality of the light beam on the plasmonic enhancement.

1. Introduction

One way to improve the light-matter interaction in graphene beyond its intrinsic 2.3% absorption [1] efficiency is to use plasmonic nanostructures in close proximity [2–6]. In a recent effort from our group, we have demonstrated a novel scheme of stacking two arrays of silver nano particles, separated just by a single layer of graphene [7]. The fabrication method was based on layer-by-layer shadow evaporation of different materials, which in the past [8] were used to fabricate three-dimensional arrays of plasmonic nanoparticles separated by a dielectric spacer. The crucial innovation was to use Graphene as the dielectric spacer layer, which allowed placement of two planar arrays of silver nanoparticles separated by 0.34 nm, which is the thickness of single layer graphene. This arrangement gave rise to intense electromagnetic field enhancement at the location of the spacer layer, which resulted in strongly enhanced Raman scattering, as well as a high photocurrent in graphene.

The purpose of this paper is explore design possibilities such as to maximize the field enhancement at the location of graphene in a dimer configuration. Orienting the dimers with respect to the angle of the incident light, as per our simulations, show little or no dependence on the direction of the electric field polarization relative to the dimer axis. This is related to the large electromagnetic retardation [9] in the relatively big particles (radius 70 nm) considered here. The study also indicates that silver gives a better enhancement as compared to gold in the visible range. The numerical simulation assumes the dimer gap to be air. Advanced simulation method using discrete dipole approximation (DDA) [10] reveals that introducing a dielectric to simulate a graphene layer in the dimer gap instead of air has relatively small effect in our field enhancement estimates.

2. Isolated Vs Single Particle

FEM based simulations using a commercial software COMSOL is used to simulate two silver nano particles (diameter=140 nm) separated by a gap of 0.34 nm (thickness of a single layer graphene). The dielectric constants of gold and silver are taken from Johnson and Christy [11]. The surrounding medium is considered to be air. Maximum net electric field enhancement $|\mathbf{E}_{total}/\mathbf{E}_{incident}|^2$ is calculated in a plane perpendicular to the dimer axis, where the graphene spacer lies in our actual experimental system [7]. The electromagnetic (EM) wave propagates along the dimer axis and the polarization is perpendicular to it.

From fig. 1(A) and (B), it can be observed that compared to an isolated nanoparticle, the magnitude of near field enhancement in case of a dimer is about 5 orders of magnitude higher, at their resonance wavelength. Also, the near field is highly confined to a tight spot in the dimer gap. Fig.1 (C) compares the maximum enhancement of a dimer to an isolated particle across various wavelengths. The field enhancement for the dimer is calculated in the dimer gap. Across all wavelengths, the enhancement for a dimer is orders of magnitude higher. The maximum enhancement peaks at the resonance frequencies: 435 nm (quadrupolar resonance) and 510 nm (dipolar resonance) for the dimer and at 365 nm (quadrupolar) for the single particle case. Due to plasmon interactions the resonance peak is red shifted for a dimer as compared to the isolated particle case.

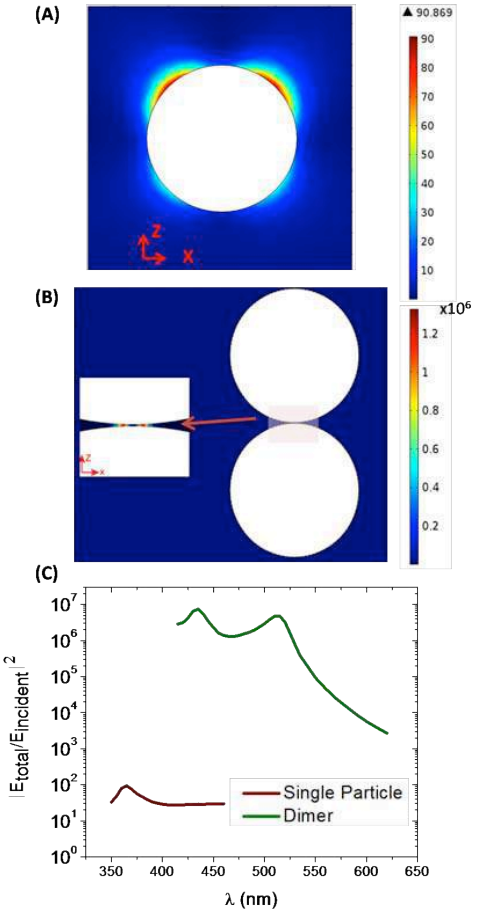

Figure 1: (A) Near field distribution around a single Ag particle; at resonance (365 nm), max($|\mathbf{E_{total}}/\mathbf{E_{incident}}|^2$) is 90.86. (B) Near field distribution around a Ag dimer; at the quadrupolar resonance (435 nm), max($|\mathbf{E_{total}}/\mathbf{E_{incident}}|^2$) is in the order of 10^6. (C) max($|\mathbf{E_{total}}/\mathbf{E_{incident}}|^2$) compared between a dimer and an isolated particle.

3. Dimer Orientation

Heeg et al. have measured the field enhancement in a dimer gap by measuring the SERS signal from a graphene layer on top of two adjacent plasmonic gold nano particles [12]. We compare field enhancement in their configuration to that of our experimental system [7]. We again consider a silver dimer (diameter = 140 nm) separated by a 0.34 nm gap. In the first case, the electromagnetic (EM) wave is propagating perpendicular to the dimer axis while the electric field is polarized parallel to the dimer axis. The enhancement is calculated at the plane, as indicated by the red dotted line in fig. 2 (A), which is similar to the experiments in ref [12]. In the second case, fig. 2 (C), EM wave is propagating parallel to the dimer axis, while the electric field is polarized perpendicular to the dimer axis, which is similar to our experiments [7]. Fig 2 (B) and (D) gives the field distribution for the two orientation in fig. 2 (A) and (C) respectively. It can be observed that in the second case, (orientation in fig. 2(C)) the field is more tightly confined to a very small area. Fig. 2 (E) plots the field enhancement across different wavelengths for both the cases. It can be clearly seen that the enhancement is six orders of magnitude greater in the second case. The arrangement of the dimer in the first case is easily achievable experimentally and has been demonstrated by several groups in the past [3,12]. But the second case where the near field is harnessed right at the dimer gap is extremely difficult to achieve. We were able to achieve such a unique configuration experimentally by the combination of several deposition techniques [7].

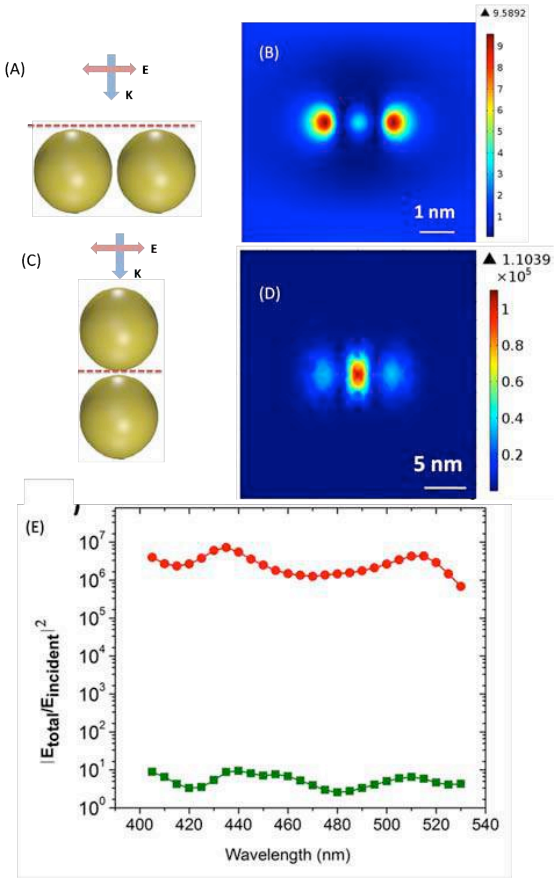

Figure 2: (A) Scheme of simulation similar to the experiments in ref [3,12]; the red dotted line indicates the plane where enhancement is estimated, (B) Corresponding electric field distribution at an incident wavelength of 440 nm. (C) Scheme of simulation similar to our experiments [7]; the red dotted line indicates the plane where enhancement is estimated, (D) Corresponding electric field distribution at an incident wavelength of 440 nm. (E) Comparison of enhancement for the two different orientations. The green and the red lines indicate the orientation similar to case (A) and (C) respectively.

4. Effect of Angle of Incidence

When the angle of incidence of the incident EM wave is varied (0 degree corresponds to **K** vector along dimer axis, 90 degree corresponds to perpendicular to dimer axis), interestingly the maximum field enhancement does not vary drastically, although there is a shift in the resonance peaks (fig. 3). This result is quite contrary to what is usually predicted in the literature [13], which states that if the polarization direction is along the dimer axis, the two nanoparticles couple and give rise to field enhancement, where as if the particles polarize perpendicular to the dimer axis, dipoles in same direction are created in each particle and there is no coupling.

The reason for such strong coupling even when the electric field polarization is in an unfavorable direction is attributed to the retardation effect due to large size [9]. In our case, due to the large size of the particle, retardation is playing an important role and there is almost an equal enhancement in both 0 degree and 90-degree case. By the time the incident EM wave crosses the first particle and reaches the second one, the phase flips, which leads to polarization in dissimilar direction, leading to coupling between the two particles. Our studies on the role of retardation on plasmonic coupling and near field enhancement will be published in near future.

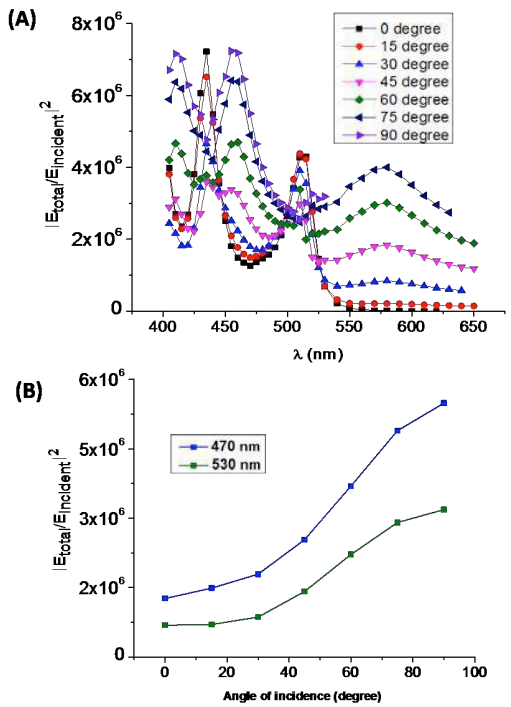

Figure 3: (A) max($|\mathbf{E_{total}}/\mathbf{E_{incident}}|^2$) with different angle of incidences. (B) max($|\mathbf{E_{total}}/\mathbf{E_{incident}}|^2$) plotted for two different wavelengths; it can be clearly observed that the magnitude remains in the same order, with a change in the angle of incidence.

5. Effect of Dielectric Spacer

In all the previous sections, we have considered the dimer gap to be air. In our experimental system, we have a dielectric spacer-graphene in the dimer gap. In order to simulate the actual system, we have tried to put a dielectric slab in the dimer gap and see its effect on the near field enhancement. Including a thin slab of high dielectric constant material in a (finite element method) FEM based simulation was computationally expensive because of the requirement of a very large number of mesh elements. Thus, another computation method known as discrete dipole approximation (DDA) [10,14] is explored for putting the thin dielectric slab in the dimer geometry to simulate our actual experimental system [7]. DDA calculations are also found to be memory intensive and that is why, we could only simulate a slab which was as low as 1.4 nm in thickness; as a thinner slab required more number of dipoles. But even with a slightly thicker dielectric slab than our actual experimental system we are able to achieve an insight about the effect of presence of a dielectric in the dimer gap.

A dielectric spacer of thickness 1.4 nm and refractive index 3 is introduced in the dimer gap. The dipole size is kept smaller than the thickness of the spacer, to ensure enough number of dipoles for discretization of the spacer. The results show that introducing a dielectric layer in the dimer gap changes the magnitude of enhancement minimally, less than 20% (see fig. 4). It is observed, that there is a red shift of the maximum enhancement position by 10 nm, which is expected, as plasmon resonance condition has a direct relation to dielectric constant of the surrounding medium.

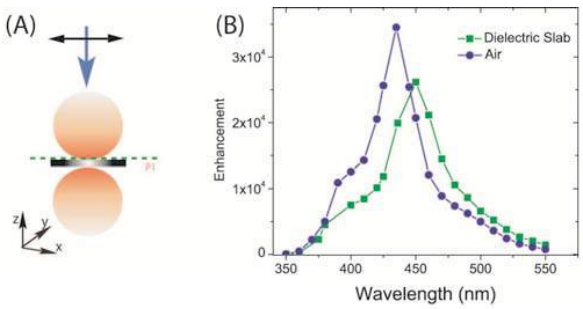

Figure 4: Scheme of DDA simulation for calculating the field enhancement at the dimer gap, in presence of a dielectric spacer. Green dotted line represents the plane considered for calculation of enhancement. (B) Maximum field enhancement at the dimer gap with a dielectric slab compared to that having no dielectric for different wavelengths.

6. Conclusion

In conclusion, we numerically estimate the near field enhancement in a system like an experimental system described before [7]. Compared to an isolated particle, a dimer tightly focuses the near field in a sub-nanometer gap. The plasmon resonance for the dimer is red shifted into the

visible and the near field enhancement is much higher than an isolated particle. Simulations with different orientations of the polarization angle of the incident field is done. Surprisingly, the simulations show that the magnitude of field enhancement varies minimally (within an order of magnitude) for different direction of electric field polarizations relative to the dimer axis. We assumed the gap between the dimers to be air in the FEM simulations. Later we used DDA to introduce a dielectric slab, which has a relative small effect on the resonance peak value and spectral position.

ABSTRACT

Near-field imaging has become a versatile technology in metamaterial-related researches, since it not only provides direct imaging of electromagnetic/acoustic wave propagation in and around metamaterials [1-7], but also can visualize the band diagrams in reciprocal space[8,9] and dynamic pulse evolution in time domain[8,10]. LINBOU Nearfield Imaging Systems provide a stable, fast and economic solution to near-field imaging of electromagnetic and acoustic waves in physical space, reciprocal space and time domain, from two dimensions to three dimensions, from near-field measurements to far-field radiation patterns.

Abstract-This paper investigate the technique of suppression of surface modes in the metamaterial grounded slab. This technique consists to sandwich a left-handed material layer between the air and the metamaterial slab. The purpose of this suppression is to reduce the mutual coupling between the elements of array antennas. The Transverse Resonance Method is applied in this analysis to find the effects of the left-handed material layer on the dispersion characteristics of transverse electric and transverse magnetic polarizations.

The array antennas play in important role in electromagnetic fields. They are used in different applications such as; mobile communications and phased-array radar. The mutual coupling of the elements of array has negative effects on the directivity, the bandwidth and the radiation of antenna. Then, it is necessary to reduce this coupling by the suppression of surface modes using the left-hand material LHM This material has an increasing use thanks to its recent realization (i. e., has a negative index of refraction) and its unusual properties [1]. To suppress the surface modes, the LHM layer is sandwiched between the air and the semi-infinite metamaterial slab, as shown Fig. 1.

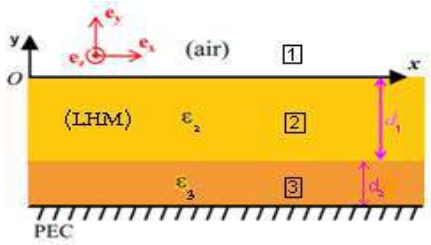

Figure 1. An infinity metamaterial grounded slab with LHM layer characterized by negative parameters ε_2 and μ_2.

Applying the Transverse Resonance Method in order to obtain the equivalent circuit that allows us to find the dispersion equation [2].

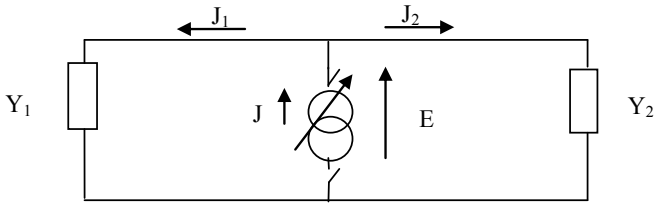

Figure 2. Equivalent circuit used to illustrate the Transverse Resonance Method.

We solve the equivalent circuit from the Kirchhoff's current and Ohm's law to find the dispersion equation:

$$(Y_1 + Y_2)E = 0 \tag{1}$$

For TM and TE polarizations, this dispersion equation may be presented as:

$$\text{TM:} \quad -k_{y2}d_1 - \coth^{-1}\left(\frac{k_{y2}}{k_{y1}\varepsilon_2}\right) - \coth^{-1}\left(\frac{\varepsilon_3 k_{y2}}{k_{y3}\varepsilon_2}\coth(k_{y3}d_2)\right) = 0 \tag{2}$$

$$\text{TE:} \quad -k_{y2}d_1 - \coth^{-1}\left(\frac{k_{y1}\mu_2}{k_{y2}}\right) - \coth^{-1}\left(\frac{k_{y3}\mu_2}{k_{y2}\mu_3}\coth(k_{y3}d_2)\right) = 0 \tag{3}$$

In the numerical study, we consider that our structure is composed by a LHM layer with ε_2= -2, μ_2= -2 and height d_1= 50mm and a metamateriel slab with permittivity $\varepsilon_3(\omega) = 1 - \frac{\omega_p^2}{\omega^2}$ and permeability $\mu_3(\omega) = 1 - \frac{F\omega^2}{\omega^2 - \omega_0^2}$ where $F = 0.56$, $\omega_p/2\pi = 10$ GHz and $\omega_0/2\pi = 4$ GHz according to the drude model and height d_2= 10mm.

The variation of the normalized real constant with the frequency is presented in Fig. 3(a) and (b) for TM and TE polarizations.

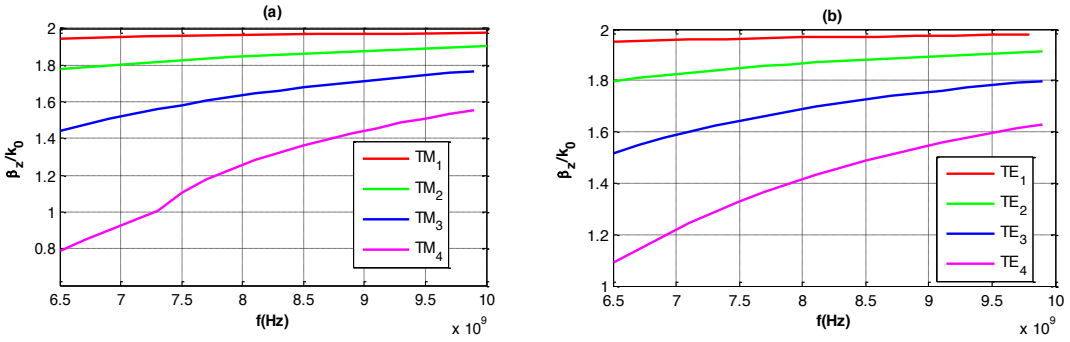

Figure 3. Dispersion of (a) TM and (b) TE surface modes in metamaterial grounded slab with LHM layer.

From these results, we observe that the fundamental modes TM_0 and TE_0 of surface mode do not exist in the metamaterial grounded slab structure with LHM layer. Higher modes of surface modes exist only in particular frequency range and have many remarkable features. When we increase the frequency, the normalized real constant of the higher modes increases approaching the $\sqrt{\varepsilon_2\mu_2}$, but it cannot exceed this value and saturates at a specific value of frequency. The saturation frequency and the normalized real constant are dependent on the mode order. We also observe that the surface mode is suppressed at the frequency band 6.5GHz to 7.4GHz of TM_4 mode because the dispersion curve is below the cutoff frequency.

Abstract- A double C-shaped resonator (DCR) unit cell metamaterial (MTM) for 5G mobile network that operates at 28 GHz is proposed. For comparison purpose, three other common unit cells which are the S-shaped resonator, double G-shaped resonator (DGR), and Omega-shaped resonator are optimized to operate at similar operating frequency. Additionally, the approach to reduce MTMs losses is presented and discussed. The losses of the proposed DCR is significantly improved in all unit cells due to the opposite directions of the induced current on both sides of the unit cell and the negativity of the constitutive parameters is maintained.

1. Introduction

MTMs have attracted great attention due to unusual electromagnetic properties such as the negative permittivity, permeability, and refraction index. However, the performance of the MTMs is primarily limited by the MTMs losses. These losses give negative influences toward the realizations of the unique electromagnetic properties of the MTMs. The losses in MTMs consists of two primary components: radiation losses and dissipation losses where losses of the first component is greater than the latter [1, 2]. Millimeter wave frequency range, on the other hand, attracted researchers in the past few years due to its advantages in the wireless communications systems such as high speed, high capacity and availability for large bandwidth. These advantages make this band the best candidate for the fifth generation (5G) cellular networks by exploiting the enormous amount of available spectrum to greatly increase the communication capacity [3]. A suitable configuration of MTM is designed to operate at 28 GHz for 5G mobile phone applications and to the best of our knowledge design an MTM unit cell that operates at this band is the first of its kind. For comparison, three other known unit cells are optimized to operate at 28 GHz. Furthermore, the major component of MTM losses which is the radiation loss is greatly suppressed by applying the principle of the electromagnetically induced transparency (EIT) phenomenon.

2. Unit-Cells Construction, Numerical Results and Discussion

The unit cells in Fig. 1(a)-(d) are constructed on Rogers RT5880 substrate with the relative permittivity of 2.2, tangent-loss of 0.0009, and a thickness of 0.508 mm. The length (L) and width (W) of each unit cells are given in the caption of Fig. 1. The performance comparison between the DCR unit cell and the other three common unit cells shapes which are S-shape, DGR, and Omega-shape to operate at 28 GHz are carried out. Fig. 2 (a) and (b) shows the reflection (S_{11}) and transmission coefficients (S_{21}) of the unit cells. It can be observed that the proposed DCR unit cell achieves a wider bandwidth than the other three unit cells which is 1.1 GHz of bandwidth as opposed to less than 0.5 GHz of bandwidth in other three unit cells. Moreover, the dimension of the proposed DCR unit cell is the smallest over all the studied unit cells with the length L = 2 mm and width W = 1 mm. On the other hand, transmission coefficient of the DCR depicts near zero loss which contribute to nearly full transmission in comparison with the other unit cells where the losses in the S-shape is at the highest, approximately -1 dB. Moreover, the induced surface current of the DCR structure induces the anti-parallel currents on the both sides of the unit cell which causes the destructive interference of the scattering fields. As a consequence, the EIT effect is induced and extremely suppresses the radiation loss. The constitutive parameters are retrieved using the robust method as described in [3]. Fig. 1(a)-(d) depict the real parts of the permittivity ε, permeability μ and refractive index, n of the unit cells at 28 GHz.

3. Conclusion

This paper introduces the DCR unit cell which operates at 28 GHz for 5G mobile network application and three others common unit cells are optimized to operate at similar frequency for comparison purposes. The reflection and transmission coefficients of four unit cells are displayed and investigated. The proposed DCR unit cell successfully achieves low radiation loss of nearly full transmission, small size, and wider bandwidth of reflection coefficient and negativity of the constitutive parameters over all other three unit cells.

Abstract- We experimentally demonstrate a thin bi-layer metamaterial supporting asymmetric transmission for linearly polarized light but not for circularly polarized light over a broad bandwidth in the near-infrared region. We provide a simple and intuitive working principle, along with full-wave simulations that agree well with the experimental results. We also prove that our design is extremely insensitive to spatial misalignment, which might occur during the nanofabrication process.

As an analogue of electrical diodes, optical diodes enable asymmetric transmission, or one-way transmission of light. Such a property is fundamentally interesting, because light transmission is normally symmetric due to the Lorentz reciprocity in time-invariant linear media. Metamaterials, engineered materials with extraordinary optical properties originated from subwavelength scale structures, provide an alternative, simple solution to break the Lorentz symmetry condition via mode conversion between specific modes, even though the system is completely reciprocal. Asymmetric transmission for circularly polarized light [1-5] and for linear polarization [6-11] has been demonstrated with various design.

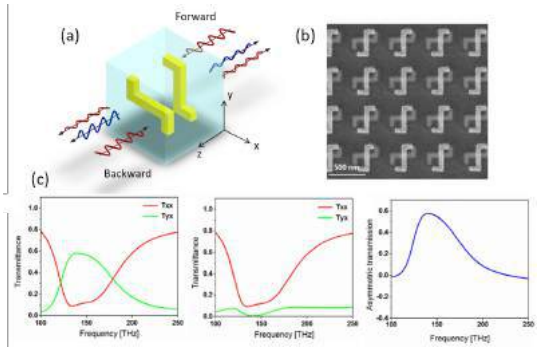

Figure 1. (a) Schematic of the metamaterial unit cell, (b) SEM image of the fabricated sample, (c) simulated transmission characteristics and asymmetric transmission of the metamaterial.

Here, a thin bi-layer metamaterial which works as an optical diode over a broad bandwidth up to 50 terahertz is introduced. Under this bi-layer metamaterial, linearly polarized light transmit the material along one direction, but not the opposite direction while circularly polarized light exhibit symmetric transmission characteristics. A simple and intuitive working principle based on the symmetry inherent in the metamaterial design, along with full-wave simulations that agree well with the experimental results are provided. We also prove that our design is extremely insensitive to spatial misalignment, which might occur during the nanofabrication process. These prominent features promise a wide range of applications, such as ultrafast optical computing, information processing and suppressing undesired interactions in integrated micro- and nano-devices.

Abstract-A wet chemistry process was designed to synthesize multi cavity magnetite(Fe_3O_4) nanorods using FeOOH as precursor. Both the precursor and magnetite were characterized by XRD. The FeOOH was measured by Thermogravimetric Analyzer (TGA) and Differential Scanning Calorimetry (DSC). And the TEM images indicate that the magnetite has a nanorod structure with multi cavity. The length of the magnetite nanorods are around 50nm. The cavities are quasi-spherical shape with a diameter of 6nm.

Study on the mutual electromagnetic couplings between vertical split ring resonators

Abstract- We demonstrate the couplings between vertical SRRs by transmittance experiments and numerical simulations. Two different arrangements inclusive of rectangular and interlacing-rectangular arrays are characterized. For both arrangements, the resonance frequencies are increased while the transmittances are decreased with decreasing distance between vertical SRRs. The weak current densities and magnetic field distribution in the small distance arrays lead to higher resonant frequencies. The interlacing-rectangular array is compared to the similar inter-distance rectangular arrays as well. Slightly increased in current density and significant drop in magnetic field strength are conclude that the electric field strength inside each meta-atom dominates the resonance behaviors.

Unusual electromagnetic properties such as negative refractive index or subwavelength imaging, which is not appeared in nature, are the interaction results while electromagnetic waves passing through the artificial metamaterials[1-2]. Split ring resonators (SRRs) have been investigated since their advent in metamaterials. Until now, they have been widely proved to exhibit negative index of refraction, magnetoinductive coupling, and additionally, extraordinary nonlinear effects and Fano resonance. Down to the scales of nanometers or micrometers, SRRs are often patterned with two dimensional planar structures. There are numerous studies concerning the coupling effects of planar SRRs. However, the studies on the coupling effects of vertical SRRs are limited since the difficulties of the fabrication process. In this work, we fabricated vertical SRRs with an innovative metal stress-driven self-assembled method [3]. The transmittance of the rectangular arrays shows a stronger resonance with blue-shift as the inter-distance decreases, which can be explained from the increased filling factors and reducing capacitances. On the other hand, the rectangular-interlacing array reveals significant transmission deep and approximate resonant frequency comparing to rectangular array with similar inter-distance were based on the fact that the increased filling factors and that the attractive electric force is relatively weak compared to the repulsive electric force between vertical SRRs. More details will be present in the conference.

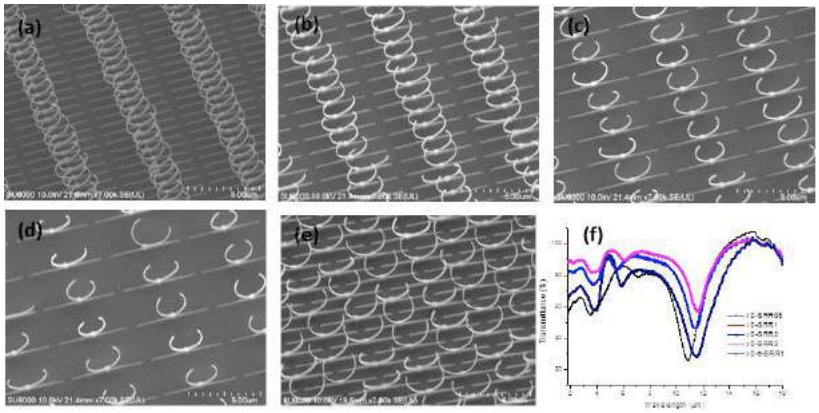

Fig. 1 (a)-(d) The rectangular arrays with inter-distances of 0.5, 1, 2, and 3 μm, respectively. (e) The interlacing-rectangular array by shifting the neighboring rows by half P_x with inter-distance of 1 μm. (f) Transmission spectra of rectangular arrays with inter-distance of 0.5, 1, 2, and 3 μm and interlacing-rectangular array with inter-distance about 1 μm, respectively.

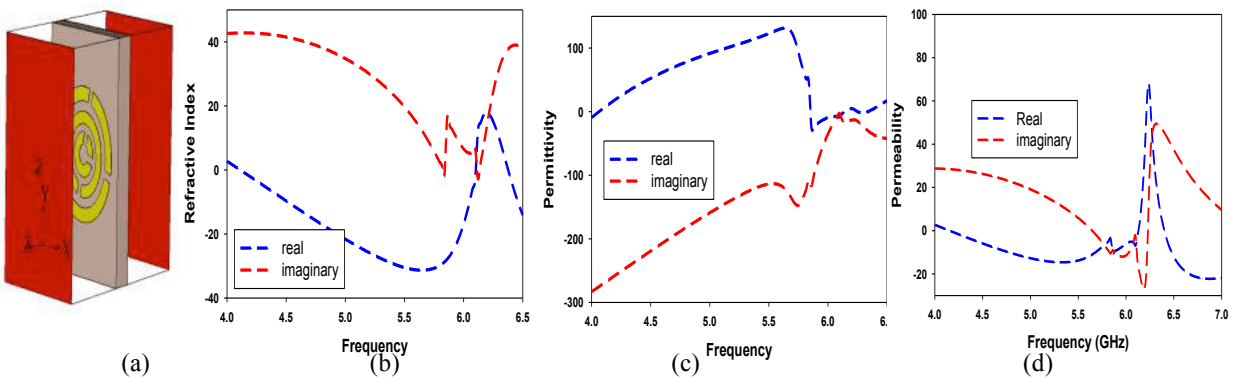
Abstract- This paper highlights a mutual coupling reduction of two closely spaced meander line antennas by using left-handed split ring resonator (SRR) metamaterial for 5.9 GHz DSRC application. The antenna consists of two closely spaced meander line antennas where SRR unit cells are placed vertically between two antennas and another 4x3 cells at the ground plane. The SRRs significantly reduce mutual coupling and good MIMO characteristics have been achieved for the designed antennas like diversity gain and effective correlation coefficient.

SUMMARY

Recently in wireless communication, meander strip line antenna has achieved a tremendous attraction for designing small size antennas. Different types of meander line antennas have already investigated in many open kinds of literature as e,g., tapered meandered, tapered meander line and self-resonant MLA [1]. However, the main challenges have come when meander line antennas need to be designed for multi-elements or MIMO application. Mutual coupling effects between two antennas generate distortion in the overall antenna performance [2].

The development of metamaterial concept is treated as a turning point to reduce mutual coupling by utilizing a natural nonexistence property material that enables different characteristics of an antenna [3]. Different types of metamaterial structure have been analyzed briefly include left-handed metamaterial with negative relative permeability and negative permittivity. In this paper, a left-handed Double Negative (DNG) circular split ring resonator (SRR) has been designed for isolation enhancement of MIMO meander strip antennas for Dedicated-Short-Range-Communication (DSRC) Vehicle-to-Vehicle (V-2-V) application working at 5.9 GHz. Fig.1 presents the structure of unit cell, permeability, permittivity and refractive index which have been obtained based from S_{11} and S_{12} [4].



(a) (b) (c) (d)

Figure 1. Left-handed unit cell (a) 3-D configuration (b) Refractive Index (c) Permittivity (d) Permeability

This left-handed circular split ring resonators (SRR) unit cell have been located vertically between meander line antennas as shown in Figure 2(a) while another 4x3 cells are placed at the ground plane, as depicted by Fig. 2(b). The effect of mutual coupling between two antennas is shown in Fig. 2(c). It is clearly seen that the mutual coupling between two antennas improved and shifted to -19 dB at 5.9 GHz when unit cells are applied in the structure. Moreover, less than 0.05 of envelop correlation coefficient (ECC) is stated with more than 9 dB diversity gain which is suit for MIMO application requirements.

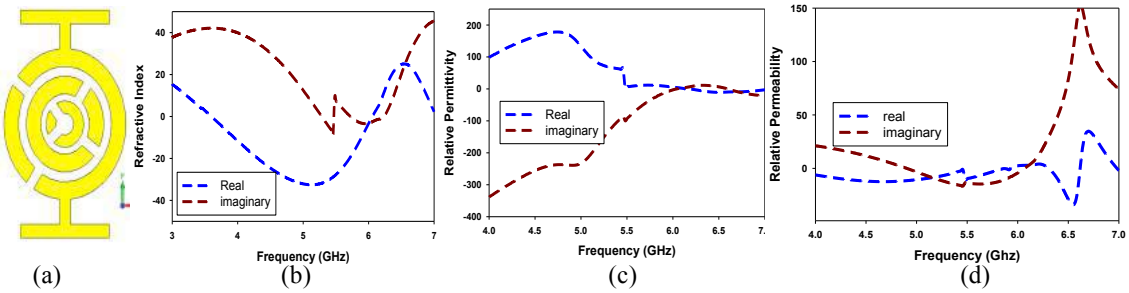
Abstract- A new design of metasurface with double-negative (DNG) characteristic has been proposed for bandwidth and gain improvement of the circular array antenna. The antenna structure is formed by circular radiating patches and DNG metasurface unit cells which are placed at the ground plane in form of 5x3 array. It is found that that DNG metasurface improved the antenna bandwidth from 2.04 GHz to 2.7 GHz and maximum gain enhanced from 5.5 dBi to 5.776 dBi at 5.9 GHz.

SUMMARY

In recent years implementing different types of material in antenna technology has attracted tremendously by researchers. For example artificial metasurface like metamaterial for antenna technology open a way to explore new ideas. Metamaterial is artificial magnetic conductor which can change the material property at certain frequency range [1]. Different types of metamaterial are explored to improve antenna's performances include frequency selective surface (FSS), electromagnetic band gap structure (EBG) and artificial magnetic conductor (AMC) [2]. Nevertheless, those techniques increase thickness of the antenna and produce higher surface wave which degraded the radiation pattern. Furthermore, double negative metasurface (DNG) has widely used where the permittivity and permeability will be negative on certain frequency range [3]. In this paper, a new design of 5x3 double-negative metamaterial array structure have been applied at the ground plane to boost antenna's performances. Figure 1(a-d) presents the metasurface unit cell structure, refractive index, relative permittivity and relative permeability. The extraction procedure has taken from the magnitude and phase of S11 and S21 [4].



(a) (b) (c) (d)

Figure 1. DNG unit cell (a) 3-D configuration (b) Refractive Index (c) Permittivity (d) Permeability

Figure 2(a) presents the front view of the circular array antenna. This structure contains 8x2 small size circular radiating patches. The diameter of circular patches 8.45 mm. Simple quarter wavelength transmission line is used to develop array structure. This structure produces the bandwidth from 4.26 -6.3 GHz. Figure 2(b) presents the metasurface row which is placed step by step. At first step, it improved the bandwidth from 2.04 GHz to 2.45 GHz. Secondly, when another row of metasurface placed, it improved from 2.45 GHz to 2.57 GHz. Bandwidth is further improved to 2.7 GHz when the third row is added as shown in Figure 2(c). Moreover, the maximum gain is increased from 5.5 dBi to 5.8 dBi at 5.9 GHz.

Abstract- Composite Langmuir-Blodgett films (8 layers) of dioctyl sodium sulfosuccinate with oligo phenylenevinylene and gold nanoparticles of size 50 to 80 nm were formed on glass surfaces. Its morphology and optical properties (phase shift) were studied.

Langmuir-Blodgett (LB) films of organic substances with silver or gold particles can be used in the field of photonics to create devices of integrated optics, to develop epsilon-near-zero or negative refraction metamaterials [1, 2]. LB method does not require high temperatures and vacuum [3]. Langmuir layers of amphiphilic compounds are close-packed structures formed at the water surface after their transfer onto a solid substrate by LB method to form defectless mono- and multilayer films [1, 3].

The objective of this work was to create composite LB films of dioctyl sodium sulfosuccinate with gold nanoparticles and investigation of their optical properties.

In order to form of LB multilayers and the hydrophobic shell on the gold particles (Au) we used dioctyl sodium sulfosuccinate (AOT). In order to visualize AOT–Au Langmuir layers at UV light with a wavelength of 365 nm we used 4,4'-(1E,1'E)-2,2'-(2,5-dipropoxy-1,4-phenylene)bis(ethene-2,1-diyl)bis(4,1-phenylene) bis(4-(decyloxy)benzoate) – oligo phenylenevinylene (PhB). AOTPhB coatings and their composition with gold particles were formed on glass plates of rectangle shape with area ~ 4 cm^2. LT – 201 device was used for the measurement of surface pressure – area per molecule (π – A) isotherms of AOTPhB and AOTPhB–Au Langmuir layers and also for the deposition of coatings by vertical deposition method (4 bilayers of Y type) under surface pressure (π) ~ 15 mN/m [3]. Compressibility (K) was calculated for linear portions of the isotherms corresponding to compression of the Langmuir layers in the phase state "solid film" [1]. Gold nanoparticles were synthesized by citrate technique[2]: 1 mM aqueous solution of chloroauric acid was heated to the 100ºC, then 3.8 mM aqueous solution of sodium citrate was added, molar ratio $HAuCl_4$:$Na_3C_6H_5O_7$=2:3.6. Obtained compound was exposed under 100ºC for 5 minutes and then cooled to room temperature. As a result aqueous colloid of gold NPs stabilized by sodium citrate was obtained. After centrifugation and fractionation colloid of gold NP with diameter from 50 to 80 nm was obtained, size of NP was determined by the method of dynamic light scattering on Zetasizer Nano ZS (UK). In order to crate AOTPhB-Au composite LB coatings the NPs aqueous solution was mixed with the 0.4M AOT in isooctane solution containing 1 mg / ml PhB solution in hexane. The thickness of the AOTPhB multilayers was measured by interferometric method using POSTMK1 device (Planar, Belarus). Phase shift of optical radiation passing through the samples measured by using the walk-off interferometer [1]. The He-Ne laser with a wavelength of 632.8 nm was used as radiation source.

The phase shift of 16 nm thick AOTPhB coating (Figure 1) is 6.2°. The incorporation of gold nanoparticles into the structure of the AOTPhB film was accompanied by a decrease in compressibility (from 0.095 to 0.012)

of AOTPhB–Au Langmuir layers relatively to AOTPhB layer. The presence of gold particles with a size from 50 nm to 80 nm in AOTPhB multilayer structure also confirmed by SEM and AFM methods (Figure 2).

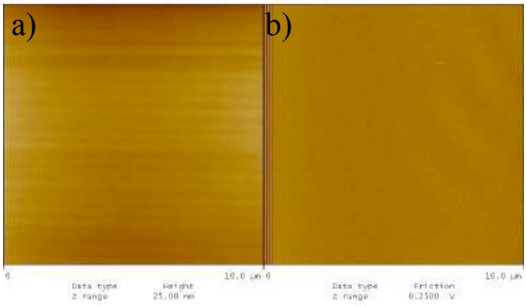

Figure 1 AFM image of topography (a) and phase contrast (b) of AOTPhB multilayer

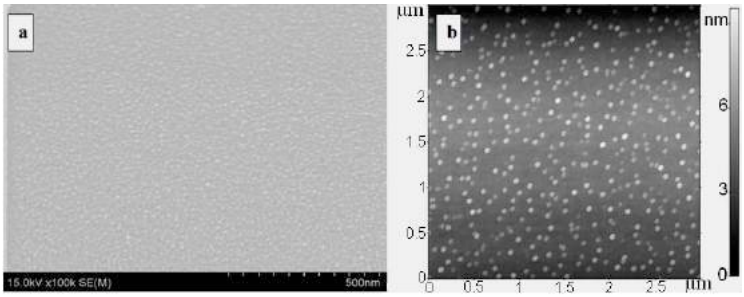

Figure 2 SEM (a) and AFM (b) images of LB multilayer based on gold particles in AOTPhB matrix

The phase shift (δφ) of the composite AOTPhB–Au coating is 1.4°. Partial oxidation of the AOTPhB matrix after 15 min treatment in UV etching with photo Surface processor PL 16-110D (SEN Lights Corp., Japan) – Figure 2 b decreases it's δφ to 0.85°.

Thus composite LB coatings of Au nanoparticles in the dielectric AOTPhB matrix can be used to create epsilon-near-zero materials.

Acknowledgements Authors express gratitude to post-graduate student A. Stankevich for kindly providing oligo phenylenevinylene.

Abstract-In the last decade hyperbolic metamaterials has become an emerging class of media offering unique electromagnetic response. Within this paper we demonstrate that functionality of such structure can be further extended by employment of stimulus-sensitive functional materials providing control of optical properties of complete Tunable Hyperbolic Metamaterial (THMM) structure. In particular, we put the main emphasis on controllable dispersion, light stopping and gain/absorption in the near- and mid-infrared range of frequency.

Hyperbolic Metamaterials (HMM) are anisotropic media characterized by unclosed surface in wave vector space, known as hyperbolic dispersion. Due to their unusual dispersion properties such media reveal wide variety of potential applications in means of nanophotonics [1]. Particularly, latest researches in field of HMM are focused on employing stimulus-sensitive materials, such as graphene [2-4], vanadium dioxide and chalcogenide glass [5], providing tunability of complete structure and giving rise to completely new potential applications.

In this paper we demonstrate interesting behavior of the passive/active bulk graphene-based HMM structure (GHMM) as well as symmetric planar waveguide composed of Type II HMM core and air cladding. Especially, in the case of bulk GHMM structures we have shown the possibility of voltage-controlling the dispersion regimes i.e., Epsilon-Near-Zero (elliptic), Type I and II HMM (hyperbolic) as well as structure's optical properties. For example, one of the effects resulting from controlling of dispersion is tunability of structure's reflectance, see Figs.1(a)-1(b), also revealing angle-sensitivity.

(a) **(b)**

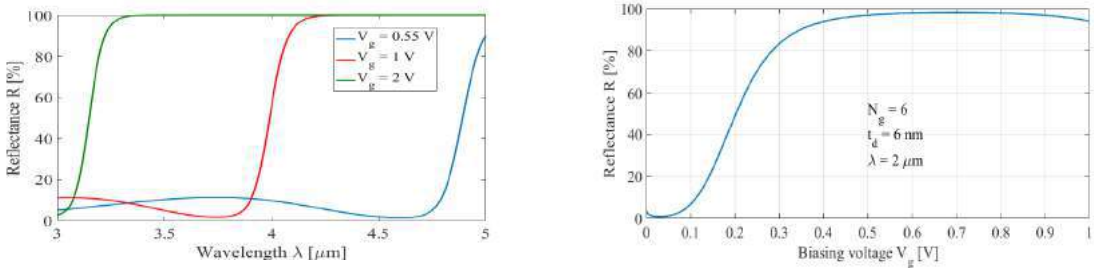

Fig. 1 a): Voltage-controlled [(a)] dispersion regimes and [(b)] reflectance of exemplary bulk THMM structure.

Another interesting behavior arising from dispersion-shape controlling is observed in bulk HMM structure composed of amplifying/absorptive material and functional material. Such structure offers modification of gain/absorption bandwidth of constituent active medium s well controllable electromagnetic transparency. As an

example, we present strong gain/absorption enhancement with significantly narrowed bandwidth, see Figs.2(a)-2(b).

(a) **(b)**

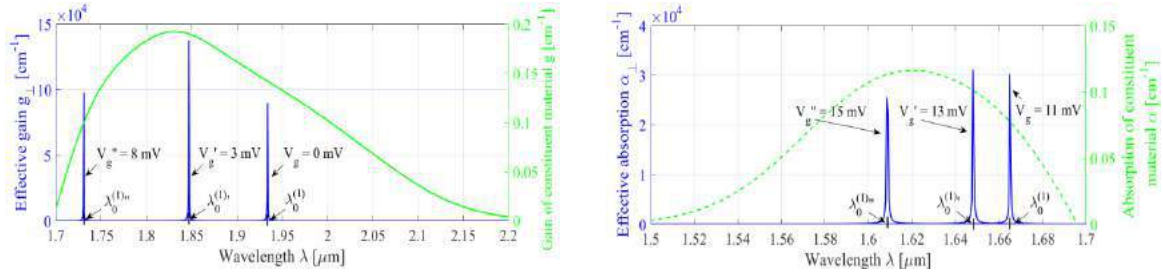

Fig. 2 Controlling of gain [(a)] and absorption [(b)] in active THMM structure.

Finally, our study concerned also the phenomenon of slow light inside a symmetric planar waveguide composed of Type II HMM core and air cladding. It has been shown that proper tailoring of structure's geometry combined with sufficient voltage biasing can lead to stopped light of selected wavelength, for example within SCLU bands (see [3] and its references), for certain waveguide width, see Figs. 3(a)-(b).

(a) **(b)**

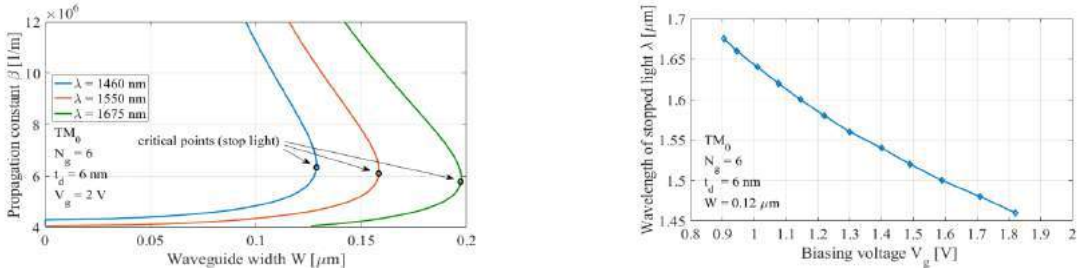

Fig. 3 Controllable light stopping in GHMM-based waveguides.

We believe that these kinds of tunable hyperbolic metamaterials could lay foundations for a new class of novel controllable photonic devices.

Magnetic Purcell effect in magnetic hyperbolic metamaterials

M. S. Mirmoosa, S. Yu. Kosulnikov, and C. R. Simovski

Department of Electronics and Nanoengineering, School of Electrical Engineering, Aalto University, Finland
mohammad.mirmoosa@aalto.fi

Abstract— We study a wire medium comprising high-index wires, and uncover topological phase transition between closed and open types of dispersion for transverse-electric (TE) polarized waves. The transition results in a filamentary pattern and remarkable Purcell factor for a magnetic dipole moment oriented perpendicularly to the optical axis of the medium.

Hyperbolic metamaterials have been widely studied in the past decade [1]. As is well known, since these artificial materials are uniaxially anisotropic and the principal components of the effective permittivity tensor do not possess the same sign, the isofrequency (dispersion) surface is open (a hyperboloid). However, this is only for transverse-magnetic (TM) waves. The isofrequency surface of transverse-electric (TE) waves is a sphere having a certain radius. That is due to the fact that the known hyperbolic metamaterials have no magnetic response. In order to have an open surface for TE waves, the effective permeability tensor should not be unity and its principal components should have different signs.

Recently, in Ref. [2], the authors studied a multilayer fishnet metamaterial, and they experimentally showed that TE waves have an open dispersion surface at optical frequencies. Concurrently with [2], we introduced a novel realization of magnetic hyperbolic metamaterials [3]. It is a wire medium whose wires are made of high-index epsilon-positive materials. It is worth noting that those materials with high refractive index can be found both in microwave and optical ranges. Firstly, we analytically derive the corresponding effective permeability tensor ($\mu_\perp$, $\mu_\perp$, $\mu_\parallel$) and subsequently, we study the isofrequency surfaces at different frequencies according to the dispersion relation of TE waves:

$$\frac{q^2}{\mu_\parallel} + \frac{\beta^2}{\mu_\perp} = k_0^2 \varepsilon_\perp. \tag{1}$$

Here, q and β are the transversal and longitudinal components of the wave vector. Also, $\varepsilon_\perp$ is the transversal component of the effective permittivity tensor and k_0 is the free-space wave number. Intriguingly, we find that at a special frequency, the medium experiences *topological phase transition* [4] between the closed and open types of dispersion. Such effect was investigated in our previous works for a wire medium of polaritonic nanowires. However, in those works, the transition was associated with TM waves [5]. Topological phase transition has a significant influence on radiation pattern and enhancement of subwavelength dipoles. Here, by positioning a magnetic dipole moment inside the medium, we observe that the energy is transferred along the optical axis of the medium at the transition frequency. Also, a strong radiation enhancement is achieved. This noticeable enhancement corresponds to the magnetic moment oriented perpendicularly to the wires axis.

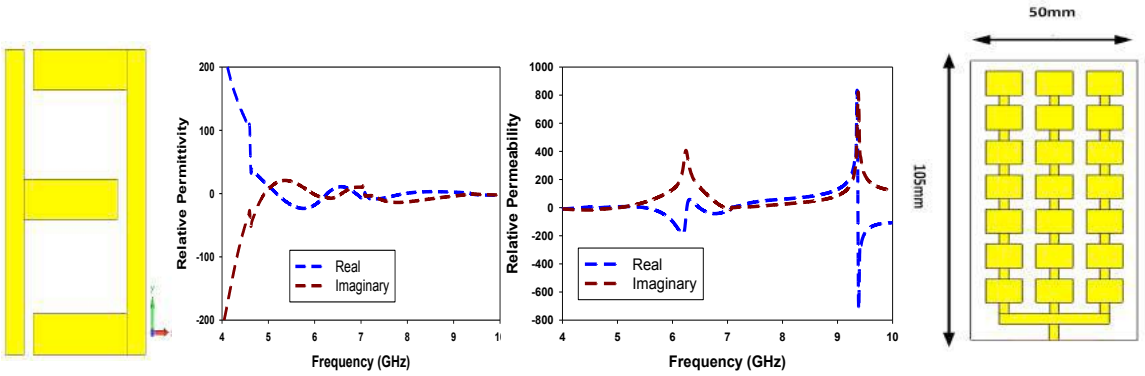
Abstract- This communication presents miniaturization of broadband series feed array antenna using double negative pi-shaped metasurface. The array antenna consists of 3×7 rectangular patches using series feeding operated from 4.38 GHz to 6.07 GHz. Double negative pi-shaped metasurface has applied in the ground plane in 7×5 form which miniaturize the array antenna size by 59.1% in length operating at 4.19 GHz to 6.09 GHz. Moreover, the maximum gain achieved is 6.7 dBi.

SUMMARY

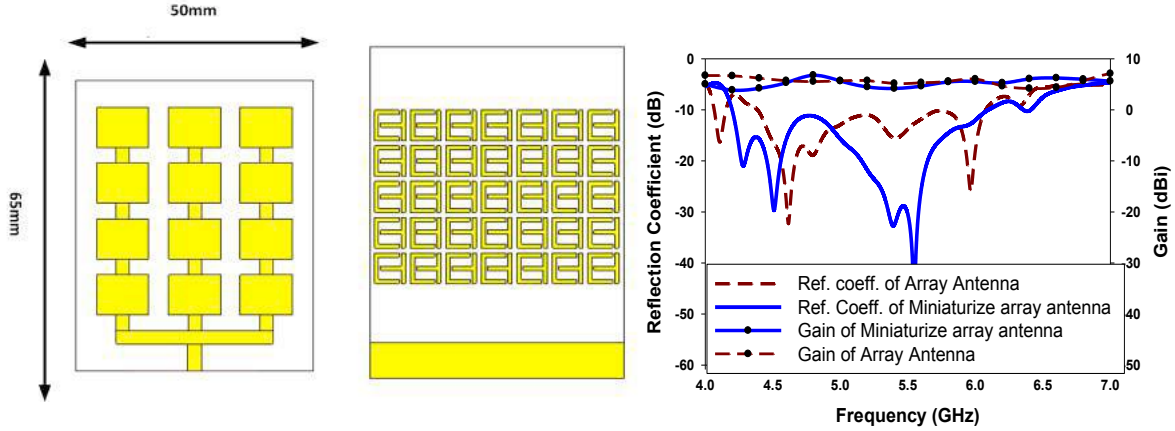
With development of modern era, it is highly required to inflate compact size antennas in order to fulfill the stringent requirements of modern communication system [1]. In last decades, several miniaturization approaches have already demonstrated in the literature for microstrip patch antennas including different types of slots, implementing shorting pins and irregular ground plane [2]. Another conventional technique for antenna miniaturization is to use high dielectric material as antenna substrate [3]. However, those all methods provide narrow impedance bandwidth. Alternatively, a material having both electric and magnetic properties can be used as substrate to reduce antenna size [4]. Nonetheless, it is difficult to find low loss magnetic material for microwave regime in nature.

Recently, metamaterials have been attained much attention in antenna technology for various application like- SAR reduction, antenna performance improvement, invisibility clocking, polarization rotator and filters because of its extraordinary electromagnetic characteristics. In this paper, a pie-shaped metamaterial unit cell having the characteristics of negative permittivity and permeability is used for antenna miniaturization. Figure 1(a) shows unit cell structure where perfect magnetic boundary condition has applied in X-direction while perfect electric boundary condition in Y-axis. The relative permittivity and permeability for this proposed unit cell are presented in Figure 1(b) and Figure 1(c). The series feed array antenna structure presents at Figure 1(d). The array antenna consists of 7×5 radiating patches. The overall size of the antenna is 105mm× 50mm which is 1.5909λ × 0.75λ (wavelength at 4.5 GHz). The overall bandwidth without the unit cells is 1.69 GHz.



(a) (b) (c) (d)

Figure 1. (a) Pi-shaped unit cell (b) Relative Permittivity (c) Relative Permeability (d) Array Antenna Structure



(a) (b) (c)

Figure 2. (a) Miniaturized array antenna structure (b) Back view (c) Reflection coefficient and gain of proposed antenna

The Pi-shaped double negative unit cell has applied in the back side of radiating patches, as shown in Figure 2. It is notified that the overall size of the antenna has reduced to 65mm × 50mm which is 1.0λ × 0.75λ at 4.5 GHz. It can be said that, the size reduced to 59.1% in length from the actual array structure. Furthermore, the overall bandwidth has been increased from 4.19 GHz to 6.09 GHz (1.9 GHz) compared to without unit cell which is 1.69 GHz.

9.5GHz Metamaterial AMC reflector for X-band Applications and Operation

M.M. Gajibo*, M. K. A. Rahim, N. A. Murad, O. Ayop, Raimi Dewan
Department of Communication Engineering, Faculty of Electrical Engineering,
Universiti Teknologi Malaysia, 81310 Johor Bahru, Johor, Malaysia
*corresponding author:*mmgajibo@yahoo.com

Abstract- A single layer structure consisting of a metamaterial (MTM) artificial magnetic conductor (AMC) reflector is presented in this paper. An FR4 substrate with thickness of 1.6mm was used and the incidental wave angles were varied from 0^o to 66^o. A peak reflection of close to 90% was achieved at 9.5GHz by the AMC reflector for both TE and TM polarization

Keywords- *Metamaterial, Reflector, AMC.*

I. Introduction

AMC as the name implies which is sometimes interchanged with electromagnetic bandgap (EBG) [1] is a structure designed with an unusual boundary conditions to be selective in supporting surface wave currents which is different from conventional metallic conductors [2] where as EBG is a high impedance surface consisting of periodic AMCs. In modern antennas, AMC's are used to replace the perfect electric conductor (PEC) ground plane, this is simply because of the AMC's ability to reduce back-radiation as well as increase gain. [3].

II. Proposed Design and Simulation

The proposed MTM structure stages an AMC Reflector on FR4 substrate with a dielectric constant of 4.6, loss tangent of 0.019 and height of 1.60mm. The major part of the AMC's structure comprises of a square box Booleaned with a circular shape as sown in figure 1a & 1b. The square shape measures 6.75mm which is also responsible for the performance of the S_{11} of the AMC. On the other hand, the circular shape measures 5.1mm in diameter and is directly responsible for determining the resonance frequency.

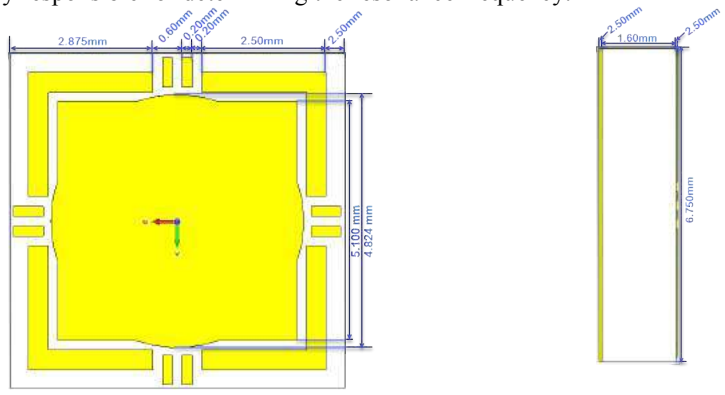

Figure:1 (a) (b)

III. Simulation Results and Discussions

a. Transverse Magnetic mode (TM) AMC's phase reflection

The AMC was simulated with different incidence wave angles (0^0, 15^0, 25^0, 35^0, 47^0 and 66^0) for TM mode and it was observed that, as the incident angle is increased, the resonance frequency across 0^0 (0 degrees) increases gradually. Take for instance, at direct incident wave (0^0) the AMC resonated at 9.50GHz, while as the incident

angle was increased to 15^0 the resonance frequency also increased to 9.54GHz. it is noted that there is no significant difference for angles below 30^0 but above 30^0, the shiftt in the resonance frequency is significantly high, in the cases of 35^0, 47^0 and 66^0, the results were 9.76GHz, 9.96GHz and 10.22GHz respectively.

b. Transverse Electrical mode (TE) AMC's phase reflection

Similar the same simulation was repeated for the same angles and this time it's for TE mode. The results for both the TM and TE mode are similar expect that for the TE mode, the increment in the resonance frequency is less when compared with that of the TM mode. For the first 3 incident angle (0^0, 15^0 and 25^0) the increment is negligible whereas for incident angles (35^0, 47^0 and 66^0) the shift in resonance frequency is high but still lower than that of the TM mode. Figures 2a & b shows the phase reflection for TM & TE respectively.

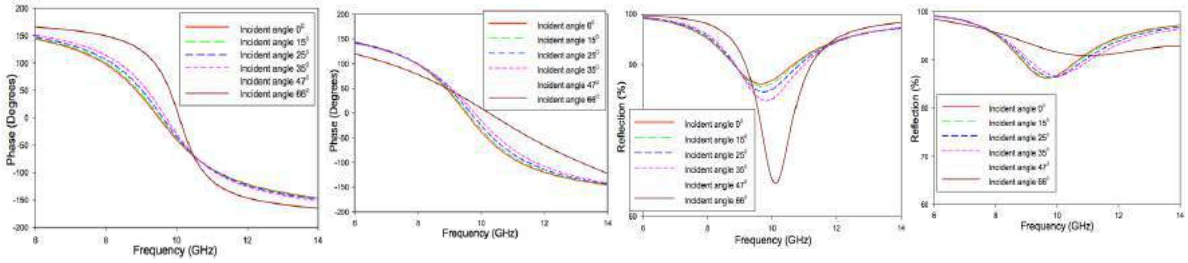

Figure 2: a. b. c. d.

c. *AMC's reflection Magnitude for Different incidental wave angles*

As mentioned earlier, the proposed AMC was simulated with different incidence wave angles (0^0, 15^0, 25^0, 35^0, 47^0 and 66^0. It was observed that for both TE and TM mode there is shift in the resonance frequency. With respect to TE mode, the frequency shift witnessed in the result of incident angles (0^0, 15^0, 25^0 and 35^0) are small and negligible whereas for incident angles (47^0 and 66^0) its considerably large as it jumped into 10.0 GHz. Figures 2c & d shows the phase reflection for TM & TE respectively

IV. Conclusions

MTM AMC reflector was designed and presented. It was simulated for various incident angles (0^0, 15^0, 25^0, 35^0, 47^0 and 66^0 and its performance was tested. It performed excellently at resonance frequency of 9.5GHz for incident angles below 30^0 where as the performance dropped for angles above 30^0 with slight shift in resonance frequency. It demonstrated a usable bandwidth (-90^0 to 90^0) of close to 2.40 GHz.

Bifurcation of microwave propagation in a negative-permeability material triggered by high density plasma generation

A. Iwai[1], **Y. Nakamura**[1], **and O. Sakai**[2]

[1]Kyoto University, Japan
[2]The university of Shiga Prefecture, Japan
iwai.akinori.83c@st.kyoto-u.ac.jp

Abstract— We performed a plasma generation experiment with metamaterial using 2.45-GHz microwave, and detected the electron density which decided the effective permittivity and transmitted 2.45-GHz signal at the position in the generated plasma. The transmitted signal sustains relatively high level with both the negative-permittivity plasma and the negative-permeability double-split-ring resonator, although each material works as reflector and absorber. This bifurcation about the wave propagation suggests that the synthesis of the plasma and the DSRR is completed, which compose the *negative-refractive-index material*.

Metamaterials which are the periodic composite of the unit cells, meta atoms, have given the supernatural electromagnetic responses. One of the conventional metamaterials is a double-split-ring resonator (DSRR) which is a good example of the resonance types proposed by Pendry *et al* [1]. DSRR includes large capacitance and inductance, and can exhibits the negative-permeability (μ) reaction to the external magnetic field near the resonance frequency. The refractive index (N) decides the relationship between the frequency and the wavelength whether the wave can propagate or not. The electric permittivity (ε) and the magnetic μ completely decides N, and the negative-μ DSRR generates the novel propagation area, *left-handed material*, with using the negative-ε materials. The experimental verification was performed [2] by using the DSRR and metal wires which were in the effective negative-ε states [3].

On the other hand, metal wires array was used as the experimental simulation for the plasma [4], and the previous researches about the negative N implies that the combination of the DSRR and the plasma, the discharged gas, can provide a negative N state. Our group has focused on this coupling and performed the experiments; we has showed the effective electromagnetic-energy input into the plasma through the DSRR existence [5] and the enhanced nonlinearity [6, 7]. In our previous paper [6, 7], we showed the ability of the dynamic N thanks to the various ε and to the electric connection between the DSRR and the plasma working as the electrode via the plasma vacant area, the plasma sheath. In this report, we focus more on the change of the wave propagation in the DSRR space induced by the plasma generation.

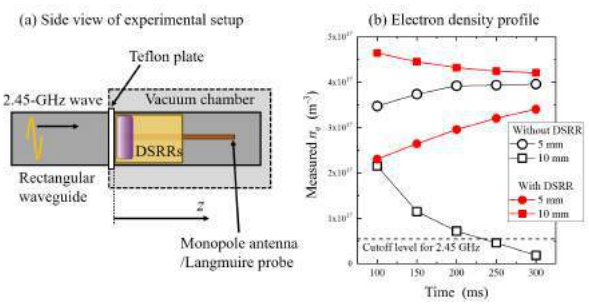

Figure 1: (a) Experimental setup. (b) Time development of measured electron density at $z = 5$ and 10 mm in cases with and without DSRRs. A dash line shows a density whose equavalent permittivity becomes 0.

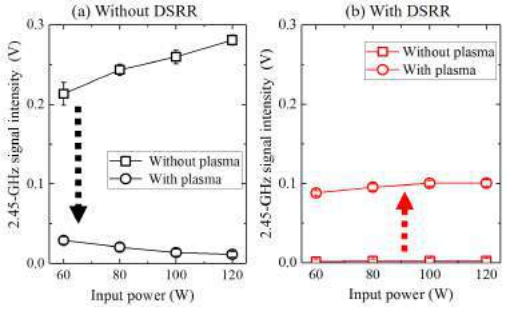

Figure 2: 2.45-GHz detected signal intensity as a function of input power. (a) Without DSRR. (b) With DSRR. Square and circle symboles express results without and with plasma generation, respectively.

Figure 1(a) shows the experimental setup. The input 2.45-GHz microwave propagates into the rectangular waveguide and enters the DSRR space in the vacuum chamber filled with Ar gas. The plasma is generated near the entrance, the Teflon plate, and it diffuses backward.

First, we monitored the electron density (n_e) of the generated plasma at the 5- and 10-mm positions in Fig. 1(a). In this measurement, Ar gas pressure was set at 200 Pa, and the net input power was about 100 and 200 W in cases without and with the DSRR, respectively. The power was the maximum which each generated plasma allowed to enter. Figure 1(b) shows the time development of n_e in the 300-ms initial period of the plasma excitation. Without the DSRR, generated plasma possesses the high n_e for the input microwave frequency, 2.45 GHz, but the density rapidly decreases as the position is far from the entrance because the plasma works like as the absorber and the reflector, which makes thin plasma. On the other hand, the plasma with the DSRR at $z = 10$ mm sustains the high n_e which is clearly beyond the cutoff level. The DSRR extends the penetration length of the input wave into the generated plasma.

We detected the transmitted 2.45-GHz signal intensity ($V_{2.45\mathrm{GHz}}$) at $z = 10$ mm in both cases, and Fig. 2 shows that the plasma generation in 200-Pa Ar gas affects $V_{2.45\mathrm{GHz}}$. In Fig. 2(a), $V_{2.45\mathrm{GHz}}$ increases as the increment of the input power and keeps the high intensity in the vacant waveguide (square symbols), but the plasma generation drastically weakens $V_{2.45\mathrm{GHz}}$ because of the evanescent mode and the energy consumption in the negative-ε plasma.

However, the plasma has the completely opposite role with the DSRR. In Fig. 2(b), $V_{2.45\mathrm{GHz}}$ in the negative-μ DSRR space is suppressed, but the plasma generation induces the higher intensity than that in the DSRR (square symbols in Fig. 2(b)) and in the plasma-filled waveguide (circle symbols in Fig. 2(a)) although the plasma is clearly the absorber/reflector in Fig. 2(a). These results imply that the negative μ of the DSRR cancels the negative ε of the plasma and this synthesization can makes propagation material for 2.45 GHz and helps the effective energy incidence into the generated plasma.

In conclusion, we performed the experiment about the plasma generation and the wave propagation into the plasma with using the DSRR. The generated plasma kept the highly ionized state up to 10 mm along the wave propagation direction, and the detected input signal intensity sustained the higher level with the DSRR and the plasma. Therefore, the DSRR and the plasma can have connection each other and it is possible that this composite works as the negative- and real-N material.

Design of Anisotropic Metamaterials by Topology Optimization

B. Ahn[1*], H. J. Lee[1], and Y. Y. Kim[1]

[1]School of Mechanical and Aerospace Engineering, Seoul National University, Korea

[*]corresponding author: topabs@snu.ac.kr

Abstract- While the resonance mechanism has been utilized for metamaterial design, extreme anisotropy has been less explored. There is indeed a wide range of material properties including extreme anisotropy, which may not be realized without designing metamaterials. Here, we present a design method suitable for anisotropic metamaterials by topology optimization. Specific design problems in consideration are those that require the tailoring of the Equi-Frequency Contour and field polarization. As a design application, we consider the design of wave-mode converting metamaterial.

Because metamaterials are artificially designed to realize various wave-specific phenomena, their design is not a trivial task. Among various design methods, we consider the use of the topology optimization method as an efficient design methodology [1-3]. There were many successful cases of using the topology optimization for metamaterial and phononic crystal design [4-8], but little attention has been paid to the design of elastic metamaterials exhibiting extreme anisotropy [9]. As a specific case, we consider the realization of anomalously polarized elastic wave motion, which can be used to make unique wedges that can convert a longitudinal mode to a shear mode and vice versa.

The phenomenon of anomalous polarization can occur only in special materials exhibiting extreme anisotropy but no progress has been made towards the design of such extreme anisotropy. Now, it may be possible to realize such extreme property by using elastic metamaterials. As the terminology “anomalous polarization” implies, the desired phenomenon requires special Field Polarization (FP). At the same, the Equi-Frequency Contour (EFC) should trace the desire contour shape. However, there appears no topology optimization design considering both the EFC and FP.

While we will discuss possible formulations to design anisotropic elastic metamaterials, we propose a new formulation that simultaneously traces the desired EFC and FP. To facilitate the design optimization process by the proposed formulation, sensitivity analysis was performed to be used for a gradient-based optimizer. We considered several design case studies to demonstrate the effectiveness of the proposed method. Some findings from the convergence behavior will be also discussed.

Abstract— We study phase transitions between metamaterials and photonic crystals by employing an inverse dispersion method that allows to construct a phase diagram for periodic structures composed of materials with high dielectric index including silicon and Ge-Sb-Te alloys. Our theoretical results are confirmed by microwave experiments with tunable metacrystals.

Photonic crystals and metamaterials are two important distinct classes of periodic photonic structures usually studied independently. Recently these structures have been considered in a unified approach [1] that analyzes how a typical photonic crystal composed of a square array of dielectric cylindrical rods [2] transforms into a metamaterial that can be characterized by averaged parameters [3]. By varying the cylinder radius and dielectric permittivity, it is possible to build a phase diagram controlled by structural parameters and allowing to introduce metamaterials with negative magnetic permeability. Here we develop deeper the concept of photonic phase transitions initiated in Ref. [1].

We study periodic structures with complex band diagrams employing the information about bands within the gaps related to Mie or Bragg resonances [4]. Usually, to study the band-gap diagrams, one reduces Maxwell's equations to the eigenvalue problem [2]

$$\nabla \times \frac{1}{\varepsilon(\mathbf{r})} \nabla \times \mathbf{H} = \frac{\omega^2}{c^2} \mathbf{H}, \tag{1}$$

where $\mathbf{H}$ is the magnetic field, $\varepsilon(\mathbf{r})$ is the distribution of dielectric permittivity in a periodic structure, ω is the frequency, and c is the vacuum light velocity. The familiar Floquet-Bloch theorem allows to define eigenfrequencies as functions of the wavevector $\mathbf{k}$. If the dielectric permittivity is a real function, the eigenvalue problem (1) is Hermitian, hence eigenfrequencies take real values only, and we cannot find the eigenmodes within bandgaps. An alternative way is to reduce Maxwell's equations to a generalized eigenvalue problem for the wavevector k

$$\begin{pmatrix} i\nabla\times & \omega\mu_0 \\ -\omega\varepsilon_0\varepsilon & i\nabla\times \end{pmatrix} \begin{pmatrix} \mathcal{E} \\ \mathcal{H} \end{pmatrix} = k \begin{pmatrix} \mathbf{n}\times & 0 \\ 0 & \mathbf{n}\times \end{pmatrix} \begin{pmatrix} \mathcal{E} \\ \mathcal{H} \end{pmatrix}, \tag{2}$$

where $\mathbf{n}$ is the direction of the wavevector $\mathbf{k} = k\mathbf{n}$, $\mathcal{E}$ and $\mathcal{H}$ are the Bloch amplitudes of the electric and magnetic fields respectively. After exception of the longitudinal waves the equation (2) can be reduced to the standard eigenvalue problem [4], that represents an inverse problem of finding k for given ω. Since this approach allows us to obtain eigenmodes for frequencies within band gaps, below we analyze the bands behavior typical for both Bragg and Mie resonances.

We consider a complex band-gap diagram calculated for a square lattice of dielectric cylinders with real dielectric constant ε of rods with radius $r = 0.3a$. In this case, the bands collapse at the Brillouin zone boundary (at the X point). However, introducing of weak losses, $\varepsilon = \varepsilon_{cyl}(1+0.002i)$, removes this degeneration. We find that for $\varepsilon_{cyl} < 18.5$ the plot of the real part of wavevector k vs. normalized frequency a/λ demonstrates a crossing behavior (Fig. 1c), so that the distance between the band going from the Γ point at the reciprocal lattice vector $\mathbf{g} = (0, 0)$, and the band going from the Γ point at $\mathbf{g} = (0, 1)$, decreases monotonically with the frequency a/l until the crossing point, then it increases again monotonically. However, for $\varepsilon_{cyl} > 18.5$, the distance between the bands decreases until a certain frequency after which they turn into an anti-crossing regime (Fig. 1d). The critical value $\varepsilon_{cyl} = 18.5$ is in excellent agreement with the value of dielectric constant defining

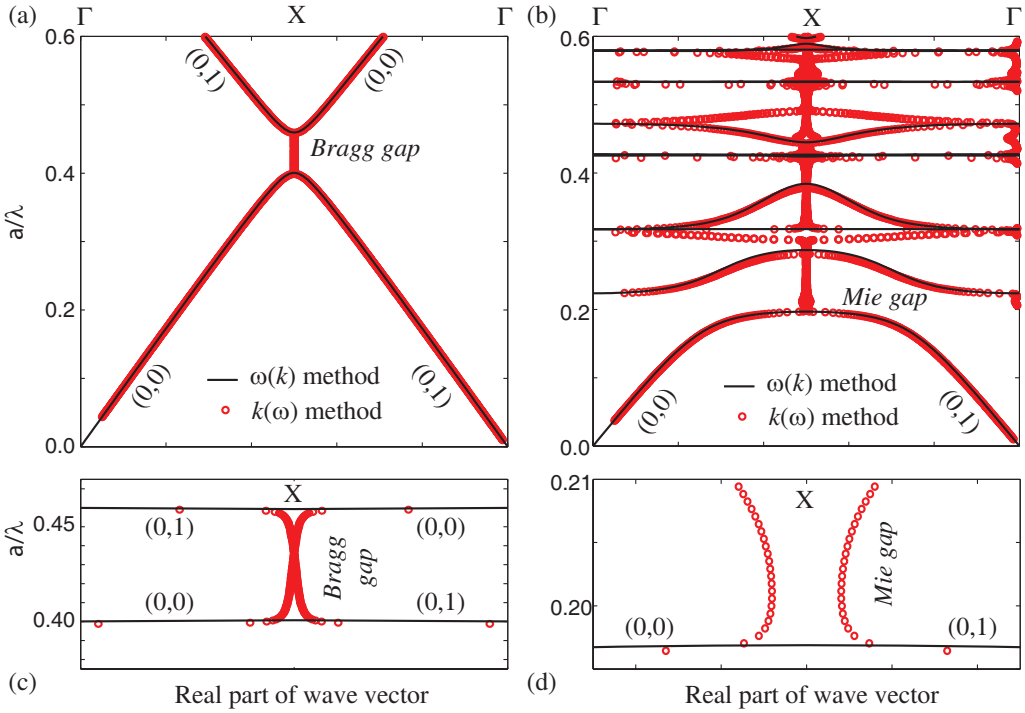

Figure 1: Complex band diagram calculated by the $\omega(k)$ method (solid lines) and inverse $k(\omega)$ method (circles) for the Bragg gap $\varepsilon_{cyl} = 3$ (a) and the Mie gap $\varepsilon_{cyl} = 40$ (b). Details of the band crossing behavior presented in a lager scale of (c) for $\varepsilon_{cyl} = 3$ and (d) for $\varepsilon_{cyl} = 40$. The data calculated by the inverse method correspond to weak losses $\varepsilon'' = 0.002\varepsilon'$. The inverse dispersion method uses 25×25 plane waves.

the boundary between the regime of photonic crystals and the regime of metamaterials obtaining from the direct $\omega(k)$ method. [1].

Since these two methods give the same results, we can use the most appropriate method. With the inverse $k(\omega)$ method we analyze a number of problems that cannot be solved with direct $\omega(k)$ methods. The first one is to build phase diagram for photonic structures composed of common high-refractive index materials such as silicon and Ge-Sb-Te alloys that have strong frequency dispersion of dielectric permittivity $\varepsilon(\omega)$. Arbitrary $\varepsilon(\omega)$ dispersion makes the usage of direct method be problematic since the operator in eigenproblem (1) depends on the eigenvalue ω. At the same time the frequency dispersion $\varepsilon(\omega)$ does not affect inverse $k(\omega)$ method, since its eigenvalue is k. The second problem is to study phase transition due to a higher order Mie modes. We verify our theoretical predictions for higher-order photonic phase transitions experimentally at microwaves. Measured data are shown to be in an excellent agreement with our theory.

Manipulating the spatial distribution of magnetic near-field by a four-unit coding metamaterial

Lifang Lang, Guo Li, Sheng Ji, Hong Chen and Yunhui Li*

Key Laboratory of Advanced Micro-structured Materials, Ministry of Education, School of Physics Science and Engineering, Tongji University, Shanghai 200092, China

Abstract- In this paper a coding metamaterial with '0' or '1'state controlled by a photo-relay is proposed, whose working frequency is about 3.0 MHz or 3.2 MHz. By arranging four units of this coding metamaterial in a square area, some special coding sequences can be easily realized, like '0000' and '0101'. As a consequence, the spatial distribution of magnetic near-field can also be modified. Both numerical and experimental results demonstrate that, under the coding sequence '0000', for instance, the magnetic field distribution are relatively uniform, as well as '0101' provides a diagonal field distribution. This work can also be extended to a large area complex structure with more unit cells.

Recently, vivid applications based on electromagnetic near-field have been emerging, such as near-field communication (NFC), radio frequency identification (RFID) and wireless power transmission (WPT). [1-3] However, the theory and technology of regulating the electromagnetic near field, especially some dynamic control strategies, are still not enough. Metamaterial is a good candidate for the control of electromagnetic waves and fields. However, for classical metamaterials, once the parameters of a metamaterial unit is settled, its electromagnetic properties cannot be changed also. Later, this problem is issued by adding some controllable elements, like variable capacitor, into the metamaterial units. In 2014, Engheta Group develop digital metamaterials , specifically synthesize an electromagnetic metamaterial with a desired permittivity, using as building blocks only two elemental materials with two distinct permittivity functions.[4] Then, T. J. Cui Group proposed the concept of coding metamaterials for convenient switching between different antenna radiation patterns.[5]

In this paper a coding metamaterial with '0' or '1'state controlled by a photo-relay is proposed. By arranging four units of this coding metamaterial in a square area, some special coding sequences can be easily realized, like '0000' and '0101'. As a consequence, the spatial distribution of magnetic near-field can also be modified.

As shown in Fig. 1, a coding metamaterial with 2×2 identical unit cells whose working frequency is about 3.0 MHz or 3.2 MHz is designed and fabricated. Each unit cell includes double-sided copper circuits, two capacity elements, a photo-relay and some connectors for controlling signals. By controlling the photo-relay, the coding metamaterial can work at 3.0 MHz or 3.2 MHz, which are named '0' and '1' states respectively. The total size of each unit cell is $50.8\times50.8\times1mm^3$.

According to the Kirchhoff Voltage Law, the currents in this four-unit coding metamaterial can be determined by the following relation: [6]

$$\begin{pmatrix} Z_1 & i\omega M_1 & i\omega M_2 & i\omega M_1 \\ i\omega M_1 & Z_2 & i\omega M_1 & i\omega M_2 \\ i\omega M_2 & i\omega M_1 & Z_3 & i\omega M_1 \\ i\omega M_1 & i\omega M_2 & i\omega M_1 & Z_4 \end{pmatrix} \begin{pmatrix} I_1 \\ I_2 \\ I_3 \\ I_4 \end{pmatrix} = \begin{pmatrix} U \\ U \\ U \\ U \end{pmatrix} \quad (1)$$

Where, I_n is the current in the n element, $Z_n=R_n+i\omega L_n+1/(i\omega C_n)$ is the self-impedance, L_n is the self-inductance, C_n is the capacitance, M_1 is the mutual inductance between nearest neighbors and M_2 is the mutual inductance between the next nearest neighbors. Consequently, based on the Biot-Savart law and superposition[7], the perpendicular magnetic field at the transfer distance（h=50mm）from surface of the structure can also be deduced, shown in Fig.2. Both numerical calculation and experimental measurement demonstrate that, under the coding sequences '0000', for instance, the magnetic field distribution are relatively uniform, as well as '0101' provides a diagonal magnetic field distribution. This work can also be extended to a large area complex structure with more unit cells.

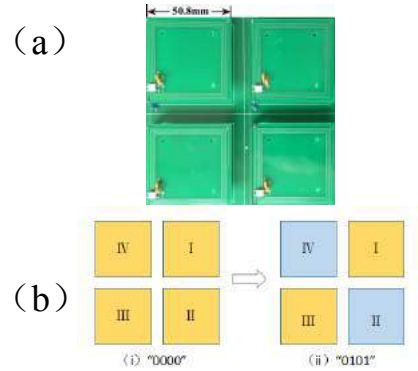

Fig. 1:（a）Photograph of a four-unit coding metamaterial and（b）Schematics of coding sequences '0000' and '0101'. Yellow: '0' state; blue: '1' state.

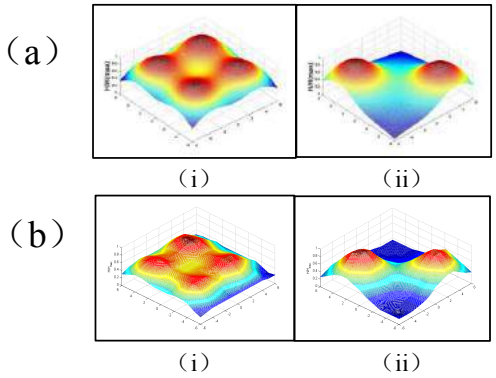

Fig. 2: The calculated (a) and measured (b) results of the spatial distribution of the magnetic near-field at h=50mm: (i), (ii) are the results of '0000' and '0101', respectively.

Enhancement of spontaneous emission in metal-dielectric structures revisited

M. A. Kaliteevski[1,2,3], A. R. Gubaydullin[1,3], K.A. Ivanov[1,3]
[1]Saint- Petersburg Academic University, 194021, St. Petersburg, Russia
[2]Ioffe Physical-Technical Institute of Russian Academy of Science, 194021, St-Petersburg, Russia
[3]Saint Petersburg ITMO University, 197101, St. Petersburg, Russia

Abstract-We have developed the procedure of the quantization of the electromagnetic field in a layered inhomogeneous media, based on the analysis of the eigenvalues of the scattering matrix (S-matrix). We present application of S-quantization for the calculation of spontaneous emission rate for different photonic structures. We study the enhancement of spontaneous emission of the dipole embedded in the layered metal-dielectric structure applying S-quantization.

Metal-dielectric multilayered systems have attracted great scientific interest over the past decade due to their special optical properties emanating primarily from hyperbolic dispersion of isofrequency surface, and therefore are generally called hyperbolic metamaterial (HMM) systems [1]. Recently appeared estimations of ultra-high values of the spontaneous emission rate enhancement of the dipole emitter centered in the stratified metal-dielectric metamaterial [2] are very interesting, offering many fascinating applications. Nevertheless, these results deserve more careful consideration since in these studies, the mode structure of the field in the space with the inhomogeneity was assumed to be identical to the mode structure of a homogeneous medium obtained using periodic BC [3].

However, in the case of an inhomogeneous medium, the approach to the problem of the mode structure of the field on the basis of periodic BC is not rigorous and self-consistent, because the presence of inhomogeneity can lead to significant changes in the mode structure (obtained by applying the periodic BC) discussed in [4],which in turn may lead to inaccuracies in the analysis of layered systems. In our study of layered metal-dielectric structures we present angular dependence of Purcell factor [5] for incidence angles inside the light cone, as proposed initially in [3]. Also we notice that the use of periodic BC limits an applicability of results obtained in [2,3], since only “symmetric” eigenvector is used in approach [3], while the mode corresponding to “antisymmetric” eigenvector is missed.

We have developed a procedure S-quantization [6] of quantization of electromagnetic field that would allow rigorous self-consistent description of the mode structure in the quantization box with inhomogeneity, and providing a way for the calculation of probability of spontaneous emission (Purcell effect) from multilayered structure for modes characterized by arbitrary direction of propagation and polarization, for arbitrary layered structures. S-quantization solves the long-standing problem coupled to normalization of the quasi-stationary electromagnetic modes.

Examples of application of S-quantization for the calculation of spontaneous emission rate for the cases of Bragg reflector and microcavity are demonstrated in [6]. We have compared S-quantization results with experimentally observed photoluminescence pattern measured on Tamm plasmon structure [7], showing a good agreement, what provide the confirmation for S-quantization method. We study the enhancement of spontaneous

emission of the dipole embedded in stratified metal-dielectric structures, illustrating dependence of Purcell factor over the inplane wavevector.

Bandwidth Optimization of Trapped-Mode THz Filters Exploiting Adjoint Sensitivity

A. Y. Elsharabasy[1*], M. H. Bakr[1], and M. Jamal Deen[1]
[1]Department of Electrical and Computer Engineering, McMaster University, Canada
[*]corresponding author: elsharay@mcmaster.ca

Abstract—In this work, we present an optimization approach to reduce the bandwidth of metal mesh THz filters on thick substrates. Adjoint sensitivity analysis is exploited to provide the derivatives of the objective function for the optimizer. Through the optimization steps, the trapped-mode response has been improved with the out-of-band rejection reduced. EM simulations are carried out to illustrate the efficiency of the technique in decreasing the filter's bandwidth and enabling integration for detection and sensing applications.

In the last two decades, the THz metamaterials have been of a great interest because they allow for powerful THz applications [1-3]. One crucial and common element in most of these applications, especially in space-based astronomy and sensing, is the THz filter. Metal mesh filter represents a simple design and relatively low-cost in fabrication [4]. The stand-alone metal mesh filters have been widely used for many decades. However, at higher frequencies, their metal sheet thickness becomes electrically thick [5]. A possible remedy is to build the filter on thick and inexpensive substrates. In addition, the out-of-band rejection can be improved by producing a trapped-mode excitation within the structure [6, 7].

Here, the THz filter template shown in Fig. 1 has the vector of control parameters is given by $\boldsymbol{x}$= [*G, J, K, a, b*]^T as shown. The initial values of these points are set and passed to the EM simulator HFSS [8]. HFSS simulates the structure and returns both the S-parameters and their adjoint sensitivities [9, 10] with respect to all the control parameters. These sensitivities are to be utilized within the optimization algorithm. Derivative-based optimization is utilized to reach the optimal set of control variables satisfying the design specifications.

In our example, we utilize a cross absent filter with initial template parameters similar to the design in [7] and a 1-μm thick copper grid operating at 0.37 THz resonant frequency. We carried out the simulations for the filter on a 1-mm thick fused silica substrate. Here, we aim to narrow the bandwidth of the initial filter. The objective function is a weighted version of the transmission response of the filter. The EM simulation is performed for 9 frequency sweep points linearly distributed from 0.34 THz to 0.4 THz. $\boldsymbol{x}_l$ and $\boldsymbol{x}_u$ are, the lower and upper bound constraints on the parameters, respectively. The main objective function can be formulated as,

$$\min_{\boldsymbol{x}} \max_{i} \left\{ \left| S_{21}(f_i, \boldsymbol{x}) \right|^2 \right\}, \quad \text{subject to} \quad \boldsymbol{x}_l \le \boldsymbol{x} \le \boldsymbol{x}_u$$
$$\text{where, } 0.34\,\text{THz} \le f_i \le 0.4\,\text{THz}, i = 1,2,..,9, \text{ and } f_i \ne 0.37\ \text{THz}. \tag{1}$$

The minimax optimizer starting point x_0 and the optimal parameters values x_f are shown in Table I. The optimal response, in Fig. 2, shows that the new bandwidth is reduced from 14% to 6.5%, which is less than half the original one.

New controllable birefringence phase matching method for the 2nd harmonic generation

T.Chang[1], **J. Shin**[1*]
[1]KAIST, Korea
[*]corresponding author: qubit@kaist.ac.kr

Abstract- We show that the new type of the phase matching technique, which is controllable birefringence based on the mesoscopic crystal. The polarization of the pump wave and 2nd harmonic wave can have orthogonal polarization, and the x- and y- directional linear property of the mesoscopic crystal can be independently controlled, and coherence length can be tuned.

1. Introduction

The nonlinear metamaterials draw much interest because of their enhanced nonlinearity. Since the frequency dispersion of the nonlinear metamaterials are generally more severe than natural nonlinear crystal, the phase matching technique for nonlinear metamaterials were also widely studied. However, the many previous phase matching technique for nonlinear metamaterials are limited to special cases, such as zero-index [1], or negative index [2]. Here, we show that the new type of phase matching technique for nonlinearity-enhanced medium based on the controllable birefringence of the mesoscopic crystal. This phase matching method is based on the controlling crystallinity of the mesoscopic structure and polling direction of the nonlinear material.

2. Results

The mesoscopic crystal structure are represented in Fig. 1a and its enhanced linear susceptibility was previously demonstrated [3]. The structural parameters are 'a', 'g', 'h_m', 'h_d', which are lateral unit cell dimension, lateral gap size, metal layer thickness, and dielectric layer thickness, respectively. Here, we assumed the filling dielectric have non-zero 2nd order susceptibility. The effective nonlinear dielectric tensor of the mesoscopic crystal can be obtained by the Lorentz-reciprocal theorem [4,5],

$$\tilde{\chi}_{eff}^{(2)} = v^{-1} \int \tilde{E}^{\mathrm{T}} p \tilde{\chi}^{(2)} \tilde{E}^{(2)} dv, \tag{1}$$

where p = +1, 0, -1 depends on the polling direction for specific points, and (i,j) component of 3-by-3 E matrix, E_i^i, is i-directional component of unitless electric field vector generated and normalized by j-directional applied average electric field. The quantitative E configuration is calculated in ref. [3]. The components of the 6-by-6 $E^{(2)}$ matrix are binomial expansion of the E matrix. Therefore, one can manipulate and enhance the nonlinear susceptibility by mesoscopic field configuration and the polling direction of the mesoscopic crystal. One representative example for the polling direction is depicted in Fig. 1b. For this configuration, the linear susceptibility, and the 2nd order nonlinear susceptibility from Eq. (1) becomes,

$$\tilde{\epsilon} = \epsilon_{33}\begin{pmatrix} \frac{1}{16}\left(\frac{a_x}{h_d}\right)^3 & 0 & 0 \\ 0 & \frac{1}{16}\left(\frac{a_y}{h_d}\right)^3 & 0 \\ 0 & 0 & 2 \end{pmatrix}, \quad \tilde{\chi}^{(2)}_{eff} = \tilde{\chi}^{(2)}_{33}\begin{pmatrix} \frac{1}{16}\left(\frac{a_x}{h_d}\right)^3 & \frac{1}{16}\left(\frac{a_x}{h_d}\right)\left(\frac{a_y}{h_d}\right)^2 & \left(\frac{a_x}{h_d}\right) & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{16}\left(\frac{a_x}{h_d}\right)^2\left(\frac{a_y}{h_d}\right) & 0 \\ 0 & 0 & 0 & \left(\frac{a_x}{h_d}\right) & 0 & 0 \end{pmatrix}. \quad \textbf{(2)}$$

It shows that the generated 2nd harmonic wave becomes x-polarization, even if input pump wave is y-polarized. Moreover, the x-component and y-component of linear effective dielectric constant can be controlled by controlling x-, and y-unit cell dimensions. Therefore, the phase matching condition can be accomplished by independent controlling of x- and y- directional dielectric constants even with the dispersion of the metal and dielectric of the mesoscopic crystal. The numerical results is represented in Fig. 1c. It clearly show that the coherence length can be controlled by the controlling of the x- and y- lateral unit cell size.

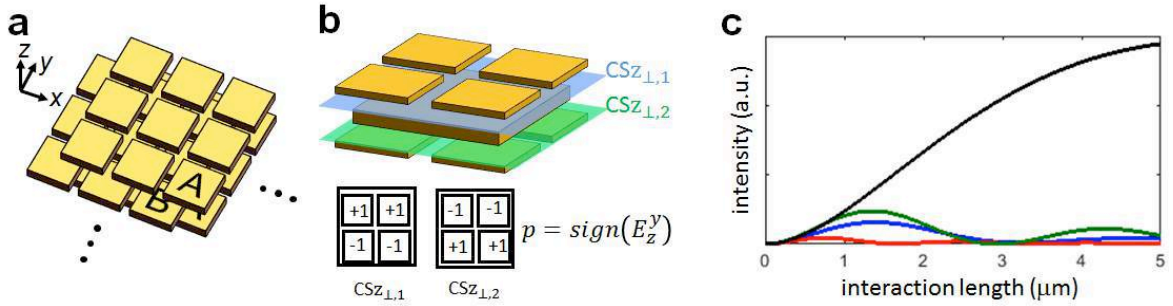

Fig. 1 (a) schematic of mesoscopic crystal (b) one example of polling direction configuration. (c) coherence length controllability (a_x = 160 nm; blue: a_y = 160 nm, red: a_y = 180 nm, green: a_y = 120 nm, black: a_y = 135 nm)

3. Conclusion

We numerically show that the controllable birefringence can be used for new type of the phase matching of second harmonic generation. Together with the enhanced nonlinearity of the mesoscopic crystal, the phased-matched harmonic generation can be widely applicable to nonlinear devices.

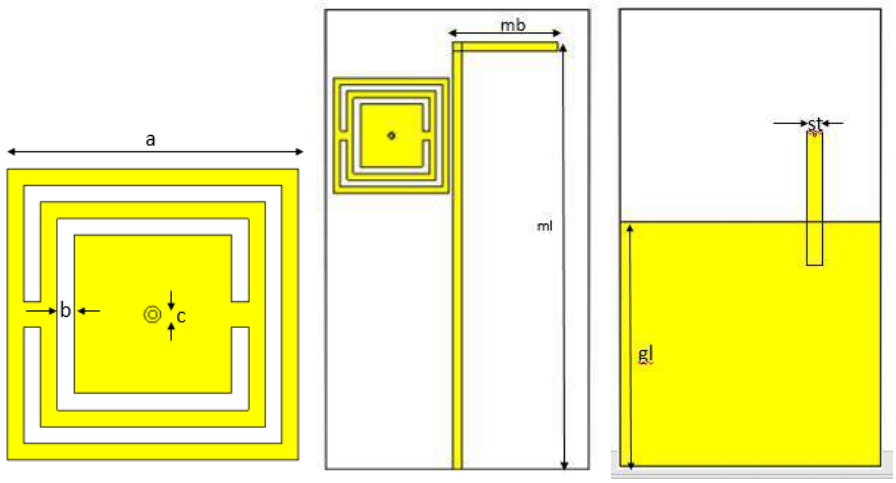
Abstract-In this paper, a design and simulation study of a bandwidth enhanced bent monopole antenna consisting a unit of CSRR, shorting via and a stub is presented. The antenna resonates at 0.75 GHz and 0.9GHz with bandwidth 32.73%. A comparison of return loss between bent monopole and bent monopole with added CSRR is shown to prove the functional of CSRR. The proposed antenna has a moderate 1.789dB and 2.047dB gain at 0.75 GHz and 0.9 GHz respectively.

1. INTRODUCTION

Recently, metamaterials(MTM) have been used widely in microwave devices and antenna application field. Broadband and compact antennas are in high demand with the fast development of modern wireless communication devices. Special properties of MTM such as zero propagation constant and negative refractive index could have enhanced the properties of the antenna [1]–[6]. At the low frequency such as Ultra High Frequency (UHF) band, using a MTM structure would be a great idea to improve the performance of the antenna as the wavelength of the antenna at this band is large. In this paper, a bandwidth enhanced metamaterial inspired antenna is proposed. The antenna is fed by a bent monopole and consists of a square shape complementary split ring resonator (CSRR), shorting via and a stub.

2. ANTENNA DESIGN



(a) (b) (c)

Figure 1: The geometry of the proposed antenna. (a) CSRR (b) Front view (c) Back view

The geometry of the proposed antenna is shown in Figure 1. The antenna consists of a square shaped CSRR, bent monopole, via and a shorted stub that connects the via to the ground plane with total dimension of 150mm x 80mm. It is designed with basic monopole antenna to be operated at 0.75GHz as the center frequency. The

monopole is bent at the end for the size reduction purpose as the bent has not change much on the antenna performance. The antenna is simulated on FR-4 dielectric substrate of permittivity 5.0, and a thickness of 1.6 mm by using CST microwave software. CSRR is chosen and added to this work for the bandwidth enhancement purpose [2]. A via of radius 0.5 mm at the center of the CSRR connects the stub at the back of the antenna that connected to the ground. Table 1 shows the dimension of the antenna parameters.

Table 1: Proposed antenna dimension

Parameters	a	b	c	mb	ml	gl	st
Dimension (mm)	35	2	2	32	130	65	5

3. RESULTS AND DISCUSSION

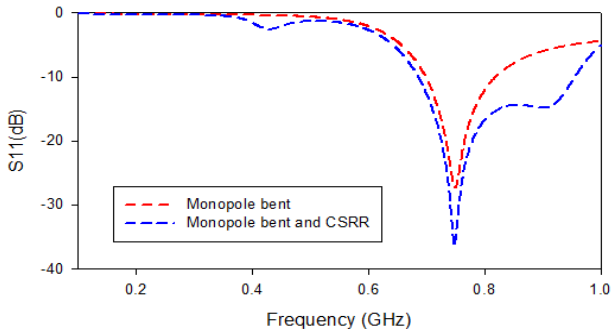


Figure 2: Return loss comparison

Figure 2 shows the comparison of return loss between bent monopole and bent monopole with added CSRR. Bent monopole resonates at 0.75 GHz with bandwidth percentage 17.22%. Then, a CSRR is added next to the monopole and it produced another resonant at 0.9 GHZ with bandwidth 32.73% at -10dB. It shows a single unit of CSRR may enhanced the bandwidth of the antenna. The proposed antenna has a gain of 1.789 dB and 2.047 dB at 0.75 GHz and 0.9GHz respectively.

4. Conclusion

A bandwidth enhanced metamaterial antenna with bent monopole at UHF band is proposed. The antenna consists of a square CSRR, via, stub and monopole bent with size of 150mm x 80mm. The antenna resonates at 0.75 GHz and 0.9 GHz with bandwidth of 32.73%.

Abstract- In this study, a flexible substrate for metamaterial based on Nickel Aluminate ($NiAl_2O_4$) synthesized by sol-gel method is presented. The optical and microwave characterization demonstrate that the $NiAl_2O_4$ substrate is consists of a dielectric constant of 4.8, loss tangent of 0.04, and an optical bandgap of 2.8 eV. The metamaterial unit cell is fabricated on prepared flexible composite employing copper coating by magnetron sputtering. The double negative metamaterial behavior is found at a frequency of 6.05 GHz in microwave spectra.

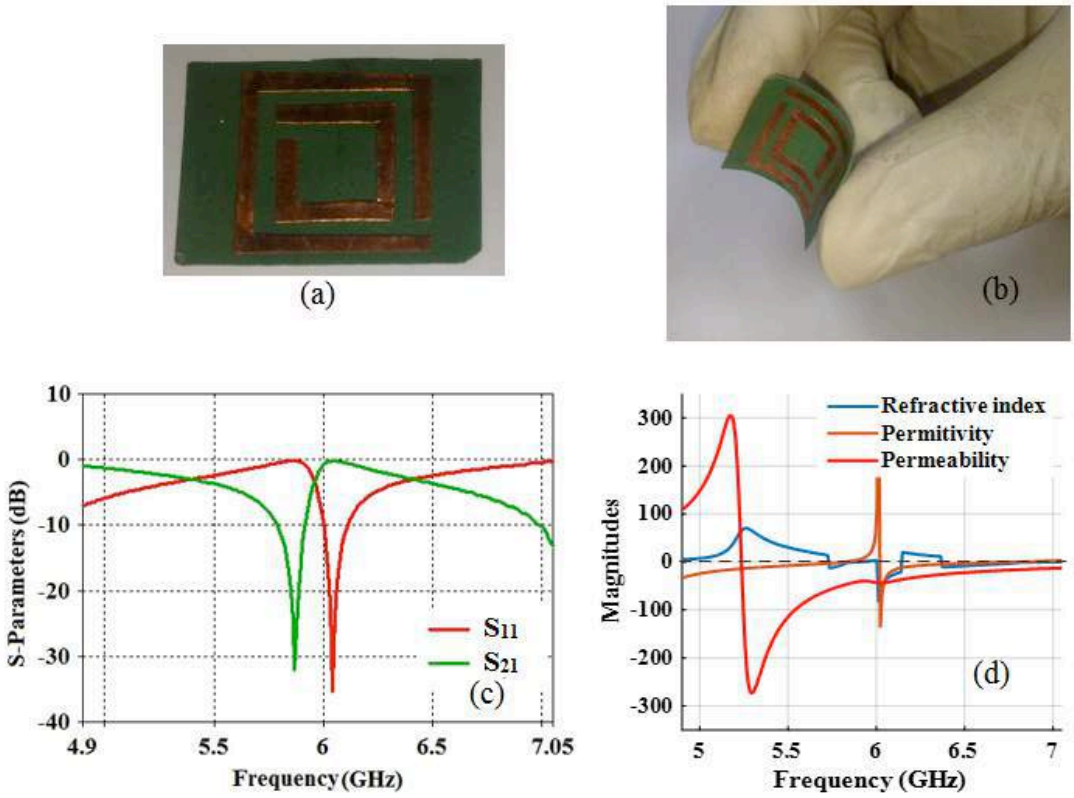

Figure: (a) The fabricated metamaterial unit cell on synthesized substrate, (b) Presentation of flexibility, (c) Reflection and transmission coefficient of metamaterial and (d) The effective parameters.

Improvements in several areas of materials science have resulted in a variety of new materials with strong potential applications to microwave components. In recent years flexible materials have earned immense interest in microwave engineering [1,2], however, there are very limited analyses on the impact of bending structures. Nano-crystalline NiAl2O4 is synthesized by many researchers with several methods [3,4], but they have not been explored much for microwave applications. The microwave dielectric properties of NiAl2O4 were investigated to find their employment as flexible material based metamaterial for microwave uses. The sol–gel method was employed to synthesize the flexible composite. The establishment of spinel assembly and crystalline dimension were assured using X-ray diffraction analysis. Morphology of the samples was clarified by means of the scanning electron microscopy. Relative permittivity and dielectric loss tangent of the specimen were restrained by DAK 200 MHz to 20 GHz dielectric measurement kit and obtained as 4.8 and 0.04, respectively. The energy bandgap was found 2.8 eV from optical analysis, which implies that the synthesized nanoparticles are semiconductors by nature. The flexible substrate layer was prepared by mixing NiAl2O4 nano-powder with polyvinyl acetate (PVA) glue dried up by means of heat. Finally, the metamaterial unit cell is fabricated on 20×18 mm2 NiAl2O4 flexible composite substrate employing 200 nm copper coating over that 1 mm thick substrate by magnetron sputtering shown in Figure (a & b). N5227A PNA microwave network analyzer and 159WCAS A-INFO Microwave waveguides are used to measure reflection and transmission parameters shown in Figure (c) of fabricated unit cell. DRI method [5] is used to extract the effective parameters shown in Figure (d) of the unit cell and double negative metamaterial behavior is found at a frequency of 6.05 GHz in microwave spectra. The overall analysis confirmed that NiAL2O4 is a highly suitable for fabrication of flexible metamaterial and desired operating parameters can be archived by modifying the synthesis and fabrication conditions.

Abstract- We derive a method for calculating effective parameters of metafluids, where the rationally designed 3D metamolecules are homogeneously dispersed in liquid-phase fluid (e.g., water). Using this method, we engineer the effective parameters of solution-processable form of metamaterials by tailoring the shape and size of plasmonic nanoparticle and geometry of cluster.

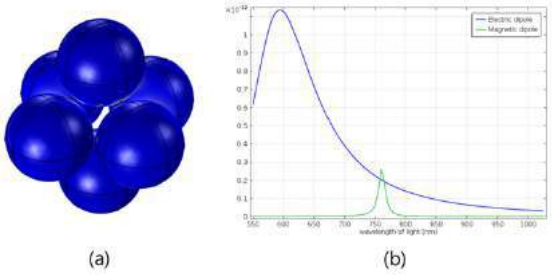
Metafluids, in which the tailored metallic nanoparticle clusters (i.e., metamolecules) are homogeneously dispersed within fluid medium, have been viewed as a practical way to use metamaterials mainly owing to their solution processability [REF 1, REF 2]. However, *S*-parameter-enabled retrieval methods, which have been widely used in analyzing a periodic metamaterial [REF 3], are not valid for retrieving effective parameters of metafluids, because metamolecules in fluid are randomly rotating and moving in real time.

In this work, we analyze the optical properties of metamolecules, which could be materialized by benefitting from the recent advances in soft matter engineering (e.g., colloidal assembly [REF 4]). Then, we derive the effective parameter determination methods for metafluid based on the Clausius-Mossotti relation combined with dressed polarizability. Finally, we apply this method to various cluster motifs and identify the required concentration of cluster to induce unnatural light-matter interaction such as negative refractive index.

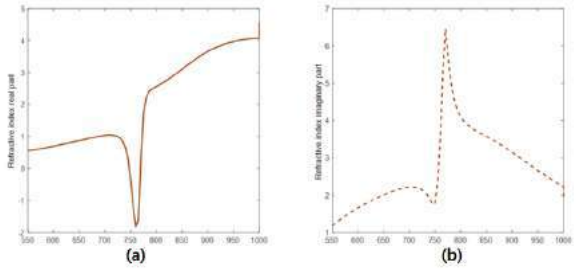
If we assume distance between each cluster and overall size of cluster are relatively small compared with the wavelength, Clausius-Mossotti relation can be applied to retrieve effective parameter (e.g., permittivity) as follows:

$$\frac{\varepsilon_r - 1}{\varepsilon_r + 2} = \frac{N\alpha}{3\varepsilon_0} \tag{1}$$

where $\varepsilon_0, \varepsilon_r$ are permittivity of vacuum and single molecule, respectively. As a representative example of our approach, herein, we exploit the available unnatural electromagnetism by using octahedron cluster motifs (Figure 1a) consisting of six 60 nm metallic nanospheres. This suggested structure has a substantial magnetic and electric dipole resonance by near-field coupling between adjacent metallic nanospheres (Figure 1b).



[Fig.1] (a) structure of octahedron. (60[nm] diameter of each constituent particle, 1[nm] gap between neighbor particles) (b)Electric dipole (blue) and Magnetic dipole (green) of this octahedron structure.



[Fig. 2] Refractive index of 0.77 micro-molar concentarion metafluid calculated by Clausius-Mossotti relation. Real part (a) and imaginary part (b) is shown in graph separately.

When this cluster motif is dispersed in water with 0.77 micro-molar concentrations, the negative refractive index at visible wavelength was found to be achieved (Figure 2). Also, we further engineered the cluster motifs such as broken symmetry to reduce the required concentration of metamolecules for negative refractive index. This design of asymmetric metamolecules was carried out under the umbrella of cluster motifs, which could be available with DNA-based programmable self-assembly [REF 5].

Comparison of E-field on Various Patch Split Ring Resonator for Energy Harvesting

M. S. Zainudin, M. K. A. Rahim, N. A. Samsuri,
Faculty of Electrical, Universiti Teknologi Malaysia, Malaysia
mkamal@utm.my, asmawati@utm.my, msyazwan42@live.utm.my

Abstract- The energy harvesting with metamaterial structure (Split Ring Resonator) are proposed. The operating frequency is 1.3GHz. Three design are simulated by using CST software shows square patch give the highest value of absorption, which is 96.57%. For E-field monitoring in CST, the even circle shows the lowest value of absorption frequency wavelength, but its shows that it has the highest value of E-field, which is 181,100 V/m.

Artificial materials showing electromagnetic properties are not attainable in naturally due to their negative value of permittivity and permeability[1]. This artificially called metamaterials. They are made from assemblies of multiple elements fashioned from composite materials such as metals or plastic[2]. The materials are usually arranged in a repeating pattern, with the scale that smaller than their operating wavelength[3]. Split Ring Resonator is the one example of design from metamaterial structure[4]. The ring design as a patch with substrate and ground plane give the negative value of permeability[5]. Since the previous work shows that SRR can be used as an absorber of microwave signal (almost 100% efficiency), here come the challenge to take it as a new platform to harvest an energy, replacing the common method of harvest an RF signal by using rectenna[6]. This research starts from the study the performance of various design for patch split ring resonator[7]. Circle, square and hexagon are the proposed design in the research to optimize which design give the highest performance in absorbing transmitting frequency signal.

The absorption performance of all the structures shows the similarities. The circle shape has absorption value of 92.72%, followed by Hexagon shape by 95.17% and square shape with the highest percentage, which is 96.57%. In this result, all three structure has more than 90% of absorption characteristics, with E-plane must be parallel to the structure. The simulation continued by looking at the E-field characteristic. All mesh value is defined as a constant parameter. The result show vice versa from the absorption result. The circle patch gives the highest value of E-field concentration compared to others two designs. The circle patch gives the value of E-field 181 100 V/m, followed by hexagon patch (158,400 V/m) and square patch (109,200 V/m).

Initial observation shows that the edge of the structure gives an influence of E-field concentration. Since the circle patch didn't have any edge of its shape, the E-field orientation is easier to concentrate at the gap of the structure. Compared to hexagon and square patch, E-field is concentrated more than one point. This makes trapped energy inside the structure spread to several points, and disappear. The propagation of wavelength must be vertical toward the patch. If the structures are rotated 90 degree either clockwise / anticlockwise, the result of E-field decreased. This is due to the reflection coefficient that has been shifted to 800MHz.

Split Ring Resonator Patch Design (0 and 180 degree)	 Circle	 Hexagon	 Square
Reflection Coefficient (S11)	-11.405 dB	-13.183 dB	-14.649 dB
E-field (V/m)	181,100	158,400	109,200
Absorption Percentage	92.72%	95.17%	96.57%
E-Field (V/m) (Rotated 90 degree)	4,238	1,527	1,036

In this study, it's important to choose the structure that has high concentration of E-field at the gap. From the table result, even though the square patch has the highest value of reflection coefficient, the circle patch got the better performance on E-field concentration. The absorption percentage of circle patch are the lowest one compared with other two patch, but its capable to capture the highest E-field. Next all three patch structures will be fabricated and measured. The result of measurement will be compared with simulation. Further study, the measurement will be done by using an oscilloscope and measure the potential energy at the gap of the structure by place a passive element (resistor or diode) as a load.

Abstract

A printed super wideband (SWB) monopole antenna for wireless communication applications using a unique double negative (DNG) unit cell metamaterial is presented. A compact key-shaped radiator is designed with electrical dimensions of 0.152 λ_o × 0.140 λ_o with respect to its lowest operating frequency. The proposed design, satisfactory far field radiation pattern, gain features fulfils the requirements to be suitable for SWB spectrum. Moreover, the 10 dB impedance bandwidth of the proposed antenna is from 3.47 to 60 GHz.

1. Introduction

In the past decades, an essential amount of research has been dedicated to microstrip antennas by increasing the utilization of the spectrum depending on the demand of wireless communication systems and the surrounding environment [1]. For instance, the current users of wireless personal area network (WPAN) are excitedly demanding super wideband (SWB) antennas to cover both long and short range transmitting for universal services [2]. These desired antennas have many benefits such as small size, lightweight, low cost, and their conveniently with integrated circuits. However, narrow bandwidth is one of the drawback challenges that limit the usages in the wideband modern wireless applications. Double-negative metamaterial (DNM), which is an example of the metamaterial unit cell can be used to improve and increase the antennas bandwidth due to the tremendous changes of its behavior to produce negative refractive index (NRI) within both negative permeability (μ) and permittivity (ε) [3]. The first engineered materials with simultaneously negative ε and μ was mathematically described by V. Veselago in 1968 [4]. Furthermore, by applying the DNM metamaterial on the antennas design, their performance will be enhanced where a new version of the antennas with an obvious improvement in terms of bandwidth, gain, size and good radiation patterns can be obtained [5].

This paper presents a miniaturized super wideband (SWB) monopole antenna using a new, wideband and compact DNM unit cell for wireless applications. Two rows of the proposed left-handed metamaterial unit cell located on the reverse side of the antenna substrate and some are placed near to the transmission line of the antenna. This structure exhibits negative permittivity and permeability and negative refractive index (NRI), which result in a compact, wide band antenna with omnidirectional radiation pattern.

2. Antenna Design and Unit Cell Geometry

The proposed DNM unit cell consists of several symmetric split ring resonators (SSRRs) assembled and combined to enable the unit cell operation over the wide band range within 3.47–60 GHz.

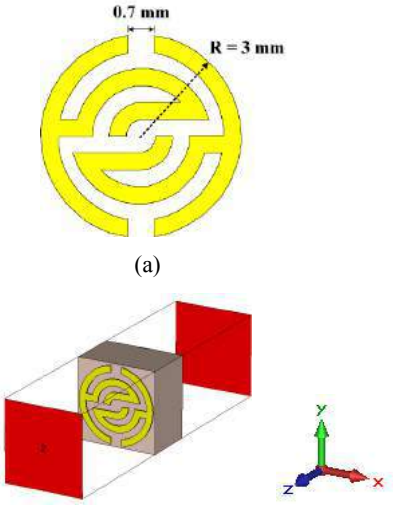

Figure 1: (a) Metamaterial unit cells structure, (b) simulation set.

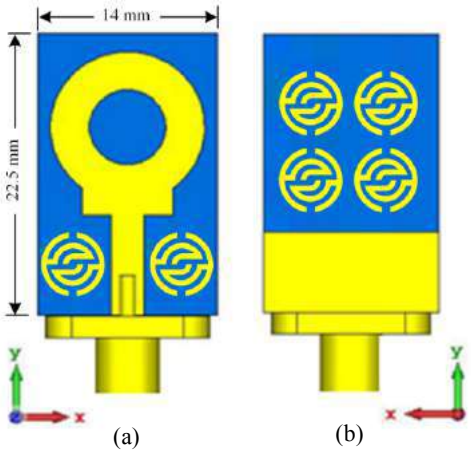

(a) (b)

Figure 2: Proposed antenna with unit cell (a) Front view (b) Back view

It was simulated using Computer Simulation Technology (CST) software for achieving the S-parameters whereas its simulated geometry is shown in Figure 1a. The simulation setup of proposed metamaterial unit cell illustrated in Figure 1b where two waveguide ports are located on each side of the z-axis. However, the proposed miniaturized SWB monopole antenna is shown in Figure 2, which is printed on a low-cost, 1.6 mm-thick FR4 substrate with a relative permittivity of 4.7 and loss tangent of 0.025. The overall size is of substrate is 22.5 × 14 × 1.6 mm^3 where the antenna is fed by 50-Ω SMA connector as shown in Figure 2.

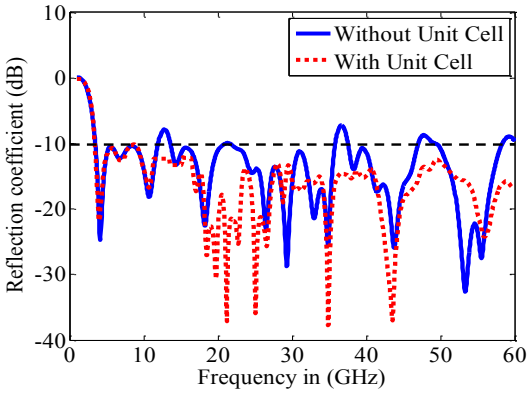

Figure 4: Comparisons of unit cell effects on reflection coefficient

It can be seen clearly that 2 × 2 unit cells are placed on the proposed antenna reverse side above the selected partial ground plane whereas two unit cells are applied horizontally close to the antenna's transmission line.

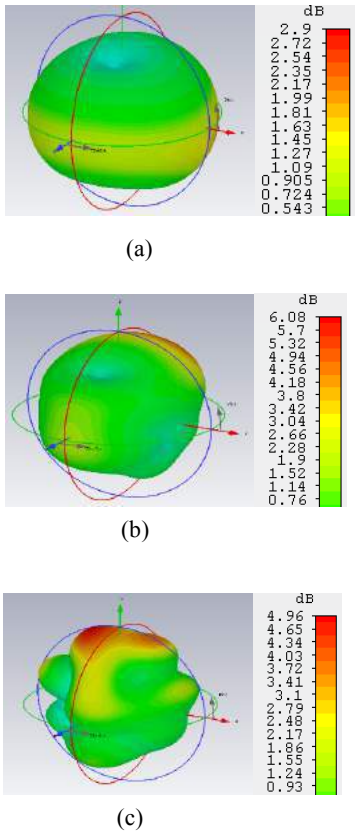

Figure 5: 3-D radiation pattern at (a) 5 GHz, (b) 10 GHz, (c) and 20 GHz.

3. Results and Discussion

Figure 3 (a-c) shows the obtained simulated results of the permeability, permittivity and refractive index within the frequency rang up to 60 GHz. The results showed the acquired wideband range of real negative values for both permeability and permittivity while the achieved real negative refractive index can be observed at the frequency span of (1-9.8 and 16.8-60) GHz as shown in figure 3.
Furthermore, it can be observed in Figure 4 that the proposed SWB antenna incorporates with unit cell can display high bandwidth from 3.47 to 60 GHz with reference to S11 < -10 dB which has too far wide bandwidth against previous antennas. The impedance bandwidth of the proposed antenna reaches 178.13% and the radiation patterns indicate that the SWB antenna radiation patterns are approximately omnidirectional as shown in Figure 5 (a-c).

4. Conclusions

A miniaturized super wideband (SWB) antenna using DNG metamaterials is presented. A novel and compact with left-handed symmetric split ring resonators (SSRRs) metamaterial unit cells is proposed. The features of negative permeability, permittivity, and refractive index (NRI) are validated from the proposed unit cell construction. Several unit cells are then placed on the antenna's backside and nearby the antenna's transmission line. The simulated reflection coefficient (S11) shows a wide bandwidth by 178,13 % (from 3.47 to 60 GHz).

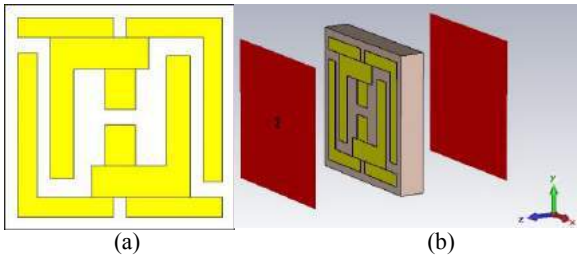
Abstract

This paper highlights a modified compact H-shaped Double Negative (DNG) metamaterial unit cell for X- and Ku-band applications. The unit cell has been constructed with the combination of two pair of L shaped resonators and two rectangular conductor blocks. The unit cell realized a highest DNG bandwidth of 4.32 GHz covering X and Ku-band (10.68 GHz to 15 GHz) with a size of 0.792 cm2. 1x1, 2x1, 2x2 and 4x4 array of the unit cell have also been analyzed.

1. Introduction

Artificial engineered materials or Electromagnetic (EM) Metamaterials (MMs) have been received a lot of attention from researchers with remarkable progress observed over the past decade [1]. The intriguing properties of MMs have inspired the researchers to implement them for various multiband applications and electromagnetic absorption reduction [2]–[4]. Different researchers have designed different alphabet-shaped metamaterial unit cell structures including U-shape, V-Shape, S-shape, H-shape, Z-shape etc. for multiband applications [2], [3], [5]. An "H-shaped" metamaterial has been proposed by Islam et al. [2], but the highest bandwidth was 0.5 GHz in C-band. Moreover Hossain et al. presented "two G-shape" DNG metamaterial for S- and C-band. In this case the highest bandwidth they achieved is 1.05 GHz (2.95 GHz to 4.00 GHz) with the lowest size of 1.2×1.2 cm^2 for the *unit cell-A* [3]. The highest DNG bandwidth in multiband operation has been reported in [5] that is 3.61 GHz which is higher than the other reported works. But in this case the size of the unit cell was 1 cm^2. Few manuscripts have been reported with multiband operation higher than 4 GHz DNG bandwidth associated with miniaturized size less than 1 cm^2.

This paper proposes a DNG multiband meta-material unit cell having negative permittivity and permeability in region of X-band and Ku-band with a highest DNG bandwidth of 4.32 GHz (10.68 GHz to 15 GHz) covering both first and second band.



(a) (b)

Figure 1: Proposed Modified H-shaped metamaterial unit cell (a) proposed geometry (b) 3D geometry

This unit cell has realized a size of 0.9×0.88 cm^2 that is less than other unit cell reported in the above mentioned literatures. The proposed unit cell has been analyzed with 1×1 , 2×1 , 2×2 and 4×4 array gestalts. It exhibits resonance in X band and Ku band respectively. Moreover, it has DNG property in these two bands with a highest DNG bandwidth of 4.32 GHz (10.68 GHz to 15 GHz) in covering both bands. For the other array configuration it also shows the DNG properties in the X and Ku bands with a common DNG bandwidth of 10.8~15 GHz.

2. Unit cell design Architecture

The proposed unit cell consists of two pair of L shaped-resonators sandwiched one another. In addition to that it has two rectangular conductors in the middle. These shapes together form a shape of Modified H shaped proposed unit cell. Both of the L shaped resonators are connected with each other as depicted in Figure 2. The whole unit cell is symmetric with respect to the horizontal axis. The unit cell is designed on an FR-4 substrate of relative permittivity, ε_r=4.3 and loss tangent, δ=0.025 , copper thickness of 0.035 mm. The dimensions of the unit cell are presented in Table 1. FDTD based Computer Simulation Technology (CST) Microwave studio is used for the design of the unit cell. In this design the incident wave travels along z axis. Perfect Electric Conductor (PEC) and Perfect Magnetic Conductor (PMC) are deployed along y and x axis

respectively. The design is simulated with a frequency range of 0.1 GHz to 15 GHz using tetrahedral mesh property. Figure 1 illustrates the unit cell's 2D and 3D view. It can be seen that the waveguide port is set in the z direction. The dimensions are elucidated in Figure 2.

Parameter.	Value (mm)	Parameter.	Value (mm)	Parameter.	Value (mm)	Parameter.	Value (mm)
a	9	f	0.95	n	3.9	t	3.75
b	4.4	g	1.2	p	1.58	u	0.68
c	0.5	h	1.22	q	1.2	v	0.75
d	0.5	k	0.5	r	0.6	w	0.7
e	0.5	m	0.8	s	1.2	x	0.6

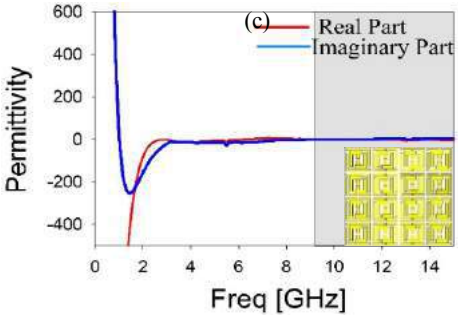
(c)



(d)

Figure 4: Relative permittivity of the unit cell with (a) 1×1, (b) 2×1, (c) 2×2 and (d) 4×4 array

3. Results

Figure 3 describes transmission coefficients, S_{21} (dB) the different array of the unit cell. All of the array structures have the resonance in X and Ku band. The 1×1 array structures exhibits resonance at 11.156 GHz and 12.944 GHz in the X and Ku band respectively. Whereas, for the 2×1 array

structure they are at 11.126 GHz and 12.72 GHz. The 2×2 array structures exhibits resonance at 10.962 GHz, 11.618 GHz while the resonances presents at 9.6563 GHz and 12.601 GHz in case of 4×4 array. Figure 4 and 5 respectively delineate the relative permittivity and permeability of different array structures.

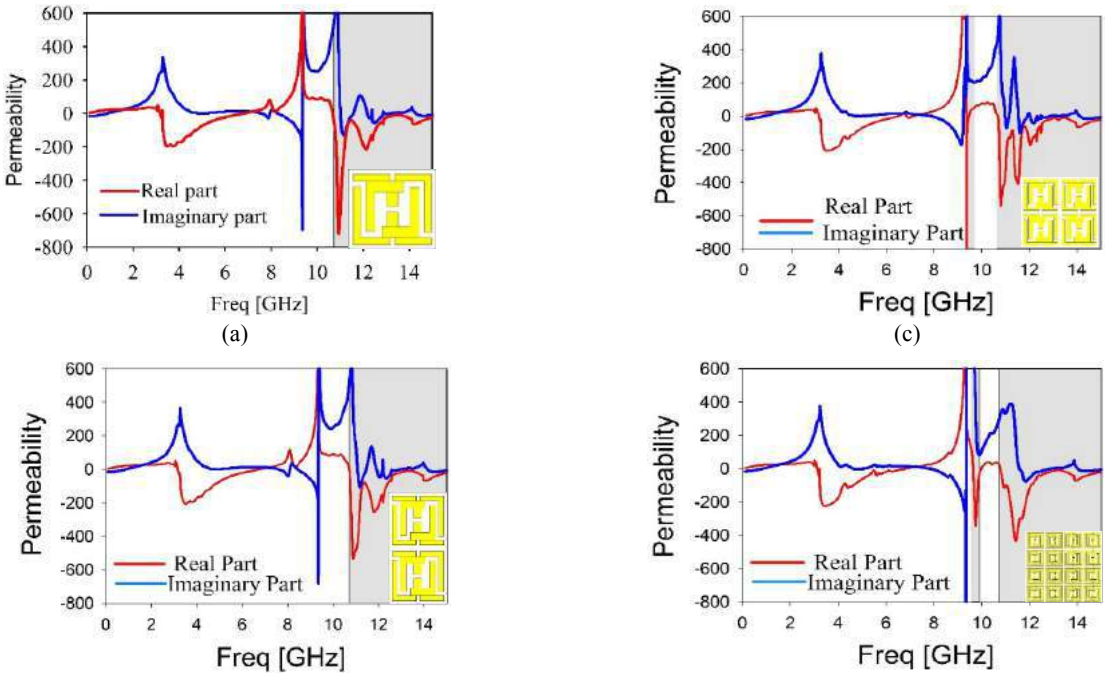


Figure 5: Relative permeability of the unit cell with (a) 1×1, (b) 2×1, (c) 2×2 and (d) 4×4 array.

In Figure 4 and 5, shaded zones in the figures illustrate the negative real part of the permittivity and permeability respectively. In Figure 5, it can be seen that 1×1 and 2×1 array configuration there is only one negative indexed band, while in 2×2 and 4×4 array configuration there is two negative bands. The negative indexed band starts from 10.68 GHz and it stops at 15GHz in case of 1×1 array while it extends from 10.72 GHz to 15 GHz in 2×1 array. For 2×2 array it is 9.37~9.46 GHz and 10.69~15 GHz. In the case of 4×4 array configuration the negative permeability band is found to be in 9.655~9.97 GHz and 10.8~15 GHz zone. From the above results it can be said that the unit cell shows DNG characteristics 10.8~15 GHz band commonly in all of the array configurations.

4. Conclusion

A modified H-shaped Double Negative (DNG) metamaterial has been proposed for the X and Ku band applications. The dimension of the unit cell is 0.9×0.88 cm^2 with a highest DNG bandwidth of 4.32 GHz covering these two band. Different array structures have been analyzed to see the efficacious inclusion of the unit cell for the intended applications. All of the analyzed array combination confirms the possible inclusion of the unit cell for X and Ku band application involving military requirements for satellite uplinks and downlinks in X band, and also for satellite communications and International Space Station (ISS) communications in Ku band.

Abstract

Investigation of Single Negative (SNG) Split Ring Resonator (SRR)-based compact symmetric reciprocal 5 Port Reflectometer (5PR) has been alluded. The 5PR realized a dual bandwidth of 1.072 GHz (0.803 GHz to 1.875 GHz) and 1.056 GHz (3 GHz to 4.956 GHz). The results of 5PR indicate a near zero magnitude of reflection coefficient and ≈ 0.5 for transmission coefficients which agree with theoretical values. The 5PR can be used for portable microwave imaging system for early breast tumour detection.

1. Introduction

Electromagnetic metamaterials have been a concentrated research activity with remarkable progress observed over the past decade [1],[2].The use of different metamaterials including Split Ring Resonators has been presented in various manuscripts for improving bandwidth as well as miniaturization of the antenna [2]. However, to the authors' best knowledge no manuscript has yet been reported to investigate the usability of metamaterial in 5PR for microwave imaging application. Microwave imaging has been proposed as an alternative approach for breast tumour detection by the medical researchers. A portable low-cost reflectometer is needed as an alternative network analyzer in lieu of conventional VNA used in microwave imaging systems which is not only costly but also retards portability owe to its large size. This shortcoming of VNA has inspired the researchers to use reflectometer as an alternative network analyzer. Few researchers have designed reflectometer to be used in breast microwave imaging but specializing for the higher frequency range [3]. This paper presents symmetric reciprocal 5PR reflectometer which can be used for the lower frequencies so as to meet the higher penetration depth as been suggested in [4]. It comprises 4×5 arrays of SNG SRR unit cells in the opposite side of the substrate. The circuitry of the 5PR is based on the microstrip technology. Simulated results shows dual band of 1.072 GHz and 1.052 GHz.

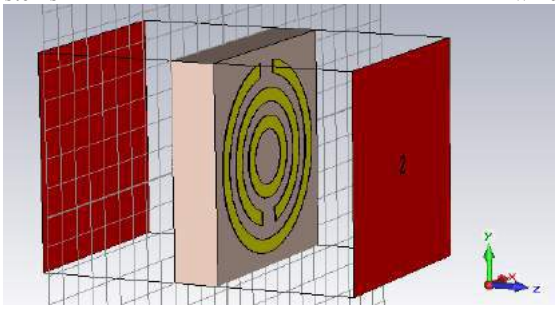

Figure 1: 3D view of the metamaterial unit cell.

2. Reflectometer design

The 5PR have been designed using Advanced Design Software (ADS). The reflectometer consists of the circuitry along with the SNG metamaterial in the ground plane of the reflectometer. The metamaterial unit cell of circular SRR kind consisting two concentric circles. The inner radii of the circles are 2 mm and 3 mm respectively while the outer radii are of 2.5 mm and 3.5 mm respectively. The unit cell is designed using FDTD based Computer Simulation Technology (CST) Microwave studio. Perfect Electrical Conductor (PEC) is placed as the boundary condition in the y axis while Perfect Magnetic Conductor (PMC) is placed in the x axis. The wave-

guide ports are applied in z axis and open boundaries are selected for this axis. The split widths of the two circles are 1 mm. which are in line with each other in the vertical direction. The reflectometer consists of 5 ports which are matched to 50 Ω. It consists of 5 curved microstrip lines which are curved by 72 °. 5 microstrip T-junctions are used in each of the ports in the reflectometer circuitry. The unit cells are applied in the opposite side of the substrate by using 4×5 array structures as can be depicted from Figure 3. The five port reflectometer was simulated from 0.5 GHz to 5 GHz. The 5PR has been designed using FR-4 substrate with a relative dielectric constant ε_r=4.3 and a loss tangent, δ=0.025 , copper thickness of 0.035 mm . The Reflectometer is shown in figure 3 in a detailed way.

3. Results

The simulated results are shown in Figure 2 and Figure 4. From Figure 2 it is noticeably seen that the metamaterial unit cell exhibits SNG from 0.5 to 5 GHz as depicted by the red line. Figure 4(a) shows the reflection coefficient of the 5PR. It can be seen that the reflectometer has a resonance of 1.072 GHz (0.803 GHz to 1.875 GHz) and 1.056 GHz (3 GHz to 4.956 GHz) as delineated by the shaded zone. From Figure 4(b) it can be seen that the difference between the phase of S_{12} and S_{13} is (158.285-(-83.762) = 242.047º) at 1.042 GHz (shown by the green dotted line), that is very near to the theoretical value of 240º. Similarly, the magnitude characteristics are also fulfilled by attaining a value of near zero value for S_{11} and a value of approximately 0.5 for the transmission coefficients. The magnitude profile of the proposed 5PR is shown in Figure 3(c).

4. Conclusion

This paper proposes a SNG metamaterial-inspired symmetric reciprocal 5PR for early breast tumour detection system. This 5PR consists of 4×5 array of SNG metamaterial unit cell in the rear part of the substrate and circuitry in the top plane of the substrate. Simulated results shows dual bands of 1.072GHz and 1.056 GHz. This 5PR can be considered as a prominent candidate for the portable early breast tumour detection system.

Abstract

A new combination polymeric magneto dielectric comb array antenna is presented. The combination substrates of Polydimethylsiloxane (PDMS) and Ferrite III oxide (PDMS-Fe_3O_4) provided huge improvement bandwidth of 49.21 % compared to existing antenna. Combination polymeric magneto dielectric, comb array antenna and PDMS-Fe_3O_4's permeability of 1.85 contributing to such bandwidth ranging from 26.823 GHz to 42.573 GHz and gain of 7.161 GHz. The radiation pattern results are also presented. Furthermore, dimension of 19x33 mm^2 is considered compact in size.

1. Introduction

Currently, modern wireless communication technologies such as medical diagnosis, navigation, and millimeter wave technologies demand robust, small, conformal and lightweight antennas [1]. In millimeter wave technologies, enhancing their bandwidth potentially improves its data-rate transmission [2, 3]. The capability in obtaining a large bandwidth for microstrip patch antenna is contributed by chosen an appropriate types of substrate material [4, 5]. For these reason, this paper introducing a new combination of meta-material substrate; Polydimethylsiloxane (PDMS) and Ferrite III oxide (Fe_3O_4) with a compact microstrip comb array antenna.

2. Polymeric Magneto Comb Array Antenna

PDMS- Fe_3O_4 is a new dielectric substrate contains of silicone based elastomer and (10 nm) nanoparticles of magnetic (Fe_3O_4) iron oxide. The magneto dielectric gives permeability more than unity which is 1.85 lead to bandwidth increment with permittivity of 3.45. The fundamental in getting a huge bandwidth is by reducing its quality factor, Q where Q is inversely proportional to permeability [6]. Hence, high in permeability provides a low Q and enhance the bandwidth.

In this paper, Figure 1(a) shows the comb array antenna which is designed with full ground plane at dimension of 19 x 33 mm^2 for width and length respectively as shown in Figure 1(b). An array structure of comb antenna is organised in zig-zag with main radiating element inclined by -90 degrees. The spacing between each array is $d = \lambda_g/2$ where λ_g is the guided wavelength at the center frequency while length, l of each array is based on formula $l = \lambda_g$ [7].

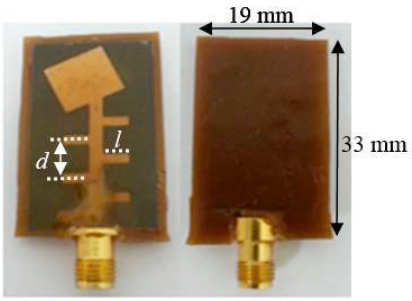

Figure 1. The fabricated polymeric magneto comb array antenna. (a) Front view (b) back view

The PDMS-Fe_3O_4 substrate layer is designed to embed the comb array antenna as depicted in Figure 2 with thickness for upper layer is v=1.4 mm and bottom layer is w=3 mm.

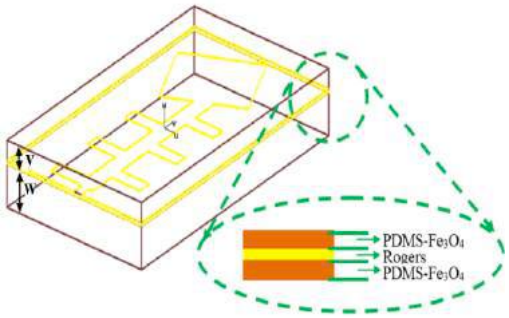

Figure 2. Perspective view for polymeric magneto comb array antenna with PDMS-Fe_3O_4

3. Discussion

Figure 3 shows the reflection coefficient, S_{11} of polymeric magneto comb array antenna. It is observed that the proposed antenna capable to operate in frequency range of 26.823 GHz to 42.573 GHz with 15750 MHz (57.27 %) of bandwidth. Besides, the simulated and measured results for S_{11} agreed well. The polymeric magneto comb array antenna also has a broader bandwidth compared to [7] up to 49.21 %.

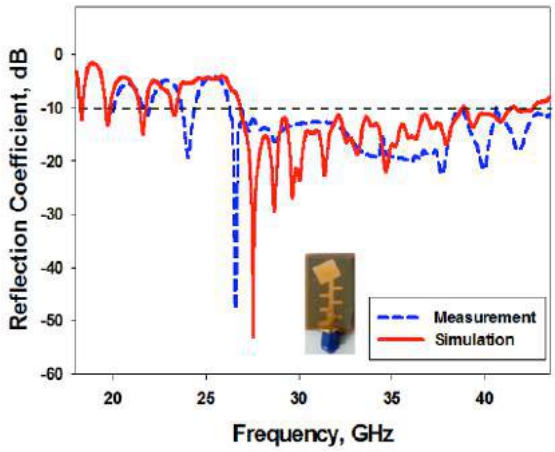

Figure 3. Simulated (solid line) and measured (dotted line) of reflection coefficient for polymeric magneto comb array antenna

Further results is on polar radiation pattern as shown in Figure 4 for XZ-plane and YZ-plane. It is observed that the simulated and measured radiation patterns agreed well. The highest gain of 7.161 dB is recorded.

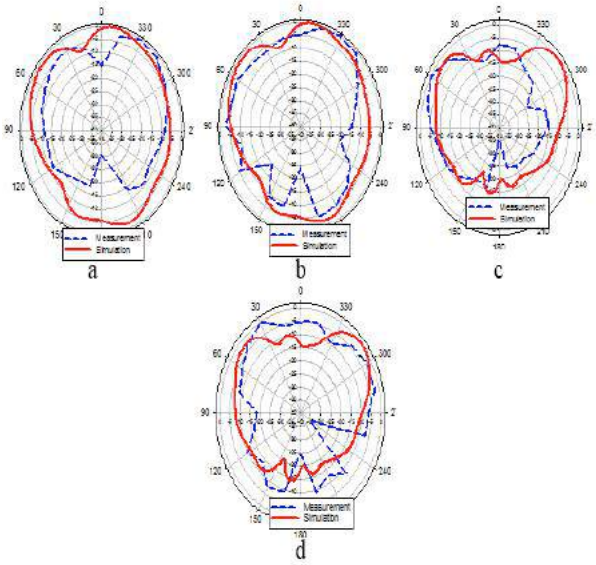

Figure 4. Simulated (solid line) and measured (dotted line) of polar radiation pattern for polymeric magneto comb array antenna

4. Conclusions

As conclusion, the new combination of PDMS-Fe_3O_4 with comb array antenna produces wider bandwidth and good gain as well as compactness of size for millimetre wave applications

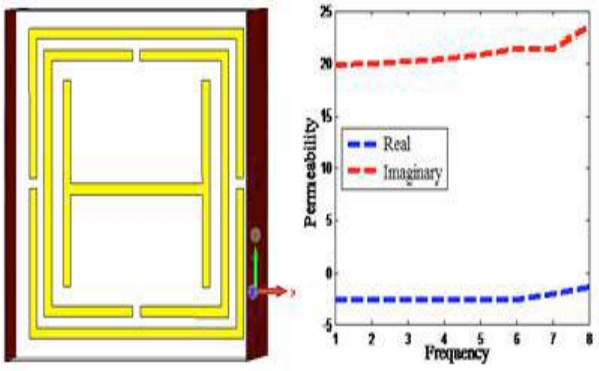
Abstract

The patch antenna gain and axial ratio enhanced when a dielectric radome double negative (DNG) metamaterial of H-shaped unit cells positioned on top of the patch. The radome is comprising of alternately two layers of negative permeability and permittivity substrate. Circular polarization's axial ratio of 2.329 dB has been realized by the presence of DNG metamaterial radome compared to 5.57 dB of without the radome. The gain has been increased as well from 8.25 dB to 9.57 dB.

1. Introduction

The opportunity of making left-handed metamaterial substrate with -ve permeability, -ve permittivity and refractive index contritely is change radically many fields including antenna design. It is extremely attractive because it shows the opportunity of reducing the difficulties experience in designing a directional antenna. In general directional antennas are either dishes or arrays. [1] They have acquired tricky feeding system. In case of arrays the number of antenna elements is fed with particular phasing and spacing. Since the gain requirement will more advanced of the feed network design becomes a tough task and controlling the side lobe level also becomes dreary. In this paper, we have used the H-shaped and Inverse H-shaped to improve the gain and axial ratio of patch antenna. The antenna gain is increased more than 1.5dB of that of the normal patch antenna. The Circular polarization's axial ratio of 2.329 dB has been realized by the presence of DNG metamaterial radome compared to 5.57 dB of without the radome, which clearly show the existence opportunity to try them as array elements or finding alternative ways of improve the gain and axial ratio of any antenna element. [3] A point-to-point wireless communication usually fails to distribute the threshold signal strength of -51 dBm. It also fails to stabilize the data rates in severe climate conditions. [4] Failing to abide such meshold brings about the slow internet connection or even disconnected. A high efficiency, gain, and circular polarized (CP) microstrip patch antenna will provide a suitable solution to avoid major signal attenuation during such conditions. [5] Rather of CP antenna, two-port MIMO methods to increase channel capacity for higher data rate and better hyperlink stability of a system. Consequently, convergence between CP technique, array antenna configuration and MIMO antenna techniques are studied to deliver effective trusted point-to-point communication. Figure. 1(a-d) presents the permeability, permittivity and refractive index where negative permeability achieved at (5.81-6.82) GHz, negative permittivity achieved (5.8-6.72) GHz and negative refractive index achieved (5.85-6.0) GHz. The effective permeability, permittivity and refractive index has been retrieved from S_{11}.



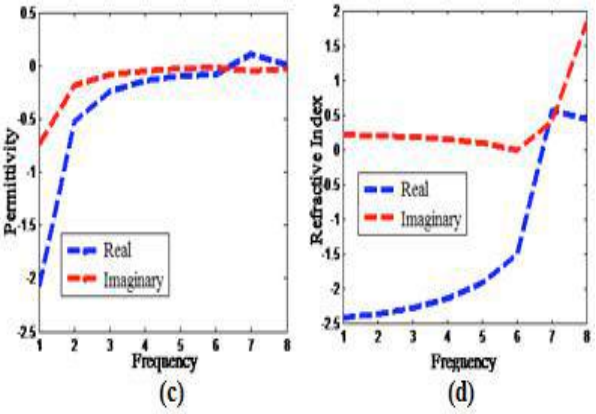


Figure 1: DNG Left-Handed Metamaterial (a) presents the structure simulated, (b) permeability, (c) permittivity and (d) refractive index.

2. Antenna Design Simulated

Metamaterial radome structure with the patch antenna is simulated using CST MICROWAVE STUDIO based 3D for electronic packages and simulated result shows in figure 2 (a-e). Likewise (b-c) shows the axial ratio bandwidth is observed to be 100MHz.As well (d-e) shows the 3D patterns of the patch antenna. The gain is observed to be 1.5dB. It also show that the antenna tunes at 5.8GHz.

3. Conclusions

We have studied the structures composed of materials. The (DNG) metamaterial of H-shaped unit cells radome base on dielectric could increase the antenna gain and axial ratio, which could be useful for antenna radome applications. The end-to-end curvy dual-coupled 90° phase shifters that is connected to each circle-segmented patch. (S11) gain in the simulated with (DNG) radome and without (DNG) radome (from 8.25% to 9.57% GHz) and axial ratio simulated with (DNG) radome and without (DNG) radome (from 5.57 to 2.329 GHz) in the axial ratio. CP array antenna radome with 90° triple-coupled phased shift polarizer at 5.8 GHz.

Abstract

This paper presents a split ring resonator based metamaterial radome for point-to-point communication. The radome structure is formed using split ring resonator at 5.8 GHz. Antenna structure has been formed using 2×2 MIMO array structure with high directivity and good isolation between two arrays. Performance of radome characteristics have been evaluated in terms of bandwidth, directivity, radiation pattern and isolation between two antennas. Small degradation has been found for antenna performance in terms of using metamaterial radome.

1. Introduction

A radome plays an important role in the practical application of antennas which are placed over antenna in order to protect from different environment like wind, rain, ice, hot, UV etc. Radome can be different types in several shapes like spherical, geodesic, planar etc. depends on the application (radar, telemetry, tracking, and point-to-point). Radomes can be designed using different types of low losses material like-fiberglass, PTFE-coated with proper integration for indoor and outdoor environment [1]. However, the main challenge for designing radome is the avoiding antenna radiation losses which occurred from attenuation, scattering and depolarization. Thus can effect on the electromagnetic signal by degrading antenna pattern. Furthermore, scattered radiation from radome may affect antenna performance by elevating side lobes which can degrade antenna directivity very highly [2].

Different types of artificial magnetic conductor has been used to design radome as- partially reflecting surfaces, frequency selective surfaces. Metamaterial based radome can be great choice because for designing radome structure because of the unusual electromagnetic property [3]. Metamatrial attains exotic electromagnetic property over certain frequency band which is not normal in nature. It can show totally opposite characteristics compare with naturally existing material in terms of negative permittivity or permeability which is absent in normal material.

2. Split Ring Resonator Based Metamaterial Radome Design

In this paper, a negative permittivity based split ring resonator metamaterial unit cell has been designed for radome structure. Figure 1(a) presents unit cell structure where the negative permittivity achieved from 3.92 GHz up to 10 GHz. Figure 1(b) presents the relative permittivity of the unit cell. This until cell has been applied in 6×4 array on FR-4 substrate which is a radome structure. Than this radome has been placed on the top of array antenna structure maintaining 4mm distance. The MIMO array antenna structure has been formed using 2×2 array. Figure 1(c) presents the MIMO array antenna structure and Figure 1(d) shows the array structure with metamaterial radome.

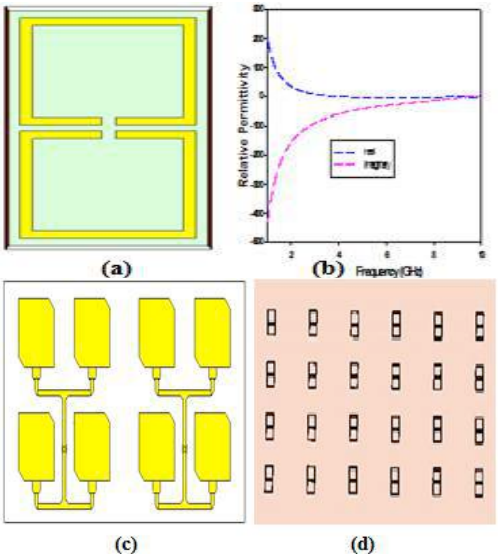

Figure 1: (a) Metamaterial unit cell radome (b) Relative Permittivity (c) Antenna Structure (d) Metamaterial radome (Below is antenna structure).

Table 1 Parameters dimensions of the proposed antenna and metamaterial radome.

Param.	Value (mm)	Param.	Value (mm)	Param.	Value (mm)	Param.	Value (mm)	Param.	Value (mm)	Param.	Value (mm)
lw	1.49	W_s	55	λ_1	27	W_1	3	L_3	13	L_{s1}	55

3. Results and Discussion

Figure 2 presents the performance of antenna with radome structure. Since the antenna have MIMO characteristics, isolation between two antenna structures is considered as important parameter. Figure 2(a) presents the performance of reflection coefficient and isolation between two antennas with radome structure.

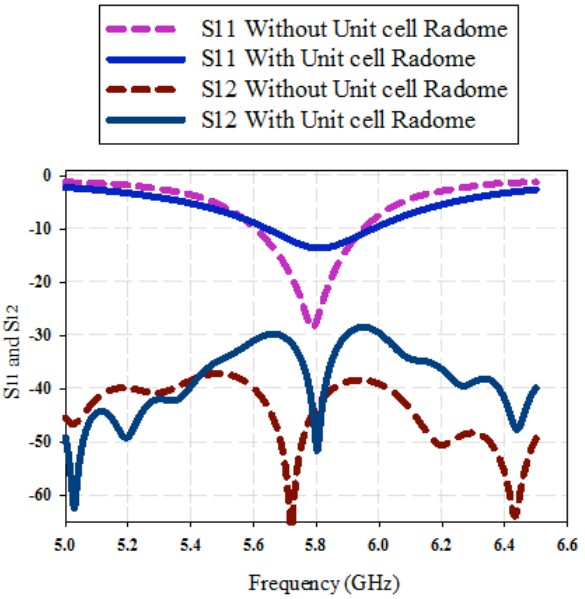

Figure 2: Performance of antenna with and without Metamaterial Radome.

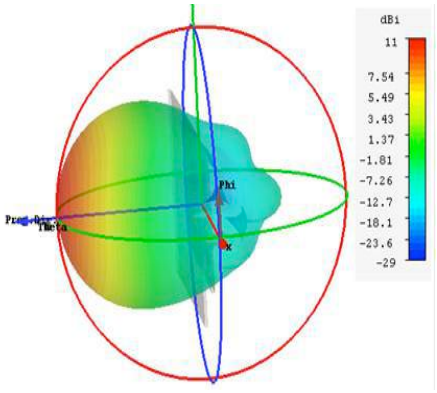

Figure 3: Illustrate the antenna radition pattern based on 3D with Metamaterial Radome.

Figure 3 presents the directivity of the antenna with metamaterial radome. It achieved 11 dBi directivity which is applicable for point-to-point communication.

4. Conclusions

Circularly Polarized Multiple Output Multiple Input (CP-MIMO) Array antenna with isolation between two array and bandwidth has been proposed. The WLAN -MIMO Array antenna's characteristics of directivity, and radiation pattern has been discussed and analyzed to have the optimum performance, which could be useful for point-to-point communication with metamaterial radome, (S11) and (S21) shows a 36% of isolation between two antenna and bandwidth (from 0.311 to 0.401 GHz). Bandwidth achieved with radome structure is 5.8% at 5.8 GHz where without radome it achieved 5.86%. However, the isolation between two antennas with and without radome also satisfactory. At both cases the minimum isolation achieved -39dB and maximum -75 dB.

Abstract

This paper presents a compact crisscross slotted log periodic fractal Koch antenna (S-LPFKA) with artificial magnetic conductor (AMC) surface that serves as a reflector. This S-LPFKA with AMC is designed to operate from 0.47 to 0.79 GHz with linearly polarized radiation, performing with 36.6% size reduction compared to stand-alone S-LPFKA. With gain from 2.57 dBi to 4.75 dBi, this antenna is suitable and has a great potential for ultra high frequency (UHF) television white space (TVWS) applications.

1. Introduction

In telecommunication, TVWS refers to the unused broadcasting frequencies in wireless spectrum which located within VHF and UHF bands [1-3]. It is very attractive due to its much lower frequency compared to current unlicensed spectrum. Operating Wi-Fi in TVWS will provide several distinct advantages such as longer range, greater speed, more reliable connections and broader coverage compared to traditional 2.4 GHz and 5 GHz frequencies [4].

Microstrip patch antennas are widely applied in various applications because of their small profile, light mass and low budget. However, they suffers from some limitations including narrow bandwidth and low efficiency [5]. Many methods have been proposed to overcome the disadvantages of microstrip patch antennas such as by applying log periodic technique. This technique manage to increase the bandwidth and potentially offer low cross-polarization ratio over a wide frequency range. Nevertheless, it unfortunately results in the expense of a large physical area [6-7].

Nowadays, the inspiration to study AMC design by most researchers are due to the advantages of AMC in increasing gain, reducing back lobe radiation, enhancing bandwidth as well as size miniaturization [8-9]. AMC is one type of metamaterial which consists of periodic structures. It acts like a regular metallic ground plane outside of its bandwidth and has a reflection coefficient phase of 0° [10].

In this paper, a S-LPFKA with AMC metamaterial is designed with a compact size of 190 x 285 mm^2 for the width and length respectively. 36.6% size reduction is obtained for the proposed antenna compared to the stand-alone S-LPFKA. The proposed antenna exhibits gain ranging from 2.57 dBi to 4.75 dBi over UHF TVWS bands. This paper is organized as follows: Section 2 begins by demonstrating an AMC single design. The S-LPFKA with AMC operating from 0.47-0.79 GHz will also be described in this section. Next, the simulated results of S-parameter, gain and radiation patterns are presented and discussed in Section 3. Finally, a conclusion will be drawn in Section 4.

2. Antenna Design

A square patch unit cell is chosen since it is easy to fabricate and provide a large bandwidth performance. A single AMC unit cell is illustrated in Fig. 1(a). The simulations were completed by using periodical unit cell simulation offered in CST Microwave Studio. The structure of AMC unit cell consists of five layers as shown in Fig. 1(b). The ground plane is located at the bottom layer of this structure. This is followed by a layer of FR-4 substrate with dielectric constant of ε_r=4.7 and loss tangent (tan δ) of 0.019, respectively. The AMC plane is located on the third layer. Another layer of substrate is placed on top of this AMC plane. The AMC plane and ground plane are made up using Copper with a conductivity and thickness of 5.8 x 10^7 S/m and 0.035 mm respectively. Finally, a plane wave source is located on the top of the AMC unit cell with a gap of 10 mm. The phase of the reflected wave is about 0° for 0.63 GHz as shown in Fig 2. The operating bandwidth of the AMC plane is defined by a ±90° phase response. The unit cell is then arranged into 2 x 3 array to form the AMC plane.

The AMC plane of the proposed antenna is integrated beneath the antenna substrate as illustrated in Fig. 3. To cover the entire bandwidth from 0.47-0.79 GHz, 10 patches were needed. Series iteration fractal Koch structure with 30° flare angle has been integrated at the radiating elements of log periodic dipole antenna (LPDA). Fractal Koch structure manage to miniaturize the size of conventional LPDA.

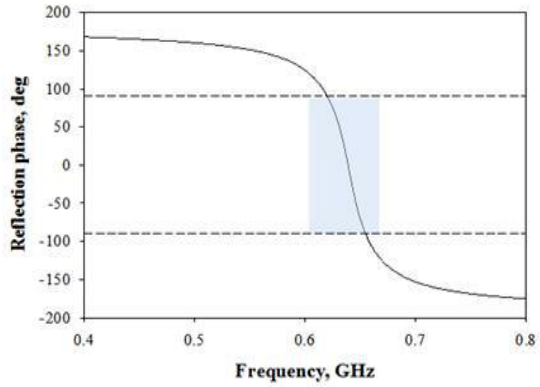

Figure 2: Reflection phase of AMC unit cell.

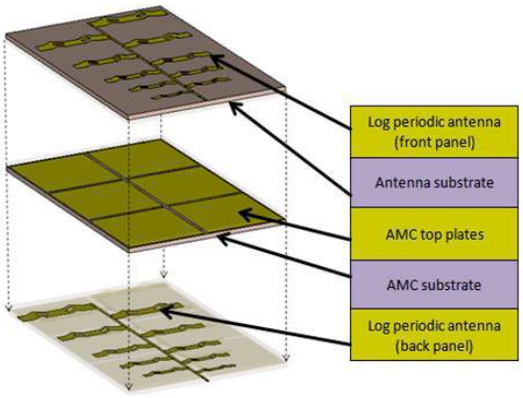
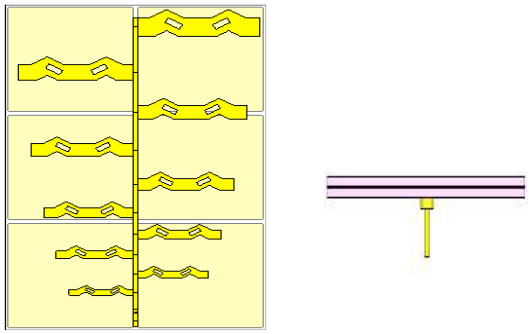


(a)



(b) (c)

Figure 3: Proposed antenna (a) 3-D configuration, (b) Top view and (c) Side view.

3. Discussion

The contribution of the AMC plane is evaluated by comparing the antenna performance against a stand-alone S-LPFKA. Fig. 4 shows the comparison of reflection coefficient, S_{11} between stand-alone S-LPFKA and proposed antenna. The graph shows that stand-alone S-LPFKA has impedance bandwidth from 0.47-0.79 GHz which covering the whole UHF TVWS bands but it has larger size which is 305 x 280 mm^2. From the analysis, the optimum dimension of the proposed antenna is 285 x 190 mm^2 which indicate 36.6% size reduction compared to stand-alone S-LPFKA. As can be seen in Fig. 4, the proposed antenna are working on channel 24-25, 28-33, 36-40, 43-46 and 56-60 with the total of 22 channels. Based on the list of TV broadcasters in Malaysia using VHF and UHF, we can notice that there are only 4 channels (channel 27, 33, 39 and 55) which are occupied by the broadcasters in UHF band and the remaining channels are being unused. The polar radiation patterns is illustrated in Fig. 5 and has been performed at 0.47 GHz and 0.79 GHz for both *E*- and *H*-planes. With the gains from 2.57-4.75 dBi, this proposed antenna has become a suitable candidate for UHF TVWS applications

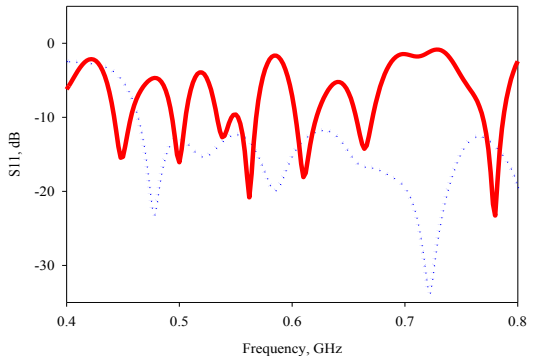


Figure 4: Graph of reflection coefficient; blue dotted line (stand-alone S-LPFKA) and red line (proposed antenna).

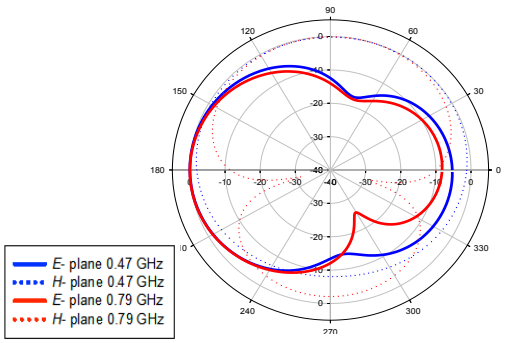

Figure 5: Polar radiation patterns of the proposed antenna.

4. Conclusions

In this work, a S-LPFKA with AMC is proposed with operating frequencies from 0.47-0.79 GHz. The size of proposed antenna is successfully reduced by 36.6% by implementing AMCs with slotted series iteration log periodic fractal Koch techniques. Both simulation and measurement result shows that the proposed antenna satisfies the impedance bandwidth requirements of UHF TVWS bands applications (0.47-0.79 GHz). Overall, the performance of proposed antenna is suitable candidate for UHF TVWS band applications.

Abstract

A multiband coplanar waveguide (CPW) fed antenna array using a novel double negative (DNG) metamaterial unit cell for GSM900, WLAN, LTE-A and 5G Wi-Fi applications is presented in this paper. The investigated DNG structure indicates wide range of negative refractive index in the frequency span (0-3.78 and 5.65-7.2) GHz. Two categories of the proposed metamaterial plane have been applied to enhance the bandwidth up to 1.2 GHz, whereas the maximum attained gain is 6.74 dBi at 3.5 GHz.

1. Introduction

Recently, the development of wireless communication has been grown rapidly especially for 5G Wi-Fi, wireless local area networks (WLANs) and Long Term Evolution-Advanced (LTE-A) [1]. A single hardware to operate in multi frequency bands is highly desired. Furthermore, the metamaterial structures has been developed significantly due to the tremendous change of its physical behaviors that leads to investigate new electromagnetic properties which is not easy to be attained in normal case [2]. Double-negative metamaterial (DNM) is an example of this metamaterial unit cell structure, which has negative properties for both permittivity and permeability to exhibit negative refractive index (NRI) electromagnetic properties [3]. However, antennas performance have been improved dramatically by applying the metamaterial due to its numerous effectiveness to produce a novel version of the antennas design with a noticeable improvement in terms of size miniaturization, gain and bandwidth enhancement, low cost and good radiation patterns [4]. Therefore, antenna design incorporates with metamaterial can offer an ultra-high performance class of these antennas.

In this paper, a multiband CPW fed antenna array using a novel and compact DNM unit cell has been proposed. The investigated DNG structure consists of several symmetric split ring resonators (SSRRs) to exhibit wide range real values of negative permeability and permittivity, hence, leading to negative refractive index (NRI) as well. The proposed antenna is suitable for GSM900 at 0.9 GHz, WLAN at 2.3/2.4/5/5.2/5.8 GHz, 4th generation LTE-A at 3.5 GHz and 5G Wi-Fi in the frequency range of (5.15~5.875) applications, while it is overall size ($0.236\lambda o \times 0.128\lambda o \times 0.005\lambda o$) with respect to its lowest operating frequency. Simulated results (with and without DNG unit cell), including the reflection coefficient and gain at indicated frequency bands are discussed prior to the concluding remarks.

2. Antenna Design and Unit Cell Geometry

The proposed unit cell and the CPW antenna structures are described below:

2.1. Proposed Unit Cell

The proposed DNG unit cell structure is shown in Figure 1a. Its overall size is (6 x 6) mm^2. The optimized line width of each SRR is 0.5 mm with split gap by 0.5 mm is used to generate negative permeability and permittivity where r_1, r_2 and r_3 equal to 2.9 mm, 1.9mm and 0.9 mm respectively. Figure 1b shows the simulation set up testing of proposed metamaterial unit cell structure, which was placed between two waveguide ports located on each side of the z-axis to attaining the S-parameters.

2.2. Antenna Design Geometry

The proposed CPW antenna array is printed on a low-cost, 1.6 mm-thick FR4 substrate with loss tangent of 0.025 and a relative permittivity of 4.7. Figure 2 illustrates the 3-D geometry of the proposed antenna array where two categories of the proposed metamaterial plane have been used, one is placed behind the antenna array and the second will be considered as a reflector within 10 mm away from the antenna. It is an array containing 2-elements; triangular-like structure forms each radiator. The antenna is feeding by narrow micro-strip line with 50-Ω SMA connector.

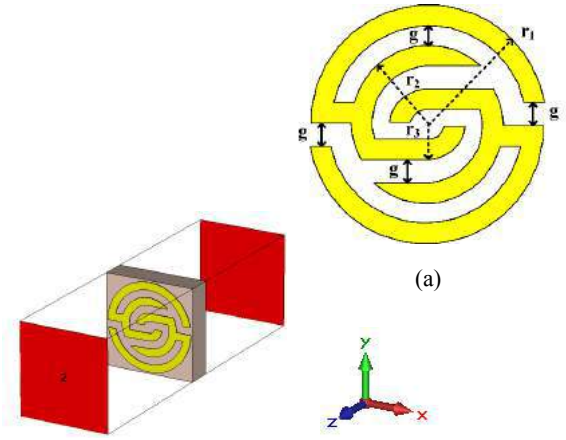

Figure 1: (a) Metamaterial unit cells structure, (b) simulation set

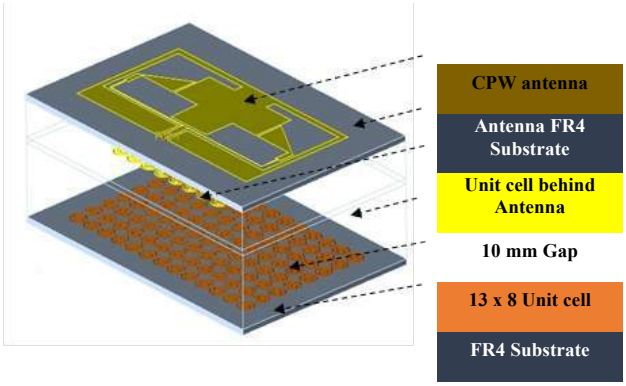

Figure 2: 3-D configuration of the Proposed antenna.

3. Results and Discussion

Figure 3 (a–c) illustrates the obtained real and imaginary values of permittivity, permeability and refractive index. The results indicated that the achieved real negative permittivity, permeability and refractive index at frequency bands of (0 ~ 6.82, 7.22 ~ 10) GHz, (0 ~ 6.96,7.31 ~ 9.36) GHz and(0 ~ 3.78,5.65 ~ 7.2) GHz respectively.

Furthermore, in Figure 4, it can be observed that the proposed antenna with unit cell features high bandwidth of 980 MHz (28 % centered at 3.5 GHz) and 1221 MHz (22.1 % centered at 5.5 GHz). In addition, the achieved gain can be increased from 3.23 dBi to 6.74 at 3.5 GHz for LTE-A and up to 5.98 at 5 GHz. Moreover, two rows structure of unit cell behind the proposed antenna array create additional resonances at 900 MHz and 2.4 GHz for GSM and WLAN applications respectively.

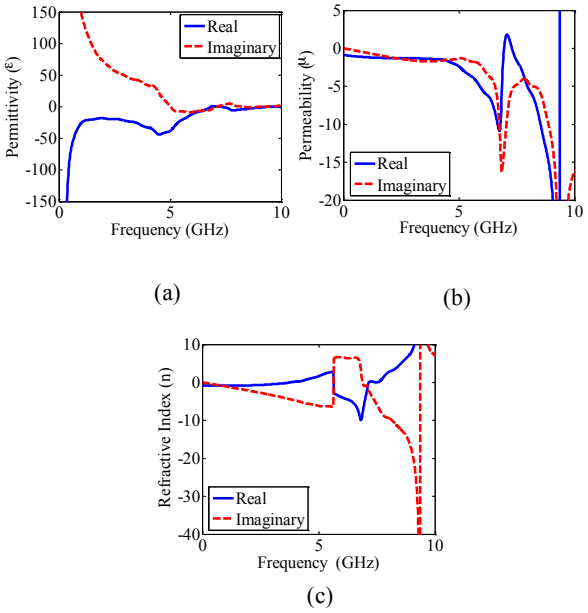

Figure 3: Metamaterial unit cell simulated results (a) Permittivity (b) Permeability (c) Refractive Index.

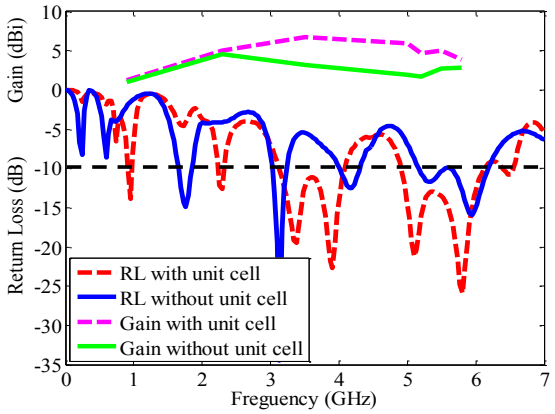

Figure 4: Return loss (S11) and gain.

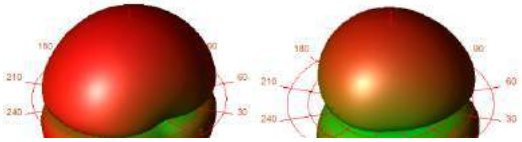
Figure 5 (a-d) shows the simulated 3D far field radiation pattern at 900 MHz, 2.4 GHz, 3.5 GHz and 5.8 GHz of the proposed CPW antenna along azimuth and elevation plane. The antenna displays almost omnidirectional radiation in the (x-y) plane and (y-z) plane. Moreover, the maximum attained gain is 6.47 dBi considered as an increase of 92.57% after applying the proposed metamaterial unit cell.



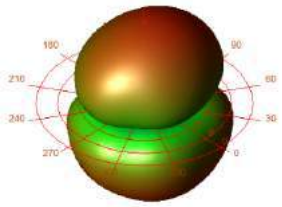


Figure 5: 3-D radiation pattern at (a) 0.9 GHz, (b) 2.4 GHz, (c) 3.5 GHz and (d) 5.8 GHz

4. Conclusions

A quad band antenna array using wide range DNG metamaterials is presented. A novel compact SSRR resonator left-handed metamaterial unit cells is proposed. The features of negative permittivity, permeability and refractive index (NRI) are validated numerically from the proposed unit cells structure. They are then placed as two scenarios on the reverse side of an antenna array. The simulated result shows that the proposed antenna integrated with the compact sized unit cell structure has proper impedance bandwidth covering the required band widths of GSM900, WLAN, LET-A and 5G Wi-Fi in the 0.865–1.06 GHz, 2.24–2.52 GHz, 3.25–4.31 GHz and 4.9–6.5 GHz respectively. The proposed antenna features omnidirectional radiation patterns.

Abstract

In this paper, the utilization of flexible polymer polydimethylsiloxane (PDMS) as the substrate for the realization of patch 3dB branch-line coupler (BLC) operated at 24GHz is presented. In advanced, the micromachine technique introduces a magnetization of magnetic filler, Fe_3O_4 into the polydimethylsiloxane (NPDMS) to be applied as transmission line of BLC for Automative Collision Avoidance System (ACAS) application. Promising elements with flexible, lightweight, resistant capability against dust and corrosion are realized. The presented design exhibited considerable return loss, S_{11}, transmission, S_{21}, coupling, S_{31} of (3±1) dB and isolation, S_{41} within ACAS Standard requirement.

1 Introduction

Significantly, enhanced innovation of polymer-based nanocomposite materials by adding magnetic nanofillers, such as carbon nanotubes, carbon nanofibers and iron oxide nanoparticles to polymeric has attracted tremendous interest exclusively on strengthening the electrical conduction, mechanical hardness, chemical stability, resistance of thermal properties as well as the possible improvement of fire behavior properties serve suitable potential applications of microwave absorbing material. These properties showed that the resonance magnetic losses in a ferrocomposite with nanosized magnetite filler are shifted to the higher frequency specifies the compatibility of this method to be applicable for higher frequency applications [1]. Polymer serve as a coupling agent has been demonstrated in preparing elastomer nanocomposites on magnetite nanoparticles [2]. Characterization of magnetic polymer superparamagnetic with good magnetic saturation, improves the permeability and good electrical conductivities [3-4].

In practical, as the higher frequency is desired for ACAS application, the wavelength will be reduced and the device miniaturized. As a proposed technique, micromachining is introduced due to their capabilities of accurately defining structural dimensions, capability to integrate with other integrated circuits and possibly realization at a lower cost [5] which outlines the most development techniques to prepare for polymer magnetic nanocomposites. The high permeability magnetic fillers, Fe_3O_4 are usually employed to increase the permeability and ferromagnetic properties with increased coercive force induced by the non-magnetic polymer spacer [6]. Magnetic nano particles have a wide range of applications, including magnetic fluids recording [7], catalysis, data storage, environmental remediation separation, purification, and biomedical uses [8-10], microwave absorption [11] and medical diagnosis using magnetic resonance imaging [MRI] [12]. The ferromagnetic resonance and intensity are strongly affected by magnetic nanoparticle content in polymer composition which modifies the permeability and permittivity of the microwave devices [13].

In this paper, utilization of magnetic filler, Fe_3O_4 branch-line coupler is designed for vehicle to vehicle beamforming application, at 24GHz ACAS frequency. A PDMS combined with increasing amounts of cross-linker utilized in 3dB branch-line coupler (BLC) as flexible substrate with flexible, lightweight, resistant capability against dust and corrosion. The presented design exhibited promising return loss, S_{11}, transmission, S_{21} and coupling, S_{31} of (3±1) dB and isolation, S_{41} within ACAS ISM Standard with minimal amplitude imbalance properties.

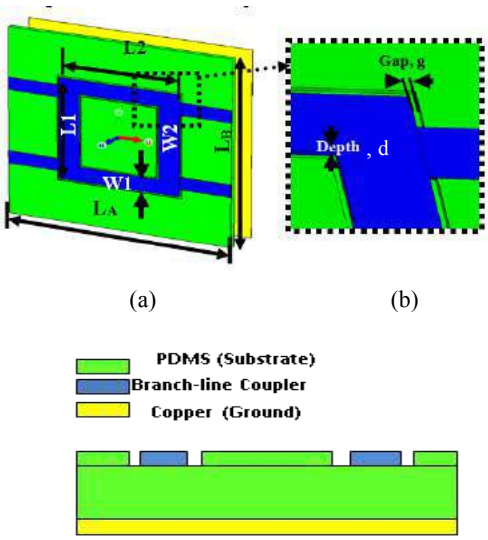
2 Branch-line Coupler Design

Branch-line couplers are utilized for beam forming network due to characteristic of input power divided equally between the output ports. The 3 dB BLCs have a degree of freedom where any of the four ports can be used as an input port. The ports opposite to the chosen input port are the output ports while the adjacent port is the isolated port. By implementing equivalent admittance approach [14-15], the four-port symmetrical network can be split into four circuits by using the two symmetry planes. Due to the decrease of the wavelength (λ_0 = 12.5 mm) at operating frequency of 24GHz, couplers using quarter-wave length lines become feasible. In this paper, a 3dB BLC line is designed using nanocomposite polymeric magneto-ferrite thin film by loading 35% of 10-nm iron oxide Fe3O4 into pure polydimethylsiloxane (PDMS) to generate nanocomposite polymeric magnetic ferrite (NPMDS) branch-line coupler illustrated with blue line with thickness of 300μm, permittivity of 2.8, permeability of 1.4 and loss tangent

0.047 at the operating frequency of 24 GHz for ACAS bandwidth of 200MHz from 24.05GHz to 24.25GHz [16].

3 Experimental Results and Discussion

A pure PDMS (εr = 2.7, loss tangent=0.04) is used as the substrate while ground plane is copper metalized. The multilayer of proposed BLC with the size of 37.49mm x37.49 mm, gap of 0.36mm, depth of 0.2mm and other parameters has been illustrated in Figure 1(a) till Figure 1 (c) and the dimensions of the proposed BLC are listed in Table1.



(a) (b)

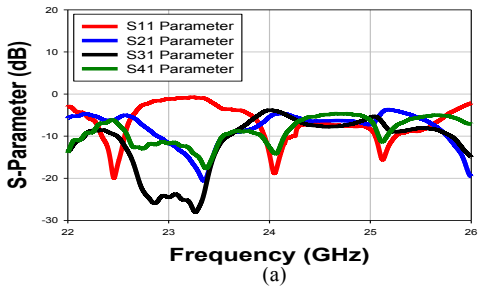
(c)

Fig. 1: The proposed BLC topology, (a) perspective views, (b) magnification, (c) cross section view.

Table 1: Parameter detailed of the proposed BLC shown in Fig. 1

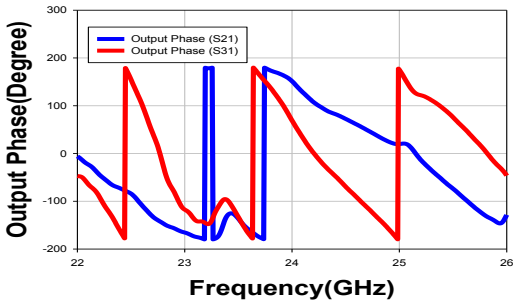
Para.	Value (mm)	Para.	Value (mm)	Para.	Value
L1	20.30	W2	3.45	Depth, d	300μ
L2	20.30	LA	37.49	Gap, g	0.36mm
W1	2.85	LB	37.49		

Figure 2(a) illustrated S-Parameter performance of the proposed BLC and phase difference in Figure 2(b).



(a)

Fig. 2: Simulated result of the proposed antenna, (a) S- parameters (b) Output phase difference.



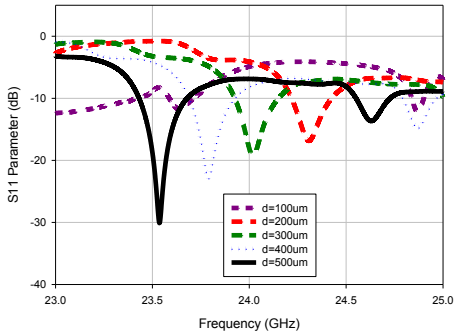
(b)

Table 2 Output simulation results of the proposed BLC

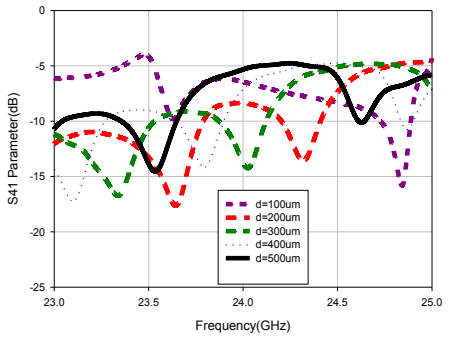
Para.	Value	Para.	Value
S11	-18.63dB	S41	-14.09dB
S21	-4.78dB	Phase Difference	89°
S31	-3.97dB	Bandwidth	(23.95-24.28GHz)

The performance of BLC is determined by the amplitude and phase imbalances, representing the difference in amplitude between the two output ports and the phase differs from the desired 90° between the two output ports. The minimal amplitude imbalance of 0.81dB and promising phase output difference, 89° with minimum variation of 1° error are shown in Figure 2(b) while bandwidth were obtained from 23.95GHz to 24.28GHz which satisfied ACAS requirement. The summarized performance of the proposed BLC is tabulated in Table2.

The magnetic filler PDMS patch is used as radiating patch of the proposed BLC by micromachining channel. Micromachining variation effect parameter depth, d of the channel has been investigated towards the BLC performance of reflection coefficient, S_{11} and isolation value, S_{41}. Once the value of depth, d of radiating magnetic filler is varied, deviations in the BLC performance are observed in Figure 3. As shown in Figure 3(a), as the depth is increased, operating frequency for S_{11} parameter are shifting homogeneously to the lower frequency but with higher percentage of transmission. However the performance at the operating frequency still achieves promising value. Conversely, isolation value didn't reflect the uniform changes due to the depth variation as illustrated in Figure 3 (b) but the value achieve less than -10dB for each depth parameter.



(a)



(b)

Fig. 3: Simulation of effect of depth parameter, d variation in term of: (a) S11 parameter, (b) S21 parameter.

Conventionally, amplitude imbalance and phase imbalance due to the depth variation are plotted in Figure 4. Minimal variation of amplitude imbalance can be clearly seen at 24GHz with an average value of 0.75dB. Moreover, phase difference imbalance observed to be uniformly changes with the changes variation of depth, d indicates equally power distributed between output ports. Ideally average of 5.5° consistent value was observed at 24GHz operating frequency with depth variation of 100µm.

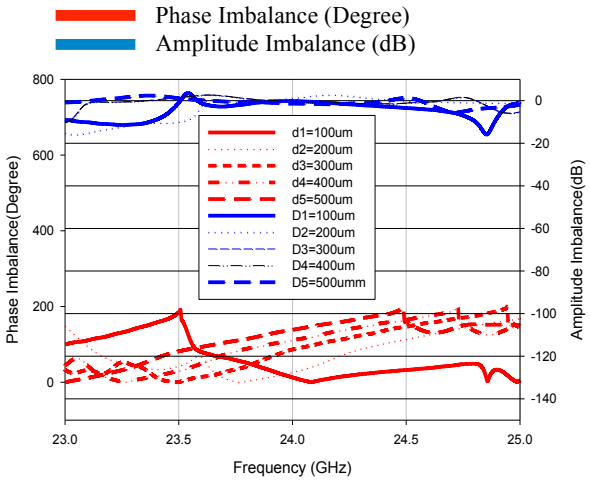


Fig. 4: Amplitude imbalance and phase difference proposed BLC.

4 Conclusions

This paper demonstrated the utilization of 35% of 10-nm iron oxide Fe_3O_4 into polydimethylsiloxane (PDMS) as the BLC transmission line with a flexible polymer PDMS as substrate, for the realization 3dB branch-line coupler (BLC) operated at 24GHz. In particular, accurately defining structural dimensions by micromachine technique contributed to the development of this design. Enhanced properties of the NPDMS is utilized for BLC which is the key element of beamforming network dedicated for vehicle to vehicle application with promising requisites of flexible, lightweight, resistant capability against dust and corrosion properties. In addition, by performing the parameter variation analysis of the polymer nanomagnetic filler radiating patch depth, d between NPDMS and substrate, analysis of BLC performance are presented. The presented design exhibited considerable return loss, S_{11}, promising results of transmission, S_{21}, coupling, S_{31} of minimal amplitude balance (3±1) dB and isolation, S_{41} within ACAS ISM Standard.

Abstract

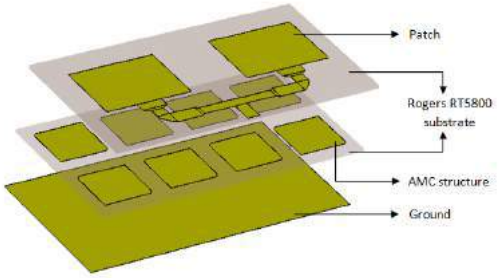
This paper proposes a microstrip rectangular patch antenna using a structure of artificial magnetic conductor (AMC). This type of antenna is designed to operate at 16 GHz, where the potential fifth generation (5G) band may be located. By adding AMC structure, the proposed antenna offers about 23.6% size reduction of the conventional antenna. Moreover, higher gain has been achieved, which is from 6.87 dB to 7.99 dB with 494 MHz of frequency bandwidth.

1. Introduction

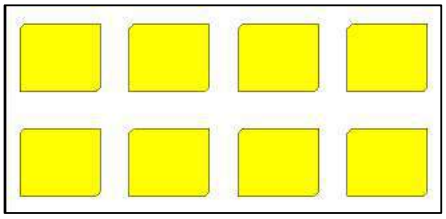
According to [1], the exploitation of 5G network will emerge between 2020 and 2030. Although there is no standard has been fixed yet, the researchers estimate that 5G frequency band starts from 6 GHz [2]. To realize this newest technology, microstrip patch antenna can be one of the possible candidates as it offers light weight and low volume [3]. However, due to the limited efficiency, low gain and narrow bandwidth, AMC structure is then invented to overcome the drawbacks mentioned. By having reflection phase characteristic of 0°, the frequency bandwidth of an AMC unit cell is determined from 90° to -90° [4-5].

2. Antenna Design

A microstrip rectangular patch antenna with AMC structure is designed on a 44x21 mm^2 Rogers RT5800 substrate with ε_r=2.2 and h=0.508 mm of thickness. The size of the antenna with AMC is reduced by 23.6% of the conventional antenna (antenna without AMC). Figure 1(a) illustrates the arrangement of the antenna, where the AMC structure is placed in between both substrates. This type of metamaterial is formed by 2x4 AMC unit cells, as shown in Figure 1 (b).



(a)

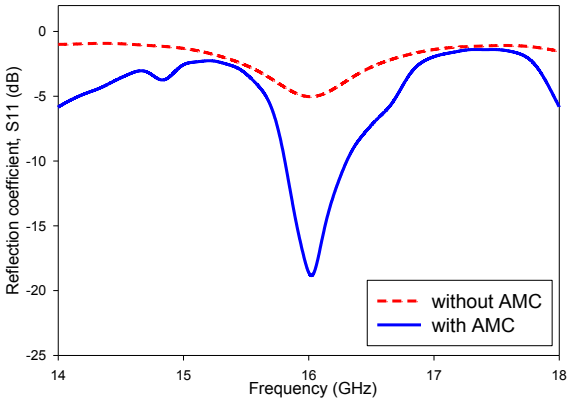


(b)

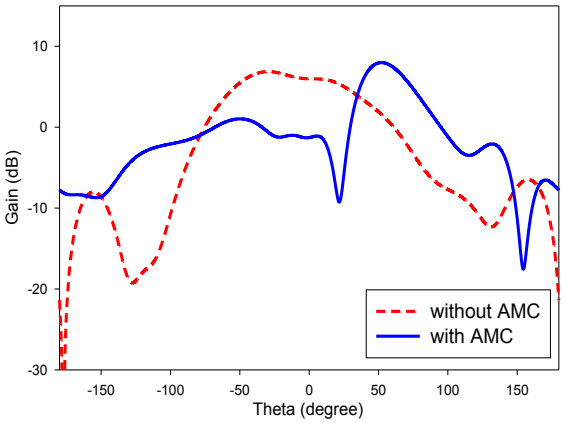
Figure 1: Proposed antenna with AMC structure (a) 3D view (b) AMC structure.

3. Discussion

To test the utilization of AMC, the performance of the proposed antenna and the conventional antenna has been compared. Figure 2 (a) shows the reflection coefficient (S11) of both antennas. It is clearly indicates that the antenna with AMC structure performs better by having -18.84 dB of S11 and 3.08% (494 MHz) of frequency bandwidth. Besides that, the radiation gain pattern of those antennas also has been analyzed as presented in Figure 2 (b). The proposed antenna obtains 7.99 dB of gain, which is 1.03 dB higher than the conventional antenna.



(a)



(b)

Figure 2: Performance of the proposed antenna and the conventional antenna (a) Reflection coefficient (b) Gain.

4. Conclusions

A microstrip patch antenna with AMC structure is presented in this paper. The implementation of AMC structure into the microstrip patch antenna offers a lot of advantages especially in antenna size miniaturization and gain enhancement. Due to the high path loss at high frequency, antenna with high gain provides wide area coverage for data exchange, hence the proposed antenna has a potential to be applied in 5G applications.

Abstract

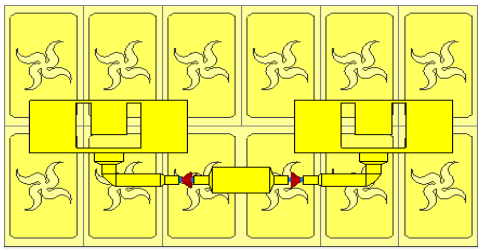
This paper presents a reconfigurable U-shaped slot patch antenna with a metamaterial structure of artificial magnetic conductor (AMC). The AMC structure that consists of windmill-shaped slot unit cells are placed in between of two substrates to boost the performances of antenna. Compared to the ordinary antenna, the antenna with AMC structure offers better reflection coefficient and wider bandwidth which is from -10.35 dB to -27 dB and from 64 MHz to 342 MHz, respectively.

1. Introduction

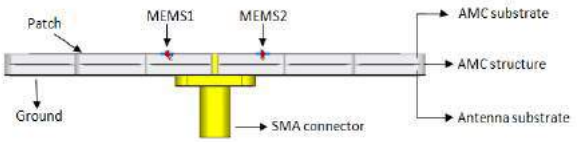
The researchers are recently working very hard to explore the fifth generation (5G) as the users now demand more bandwidths to transmit data at the speed of 1 Gbps and above [1]. As higher frequency needed to realize 5G network, many types of reconfigurable antennas have been proposed but the antenna using RF MEMS switches has a good potential to be applied as they can be operated at high frequency band, have low insertion loss and allow zero standby power consumption compared to others tunable components [2]. The idea of using AMC structure seems to be possible in 5G applications as the ordinary reconfigurable antenna offers narrow bandwidth and poor reflection coefficient. AMC is actually a metamaterial which performs zero degree reflection phase characteristic of Perfect Magnetic Conductor (PMC) at resonance frequency [3-4].

2. Antenna Design

In this paper, a reconfigurable antenna using AMC structure has been designed to operate at 11 GHz, as illustrated in Figure 1. The proposed AMC consists of 2x6 rectangular with windmill-shaped slot unit cells. The structure is placed in between Rogers RT5880 substrates with ε_r=2.2 and thickness, h=1.575 mm.



(a)



(b)

Figure 1: Proposed reconfigurable antenna with AMC structure (a) Top view (b) Side view

3. Discussion

The phase reflection performance of an AMC unit cell is shown in Figure 2. The bandwidth of AMC is determined when phase shifts between +90° to -90°, therefore the bandwidth of this proposed AMC is 37% at a frequency band from 8.1 to 11.78 GHz.

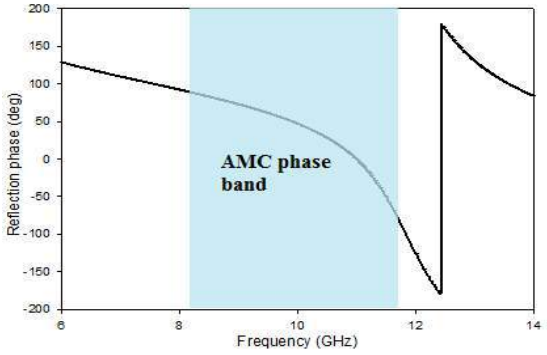


Figure 2: Reflection phase of an AMC unit cell

Table 1: Configurations of RF MEMS switches

State	MEMS1	MEMS2
1	ON	OFF
2	OFF	ON
3	ON	ON
4	OFF	OFF

As two RF MEMS switches have been used in the proposed antenna, four states are defined as tabulated in Table 1. The comparison of reflection coefficient (S11) between the ordinary antenna and antenna with AMC structure has been presented in Figure 3. Based on the figure, the antenna with AMC offers better reflection coefficient and wider bandwidth compared to the ordinary antenna. When MEMS2 is activated or both switches are activated, S11 shifted to the left and vice versa. Besides that, wider overall frequency bandwidth is obtained which is only 64 MHz for ordinary antenna to 342 MHz for antenna with AMC structure.

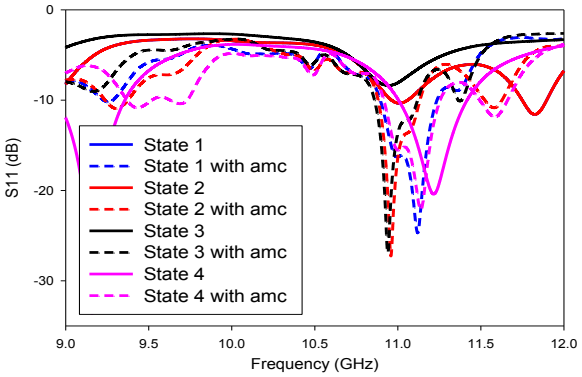

Figure 3: Reflection coefficient of the proposed antenna for each state.

4. Conclusions

A reconfigurable U-slot patch antenna with windmill-shaped slot AMC structure is proposed in this paper. By implementing the AMC structure into the reconfigurable antenna, the proposed antenna offers better reflection coefficient and wider bandwidth compared to the antenna without AMC structure. Therefore the proposed antenna could be the potential candidate to fulfill one of the 5G requirements.

Abstract

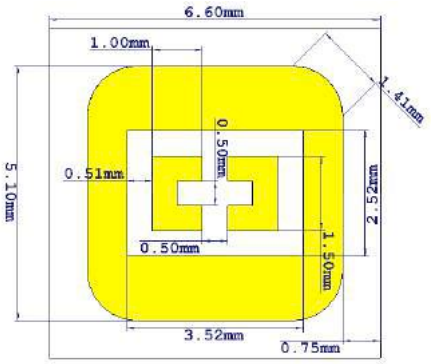
Integration of crescent shaped array antenna into a metamaterial of single resonant Artificial Magnetic Conductor (AMC) at 9.41 GHz is proposed. AMC plane stacked with crescent shaped array has successfully increased the gain, efficiency and bandwidth of the antenna to 9.73 dB, 97% and 398 MHz respectively compared to 8.46 dB, 96% and 393 MHz without AMC. It is observed that the characteristics of the proposed AMC plane significantly contributed to such results.

1. Introduction

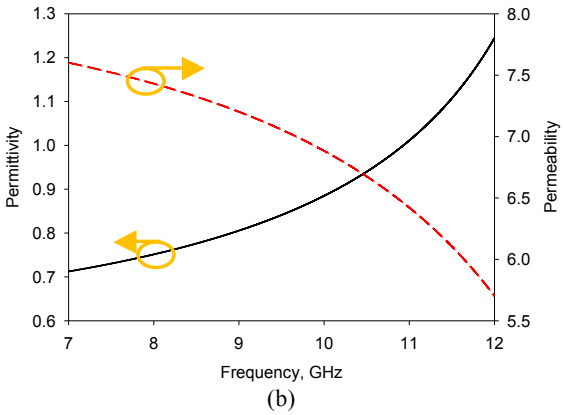
Due to the main characteristic of Perfect Magnetic Conductor (PMC) which exhibits 0o reflected phase, therefore it is potentially to improve the antenna performances [1]. However, the PMC is not available in nature [1]. However, an Artificial Magnetic Conductor (AMC) which is classified as a metamaterial [2] capable to exhibits the PMC characteristic at a specific frequency for each resonant response [3]. This research aims to design an AMC ground layer which can be placed closer to the resonant structure while improve the performance. For that reason, a microstrip array antenna is proposed as the radiating structure due to its fabrication simplicity and low profile characteristics.

2. Results and discussion

In this research, a crescent shaped array antenna has been designed as the radiating structure on the top of AMC plane. The design of the AMC unit cell is illustrated in Figure 1(a). The AMC is capable to exhibit 0^{o} phase response at 9.41 GHz with 2.83 GHz of bandwidth. As depicted in Figure 1(b), the AMC shows positive permittivity and high permeability at the desired operating frequency. To the best of author knowledge, a microstrip patch antenna one of the most popular antenna among researcher. However, this type of antenna is suffered in term of its performance due to the ground effect. Nevertheless, this risk can be eliminated by incorporating the AMC plane at the microstrip antenna as shown in Figure 2. As the result, the proposed antenna with AMC is capable to enhanced the antenna performances especially the gain, bandwidth and efficiency while reducing the radiating surface up to 6%. The performance of the crescent array antenna with and without AMC plane is tabulated in Table 1.



(a)



(b)

Figure 1: Simulated AMC unit cell (a) dimension and (b) results of permittivity and permeability.

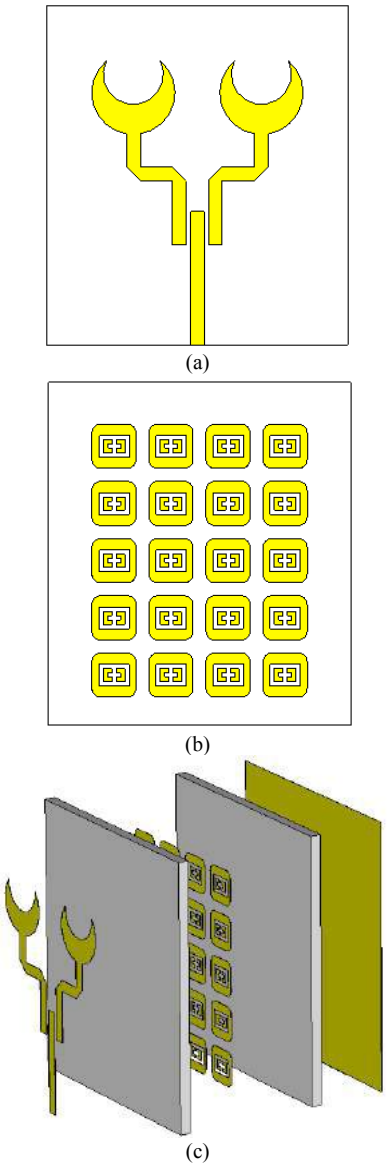


Figure 2: (a) Radiating crescent shaped array antenna, (b) AMC plane and (c) structure of the array antenna with AMC.

Table 1: Comparison performance of the crescent shaped array antenna with and without AMC.

Antenna performance	Crescent array antenna without AMC	Crescent array antenna with AMC
Radiating surface (mm^2)	165.74	155.62
Gain (dB)	8.44	9.73
Bandwidth (MHz)	393	398
Efficiency (%)	96	97

3. Conclusions

An incorporate of crescent shaped array antenna with AMC plane is proposed. Through the simulation process, the AMC plane is capable to be placed near to the radiating element. With aid of AMC plane which potentially exhibits as PMC, therefore the bandwidth, efficiency and gain of the crescent array antenna are enhanced up to 398 MHz, 97% and 9.73 dB respectively.

Abstract

A compact UWB MIMO antenna with metamaterials Split Ring Resonator (SRR) etched in between elements is presented. Its reverse side integrated with a partial ground plane to enhance bandwidth and improve inter-element isolation. The SRR metamaterial structures are significantly reduced the mutual coupling and improve antenna isolation, through exhibiting the negative characteristics for both permittivity and permeability. Results show that the isolation below than 20 dB in the entire UWB band, from 3.1 to 10.6 GHz.

1. Introduction

The demands of high data rates and channel capacity are the major issues of interest in wireless communication. This attention contributes to the increasing popularity of multiple-input multiple-output (MIMO) systems, which employs diversity techniques to improve communication systems reliability via multipath fading reduction [1]. Meanwhile, the ultra-wideband (UWB) spectrum which ranges between 3.1 and 10.6 GHz is capable of providing high data rates [2], [3]. To simultaneously increase data rates while mitigating multipath fading, the MIMO diversity technology can be integrated within UWB systems [4-6]. Recently, implementing the metamaterial unit cells structures for antenna design enable the performance improvement of MIMO antenna system through the isolation enhancement [7]. The electromagnetic metamaterial is defined as the artificial material structures that can be designed to explain the electromagnetic features that not present in nature [8]. Using the periodic structure of Split Ring Resonator (SRR) with the metal wires, correspondingly the negative relative permittivity and permeability are obtained [9-12]. To decrease the resonant frequency value of an antenna, the metamaterial structures of SRR unit cells are placed along an antenna to be used as a loading structure [13-16].

This work is an effort in designing a compact UWB MIMO antenna with a low inter-element mutual coupling. The proposed antenna operates with from 2.95 to 12.2 GHz and dimensions of ($0.3\lambda \times 0.2\lambda$) at the lower cutoff frequency 2.95 GHz. The Split Ring Structure combination with ground plane effectively reduces inter-element pattern correlation across the operational band with the isolation of 20 dB. Satisfactory diversity performance is confirmed via the envelope correlation coefficient and diversity gain (DG) of 0.2 and 9.8, respectively. Meanwhile, its mean effective gains (MEGs) ratio is nearly unity.

2. Antenna Design Geometry

The structure of the single ring resonator unit cells metamaterial was shown in Figure 1 (a) and (b). The geometrical dimensions of the proposed unit cell are listed in Table 1. The mathematical formulation in [17], [18], were used to evaluate the negative index parameters such as permittivity and permeability that produced through exciting the electric and magnetic fields in the wire SRR unit cells. The real and imaginary values of permittivity, permeability refractive index, and impedance are illustrated in Figure 1 (c), (d), (e) and (f). The geometry of the proposed UWB MIMO antenna was depicted in Figure 2 (a) and (b). It is designed on an FR-4 substrate with a thickness of 1.6 mm, permittivity ϵ_r= 4.7 and loss tangent tan δ = 0.025. The overall structure consists of two identical monopole antenna elements (denoted as MA1 and MA2) placed in parallel on the same side of the substrate with metamaterial structure of unit cells of SRR in between antenna elements. The partial ground plane and long wire of the unit cells are located on the reverse side of the substrate to reduce mutual coupling and improve isolation between ports.

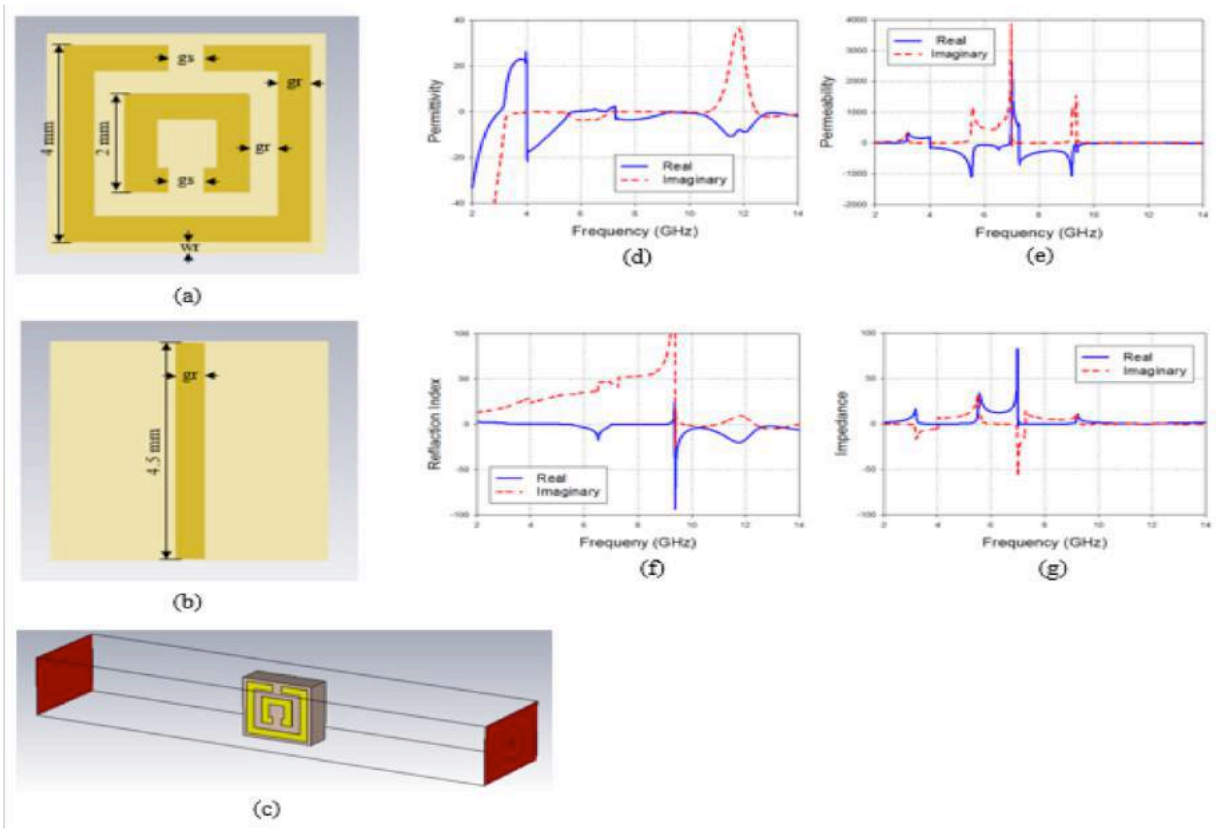

Figure 1: Geometry of the single ring resonator (SRR) unit cell structure, (a) unit cell front view, (b) unit cell back view, (c) simulation setup, (d) permittivity, (e) permeability, (f) refractive index, (g) impedance.

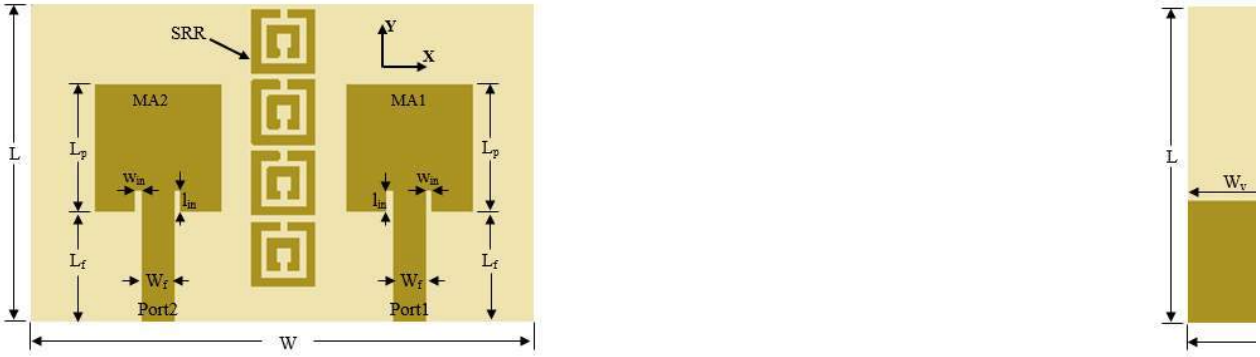

Figure 2: Geometry of the proposed UWB MIMO antenna, (a) front view, (b) back view.

Table 1: Parameters dimensions of the proposed antenna

Para.	Value (mm)	Para.	Value (mm)	Para.	Value (mm)	Para.	Value (mm)	Para.	Value (mm)	Para.	Value (mm)	Para.	Value (mm)

L	20	L_f	7	W_v	6	l_r	16.2	gs	0.6	L	20	L_f	7
L_p	8	W_f	2	w_{in}	0.5	Θ	15°	gr	0.5	L_p	8	W_f	2

3. Results and Discussion

Figure 3 compares the simulated and measured S_{11} and S_{21}. Simulations indicate a bandwidth from 2.95 to 12.2 GHz. A downwards shift is seen as the measured bandwidth covers the UWB band from 2.5 to 11 GHz for the reflection coefficient below -10 dB. The simulated and measured S_{21} shown in Fig. 4 indicate a mutual coupling of less than -20 dB between within the operating band (from 3 to more than 12 GHz).

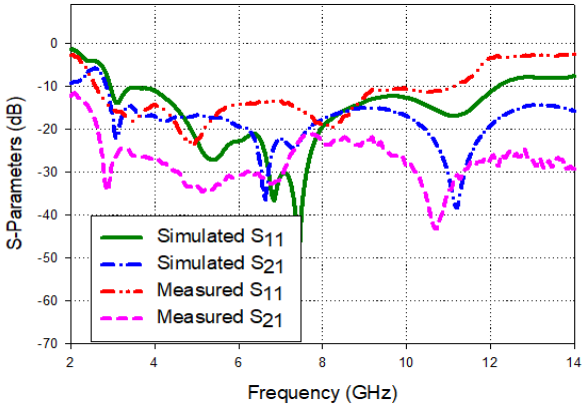

Figure 3: Simulated and measured S_{11} and S_{21} of the proposed UWB MIMO antenna.

The proposed MIMO antenna accomplished a 2:1 VSWR bandwidth of 2.5 to 11 GHz, which enabled operation throughout the whole UWB band and showed isolation better than 20 dB.

Abstract

The paper presents enhanced performance of 3dB branch-line coupler (BLC) by implementing diamond shaped unit cell negative permittivity metamaterial with 2×2 array cell configuration. S_{11} of less than -10 dB, equally power distributed of coupling, S_{31} and transmission, S_{21} of less than -3 dB, low magnitude imbalance of 0.01dB and enhanced bandwidth of 103% are achieved from 4.66GHz to 12.54GHz. Such features are highly potential and suitable to be implemented for 5.9GHz automotive Dedicated Short Range Communication (DSRC) application.

1. Introduction

Extraordinary electromagnetic properties possess of negative refractive index revealed initially by Veselago theorized that a left-handed medium (LHM) was implied from the presence of simultaneously negative permeability or permittivity which drastically drawn significant scientific interest [1-2]. Due to the propagation of electromagnetic waves in matter, this unprecedented metamaterials with negative permittivity and negative permeability are artificially constructed into materials design which in turn provides enhanced performance [3-4]. Possessing these intriguing electromagnetic properties, metamaterials widely utilized as a part of applications, such as super-lenses [5], waveguides, filters [6], antenna design, invisibility cloaking, electromagnetic absorbers, and electromagnetic band gaps [7], and branch-line coupler [8-11]. Different techniques of metamaterial was designed in the scaling of artificial structures has already been demonstrated from radio frequencies (RFs) to millimeter-wave application [12-14].

Metamaterials can be classified into three categories: zero-index materials, single-negative media, and double-negative media, where these artificially structured composites potential in the electromagnetic spectrum with material response is limited and the construction of novel devices is simplified. Metamaterial with either a negative permittivity or permeability is known as single-negative (SNG) medium. Significantly, metamaterial emphasis on solving the conventional physical limitations, miniaturization in size, improving gain, bandwidth and efficiency in multi-band operation of the antenna design [15].

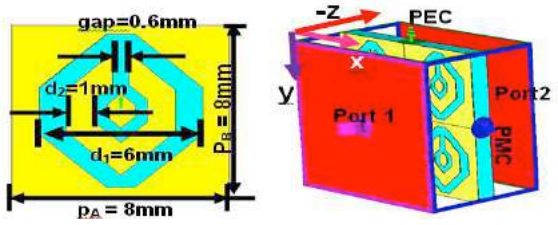
In this study, the proposed design of $0.16\lambda_0 \times 0.16\lambda_0$ diamond shaped unit cell array are etched on one side of a FR4 substrate exhibits resonance at DSRC frequency, 5.9GHz for vehicle to vehicle communication elements. The proposed structure exhibits resonance with a wider bandwidth of 50% enhancement in comparison with the BLC design without metamaterial. Moreover, the proposed BLC structure's dimension is 8.72mm × 9.69mm, which is significantly reduced compared to the BLC operating at the same frequency presented in [16]. The results towards enhancement of BLC performance is discussed in detailed in the subsequent part.

2. Branch-line Coupler Design

Specifications for the response of each unit cell are predetermined prior to construction before the entire constructed BLC design is finalized. Fig. 1(a) shows the geometrical parameters and dimension detailed of the proposed diamond shaped unit cell with the size of $0.16\lambda_0 \times 0.16\lambda_0$ in area. As per illustrated in Fig. 1 (b) the unit cells are arranged in the 2×2 array. Subsequently, transmission unit cell is altered by adjusting the shape, size, and configurations of the unit cells, which control over permittivity and magnetic permeability parameters that indicates the propagation of electromagnetic waves in matter.

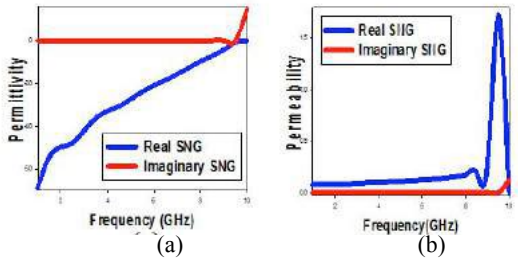
The negative permittivity and positive permeability behavior are observed through S-parameters response obtained from CST Microwave Studio (MWS) and evaluated by the mathematical formulation in [17-18] which then simulated through Matlab coding. As shown by the frequency-domain solver for the simulation of the metamaterial structure in Fig. 2(a) and (b), negative permittivity was observed with frequency range of 0.5 GHz to 8 GHz. Diamond shaped unit cell array are designed using one side of a FR4 substrate with thickness of 1.6mm, dielectric constant of 4.6, loss tangent of 0.019 and copper thickness of 35μm. The proposed unit cell array was placed

at the center of a waveguide with perfect electric wall in the x−z plane and perfect magnetic wall in the z−y plane to realize TEM mode excitation in the z-direction while the two open ports were in the z-direction.



(a) (b)

Figure 1: Diamond shaped unit cell, (a) unit cell (b) 2×2 arrays metamaterial.



(a) (b)

Figure 2: Unit cell response, (a) permittivity (b) permeability.

Conventionally, directional couplers have four ports, in which the first port is regarded as the input, the second port is regarded as through port, the third port is regarded as the coupler port, and the fourth port is regarded as isolated port. Diamond shaped unit cell metamaterial array is implemented at the bottom layer of the BLC while the center of the substrate is kept metalized serving as a ground plane as shown in Fig. 3 and Fig. 4 accordingly.

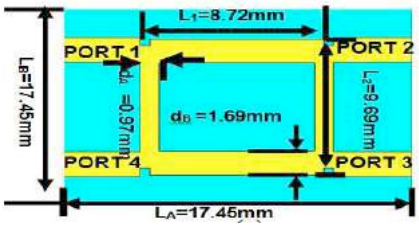


Figure 3: BLC Geometry transmission line dimension.

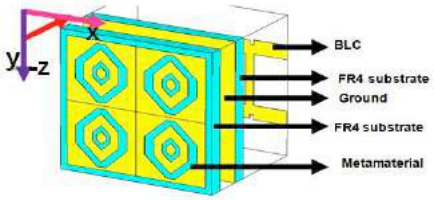

Figure 4: Exploded view structure.

3. Results and Discussion

As can be seen from Fig. 5, simulated results between the BLC design with metamaterial and without metamaterial in term of reflection coefficients (S_{11}), transmission (S_{21}), coupling (S_{31}) and isolation (S_{41}) value is illustrated. Fig. 5(a) and (b) shows S-parameter value of BLC with a good reflection coefficient (S_{11}) value of -20.8dB, transmission (S_{21}) of -3.99dB, tight coupling parameter (S_{31}) of -3± 1 dB, low magnitude imbalance, 0.01dB and isolation (S_{41}) improvement to -28.58 dB at the operating frequency, 5.9 GHz. Fig. 5(c) demonstrates a promising phase output difference between Port 2 and 3, (90°±5) °. Enhanced bandwidth of 103% was obtained from the proposed BLC, operated from 4.66GHz to 12.54GHz. The proposed metamaterial has enabled the concentration of the electromagnetic field and currents nearby radiating elements instead of distributed them along the ground plane which allows BLC to be utilized with enhanced bandwidth as the surface current distribution had been illustrated in Fig. 6.

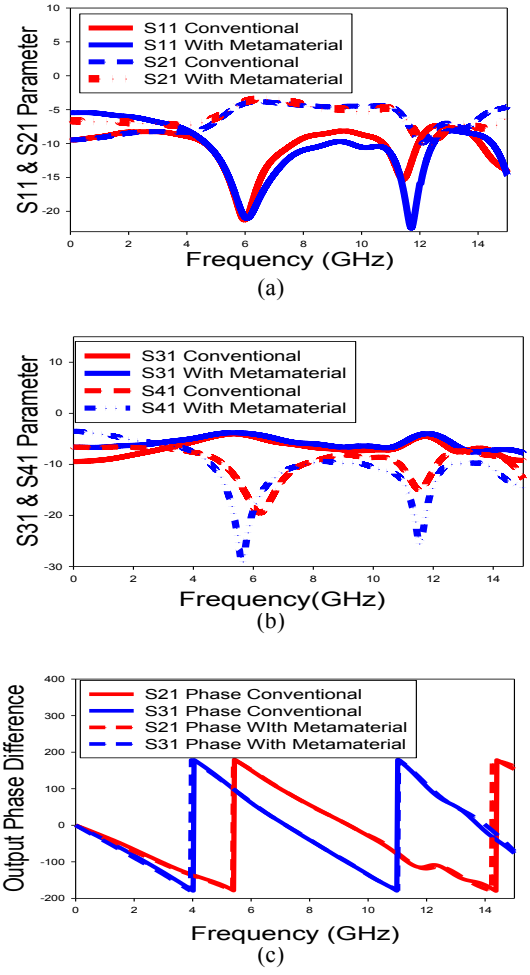

Figure 5: The simulated BLC performance, (a) S11 & S21 (b) S31 & S41 (c) Output phase difference.

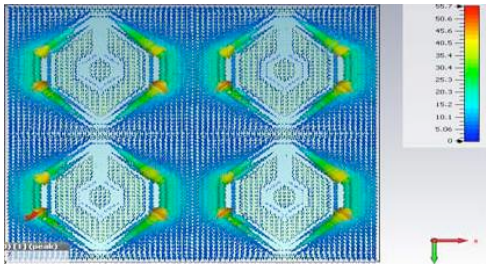

Figure 6: Surface Current distribution in the metamaterial unit cell.

4. Conclusions

In this paper, enhanced performance of BLC operating at 5.9GHz for DSRC application realized using negative refractive index metamaterial unit cell. A novel design of negative permittivity diamond shaped unit cell with considerable small size of $0.16\lambda_0 \times 0.16\lambda_0$ is proposed. The features of negative permittivity are validated numerically from the proposed unit cells structure using Matlab simulator. In advanced, the proposed unit cell array is etched at the bottom layer of the BLC while the center of the substrate is kept metalized serving as a ground plane which provides the higher percentage of transmitted signal into the proposed design. The promising S parameter value in terms of reflection coefficient, S_{11}, insertion loss, S_{21}, coupling, S_{31} and isolation, S_{41} provide promising results to serve as a platform for vehicle to vehicle beamforming element design at DSRC frequency, 5.9GHz.

Abstract

A broadband MIMO antenna at size 36 × 22 mm^2 is proposed. The antenna consists of two identical monopole antenna elements (MA) with T-shaped stub ground plane and metamaterial Single Ring Resonator (SRR) to reduce mutual coupling and enhanced isolation between antenna elements by exhibiting the negative characteristics for both permittivity and permeability. The overall antenna performance is optimized in terms of the reflection coefficient (S_{11}), and mutual coupling (S_{21}), radiation pattern across frequency from 2.8 to 4.95 GHz. A broadband frequency from 2.8 to 4.95 GHz is achieved, which covers WiMAX and the lower UWB band (3.1–4.8 GHz) operation. The dimension of the proposed MIMO antenna is (0.32λ × 0.21λ) at the lower cutoff frequency 2.8 GHz. The Split Ring Structure combination with ground plane effectively reduces inter-element pattern correlation across the operational band with the isolation of 16 dB. Satisfactory diversity performance is confirmed via the envelope correlation coefficient and diversity gain (DG) of 0.02 and 9.7, respectively. Meanwhile, its mean effective gains (MEGs) ratio is near unity.

1. Introduction

The wireless revolution in recent years has increased the demands for devices which is capable of operating across multiple frequency bands with enhanced radio link performance through using the multiple-input multiple-output (MIMO) technology, which employs diversity techniques to improve communication systems reliability via multipath fading reduction [1], [2]. When applied the MIMO antennas in multi-standards devices, the demand is growing on a wideband and high isolation [3]. Thus, bandwidth enhancement and size reduction are becoming main design requirements for printed antennas in different applications [4-6]. Recently, implementing the metamaterial unit cells structures for antenna design enable the performance improvement of MIMO antenna system through the isolation enhancement [7]. The electromagnetic metamaterial is defined as the artificial material structures that can be designed to explain the electromagnetic features that not present in nature [8]. Using the periodic structure of Split Ring Resonator (SRR) with the metal wires, correspondingly the negative relative permittivity and permeability are obtained [9-12]. To decrease the resonant frequency value of an antenna, the metamaterial structures of SRR unit cells are placed along an antenna to be used as a loading structure [13-16]. This work is an effort in designing a broadband MIMO antenna with a low inter-element mutual coupling.

2. Antenna Design Geometry

The structure of the single ring resonator unit cells metamaterial was shown in Figure 1 (a) and (b). The geometrical dimensions of the proposed unit cell are listed in Table 1. The Using of mathematical formulation in [18], [19], is to evaluate the negative index parameters such as permittivity and permeability that produced through exciting the electric and magnetic fields in the wire SRR unit cells. The real and imaginary values of permittivity, permeability refractive index, and impedance are illustrated in Figures 1 (c), (d), (e) and (f). The geometry of the proposed broadband MIMO antenna was depicted in Figure 2 (a) and (b). It is designed on an FR-4 substrate with a thickness of 1.6 mm, permittivity $\varepsilon_r = 4.7$ and loss tangent tan $\delta = 0.025$. The overall structure consists of two identical monopole antenna elements (denoted as MA1 and MA2) placed in parallel on the same side of the substrate with metamaterial structure of unit cells of SRR in between antenna elements. The ground plane with T-shaped stub and GPA are placed on the other side of substrate, to reduce mutual coupling and enhanced the isolation between antenna elements. The optimized dimensions of the proposed antenna are listed in Table 1, and optimization process will be discussed in the next section.

3. Results and Discussion

Figure 3 shows the simulated s-parameters of the proposed MIMO antenna, indicating the operation in broadband from 2.5 to 2.85 GHz and from 2.8 to 4.95 GHz. Its operation supports multi-standard operation across WiMAX and the lower band of UWB. Simulated mutual coupling (S_{21}) shown in Fig. 3 indicates the value of -16 dB at lower band and below -20 dB at upper band. This indicates that the proposed antenna is suitable for portable MIMO applications.

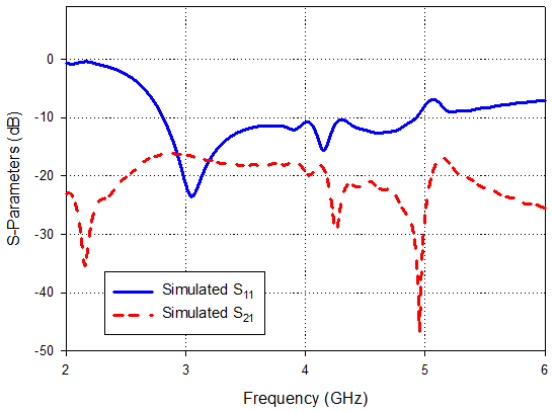

Figure 3: Simulated S_{11} and S_{21} of the proposed broadband MIMO antenna.

The MIMO antenna's radiation patterns evaluated by computer simulation as illustrated in Figure 4. Three dimensions (3D) simulated radiation patterns at the two resonance frequencies 3 GHz and 4.1 GHz are obtained when port 1 is excited, as shown in Figs. 4a and 4c, respectively, Meanwhile 3D radiation patterns exciting from port 2 at the same frequencies are shown in Figs. 4b and 4d, respectively.

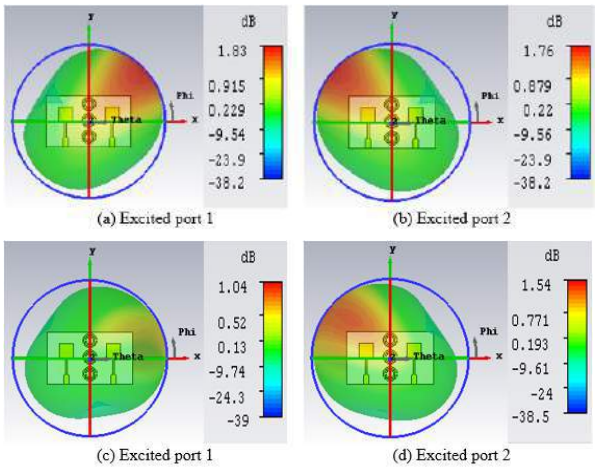

Figure 4: 3D radiation patterns at; (a) 3 GHz and (c) 4.1 GHz when port 1 excited and port 2 terminated with 50-Ω load and 3D radiation patterns at; (b) 3 GHz and (d) 4.1 GHz when port 2 excited and port 1 terminated with 50-Ω load.

4. Conclusions

A compact broadband MIMO antenna sized at 36 × 22 mm^2 is proposed for portable systems. The overall structure consists of two identical planar monopole antennas and a Single Ring Resonator (SRR) metamaterial structure is proposed to reduce the mutual coupling and improve antenna isolation, they located on same side of the substrate. The reverse side contains a ground plane with T-shaped stub designed to reduce mutual coupling and enhance the isolation and Ground Plane aperture (GPA) placed on the other side of substrate, to reduce mutual coupling and enhanced the isolation between antenna elements. The proposed MIMO antenna accomplished a 2:1 VSWR, covered broadband from 2.8 to 4.95 GHz to support multi-standard operation in the WiMAX and the lower band of UWB bands, and featured isolations of at least 16 dB in the desired band. The envelope correlation coefficient of less than 0.05., and its MEG_1/MEG_2 ratio is nearly equal to unity. Its size and results with performance indicated the suitability of the proposed MIMO antenna for portable applications.

Abstract

The analytical analysis of the metamaterial boundary with the rotational disorder reveals both bound and leaky surface plasmon (SP) modes. The dispersion relations of SPs propagating on a surface of these metamaterials are presented along with the propagation lengths. The rigorous modeling and analysis of surface waves at the boundary of two metamaterials possessing rotational disorder are presented. Dispersion properties of two different metamaterial boundaries have been investigated. The results show that the boundary of the metamaterials having different dielectrics employed allows for the presence of the particular modes crossing the light line with the significant portion at lower frequencies lying above the free space light line.

1. Introduction

Guiding the surface wave by artificial metamaterial structures has been the subject of extensive interest over the past decades [1, 2]. This can be explained by two factors. The first one is related to the fact that the dispersion of the surface waves is governed by geometrical considerations. Necessarily, the definite geometry and arrangement of nanoscale enclosures that are typically associated in a periodic lattice determine the unique optical properties of metamaterials [3]. The second favorable factor concerns their sub-wavelength dimensions offering new degrees of freedom for the design of devices [4] with a thickness much shorter than the wavelength.

Since the emergence of the metamaterial, the disorder within artificially structured materials has been a subject of extensive discussions [5-7]. Metamaterial at optical frequency can be considered as a kind of man-made architecture material possessing unusual properties [8]. One of its remarkable features is that the equivalent permittivities on different directions differ from each other and can be varied by designing its structure elaborately [8]. It is worthwhile mentioning, that this property enhanced by the presence of the disorder promises that metamaterial may serve for SP propagating with more flexible performances than conventional metal or ordered metamaterial. For instance, dealing with the photonic crystals, some disorder can dramatically degrade the reflection and transmission properties, which are based on constructive interferences. In contrast, metamaterial media, by taking benefit of strong localization effects is, in theory, not affected by a positional disorder as long as the coupling between these resonators can be avoided [9]. It is worthwhile mentioning, that even in right-handed random media, localization of waves also exists [10-12]. Sometimes the localized modes may accidentally couple to each other and form a propagating channel, the "necklace states" [13]. A variety of metamaterials has been studied from the perspective of applying the disorder to the arrangement of the elements comprising the array. The exceptionally fertile ground to achieve effects of disorder on the electromagnetic properties of two-dimensional metamaterial arrays has been provided by the latest development of techniques for fabrication of metamaterials yielding randomized arrays of metamolecules [14] and new ideas for using metamaterials in coherent sources of electromagnetic radiation [15]. The transmission of randomly distributed circular elements over a series of filling fractions has been explored in [16]. Related findings at terahertz frequencies, demonstrating the ability of periodic hole arrays to support surface plasmon like waves as well as indicating the disability of similar arrays consisting of randomly distributed holes to behave in the same way are reported in [17].

When designing the metamaterials, it is generally assumed that these structures are identical, but in fact, fabrication error will have a dramatic impact on geometrical perturbations thus causing some degree of deviation in their resonant properties. As has been proposed earlier [18, 19] a spreading of the oscillator strengths across a finite bandwidth, arises due to the variation in the geometrical parameters of resonant metamaterial elements. It has been demonstrated [20] that a significant variation of the metamaterial magnetic properties may be caused by the even weak microscopic disorder. Additionally, a substantial suppression of the wave propagation in a wide frequency range may happen due to a 10% deviation in the parameters of the microscopic resonant elements may lead to [20]. The disorder effects of left-handed metamaterials with unitary dendritic structure cell have been proposed in [20]. However, the disordering array and geometrical variations have been achieved separately within this studies, and besides, they are at microwave and infrared wavelengths [21, 22]. In recent times, the negative refractive index and permeability in the visible regime have been recognized by means of a disordered silver metamaterial thin film [23]. To the best of our knowledge the limited number of studies

examining the SPs deals with the disordered metamaterial case [24, 25].

The possibility of reconstructing an image with subwavelength details has provided the fertile background for the the development of SRR/wire media composite metamaterials [26]. However, several studies [27] have shown that disorder suppresses the left-handed behavior, which is critical for this imaging. It is worthwhile mentioning, that robustness to disorder is crucial when scaling a structure down to the scale of THz or optical wavelengths, where precise control of dimensions becomes more difficult.

In this study, we intentionally perturb the perfect checkerboard geometry taking a similar approach to [28]. Doing so, the rotational disorder is introduced by changing the orientation of the nanobeams with respect to the unit cell. However in this case the square size is not fixed and a random rotation is applied to each element with the metamaterial unit cell having the hexagonal shape. We explore how disorder in element rotation affects the dispersion diagrams of the surface plasmon polaritons. It is worthwhile mentioning, that the interface modes in nanostructure metal-dielectric metamaterials have already been considered in [37], however the effect of the rotational disorder has not been taken into consideration.

2. Modeling and the analytical solution

The proposed geometry of the nanobeam composites is shown in Figs. 1, 2. The nanobeams with permittivity ε_m are embedded into a host material with permittivity ε_d..

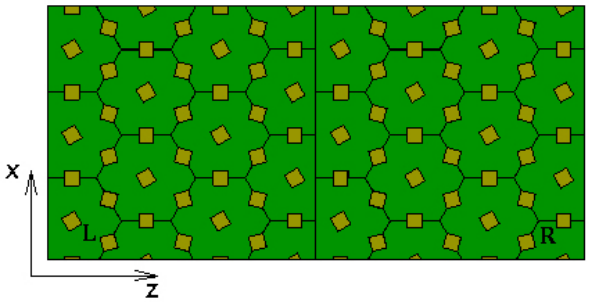

Fig. 1. Schematic view of an interface separating two different nanobeam composites

It should be mentioned, that the optical response of the nanobeam composite resembles that of uniaxial media. It has been proposed that at optical frequencies, Maxwell-Garnett type effective medium theory describes the behavior of the dielectric permittivity tensor components [29-33]. Thus, by means of effective medium approximation it is possible to evaluate the effective permittivities of the nanobeam metamaterial which are described by the following equations:

$$\varepsilon_z^L = \varepsilon_d^L \left[\frac{\varepsilon_m^L \left(1+\rho^L\right) + \varepsilon_d^L \left(1- \rho^L\right)}{\varepsilon_m^L \left(1-\rho^L\right) + \varepsilon_d^L \left(1+\rho^L\right)} \right] \tag{1}$$

$$\varepsilon_z^R = \varepsilon_d^R \left[\frac{\varepsilon_m^R \left(1+\rho^R\right) + \varepsilon_d^R \left(1- \rho^R\right)}{\varepsilon_m^R \left(1-\rho^R\right) + \varepsilon_d^R \left(1+\rho^R\right)} \right] \tag{2}$$

$$\varepsilon_x^L = \varepsilon_m^L \rho^L + \varepsilon_d^L \left(1 - \rho^L\right) \tag{3}$$

$$\varepsilon_x^R = \varepsilon_m^R \rho^R + \varepsilon_d^R \left(1 - \rho^R\right) \tag{4}$$

Here, subindexes *L* and *R* refer to the left and right metamaterial under consideration, respectively. Moreover, ρ is the metal fill fraction ratio enabling to control the metamaterial disorder mechanism and is defined as:

$$\rho = \frac{nanowire\ area}{unit\ cell\ area} \tag{5}$$

To exemplificatively demonstrate the properties of surface waves, we adopt a Drude model to characterize the metal (i. e. silver) in which the permittivity is expressed as $\varepsilon_m(\omega) = \varepsilon_\infty - \dfrac{\omega_p^2}{\omega^2 + i\delta\omega}$.

The parameters are obtained by fitting this dielectric function to a particular frequency range of bulk dielectric data [34]. It is found [35] that for silver, the values of $\varepsilon_\infty = 5$, $\omega_p = 9.5eV$, $\delta = 0.0987eV$ give a reasonable fit to the bulk dielectric data.

A possible way to calculate the metal fill fraction (ρ) is to obtain values for square side (a) and spacing (S) and apply the following equation (assuming perfect hexagonal structure) [36] for the square pore:

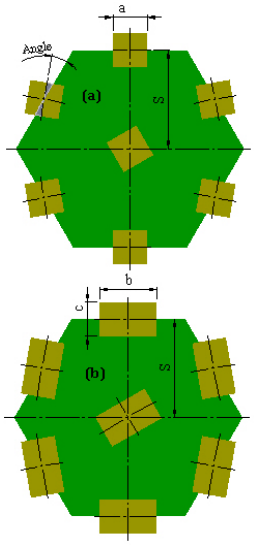

Fig. 2. A metamaterial unit cell with nanobeams having square (a) and rectangular (b) shapes

$$\rho = \frac{2a^2}{\sqrt{3}S^2} \tag{6}$$

and for the rectangular one correspondingly:

$$\rho = \frac{2bc}{\sqrt{3}S^2} \tag{7}$$

Under this assumption, it is possible to derive the dispersion relation for the surface modes localized at the interface between two anisotropic media, we evaluate the tangential components of the electric and magnetic fields at the interface and obtain a single surface mode with the propagation constant [35]

$$\beta = k\left(\frac{\left(\varepsilon_x^R - \varepsilon_x^L\right)\varepsilon_z^R\varepsilon_z^L}{\varepsilon_z^R\varepsilon_x^R - \varepsilon_z^L\varepsilon_x^L}\right)^{1/2}, \tag{8}$$

where k is an absolute value of wavevector in vacuum and β is the component of the wavevector parallel to the interface.

It is worthwhile mentioning, that the reported approach is applicable to any kind of the disordered metamaterial. The effect of the disorder is taken into consideration through the metal fill fraction ρ.

It is interesting to notice that in case of $\varepsilon_m^L = \varepsilon_m^R$ and $\varepsilon_d^L = \varepsilon_d^R$, the obtained result coincides with the dispersion as follows:

$$\beta = k\left(\frac{\varepsilon_d^L\left(\varepsilon_d^L + \varepsilon_m^L - \varepsilon_d^L\rho_L + \varepsilon_m^L\rho_L\right)\left(\varepsilon_d^L + \varepsilon_m^L - \varepsilon_d^L\rho_R \quad \varepsilon_m^L\rho_R\right)}{\sqrt{a+b}}\right) \tag{9}$$

Where

$$a = 4\varepsilon_d^L\varepsilon_m^L - \left(\varepsilon_d^L\right)^2\rho_L - \left(\varepsilon_d^L\right)^2\rho_R + \left(\varepsilon_m^L\right)^2\rho_L + \left(\varepsilon_m^L\right)^2\rho_R + 3\left(\varepsilon_d^L\right)^2$$
$$b = \left(\varepsilon_m^L\right)^2 - \left(\varepsilon_d^L\right)^2\rho_L\rho_R - \left(\varepsilon_m^L\right)^2\rho_L\rho_R \quad 2\varepsilon_d^L\varepsilon_m^L\rho_L\rho_R.$$

On the other hand, the dispersion for the case of $\varepsilon_m^L = \varepsilon_m^R$ and $\varepsilon_d^L \neq \varepsilon_d^R$ depends on the metamaterial parameters as follows:

$$\beta = k\sqrt{\left(\frac{-\left(\varepsilon_d^L\varepsilon_d^R ca\left(\varepsilon_m^L\rho_L - \varepsilon_m^L\rho_R - \varepsilon_d^L\left(\rho_L - 1\right) + \varepsilon_d^R\left(\rho_R \quad 1\right)\right)\right) -}{\left(\frac{\varepsilon_d^L\left(\varepsilon_m^L\rho_L - \varepsilon_d^L\left(\rho_L - 1\right)\right)c}{d} - \frac{\varepsilon_d^R\left(\varepsilon_m^L\rho_R - \varepsilon_d^R\left(\rho_R - 1\right)\right)a}{b}\right)db}\right.} \tag{10}$$

Where

$$a = \varepsilon_d^R\left(\rho^R - 1\right) - \varepsilon_m^L\left(\rho^R + 1\right),\ b = \varepsilon_d^R\left(\rho^R + 1\right) - \varepsilon_m^L\left(\rho^R - 1\right),$$
$$c = \varepsilon_d^L\left(\rho^L - 1\right) - \varepsilon_m^L\left(\rho^L + 1\right),\ d = \varepsilon_d^L\left(\rho^L + 1\right) - \varepsilon_m^L\left(\rho^L - 1\right).$$

3. Discussion

In the following, we study the influence of the square side of the L metamaterial on the surface modes. According to the assumption, the square side varies from 10 nm to 40 nm. Figs. 3-6 show the dispersion curves of the disordered metamaterial. Although the graphs possess the similar outline with that of traditional metal-SP, the dispersion curves for the disordered nanobeams have some particularities that deserve further considerations. Figure 3 is plotted to show the impact of the square side on the surface modes dispersion diagrams. Fig. 3 (a) shows the dispersion curves of the structure under consideration. As a_L increases from 10 to 40 nm, the dispersion curve deviated gradually from that of the a_L=10 nm and is well distinct from the light line and asymptotically approaches different cutoff frequencies. This is similar to the phenomenon originally appearing in the optical frequencies for natural SPPs. The surface modes move to the higher frequencies as the square side increases. Moreover, the frequency range of the waves existence is broadened in comparison with the case of the circular nanowires [38]. Herein, the chosen square side values correspond to the case of the circle inscribed in a square.

Finally, we investigate the influence of the nanobeam shape of the L metamaterial. The square nanobeams are replaced now by the rectangular ones. The side of the rectangle b varies from 10 nm to 70 nm. The surface modes are shown in Fig. 4. As can be seen in Fig. 4, the dispersion curves of the surface modes move to the lower frequencies as b_L decreases.

Generally speaking, the materials composing the metamaterial itself play an important role in studying the surface modes. So it is interesting in the study of the dependence of surface modes on physical parameters of the employed materials. Here, we employ HfO_2 as the dielectric of the R metamaterial. In Fig. 5, we plot the surface modes at the interface of two metamaterials whose parameters are S_L=66 nm, a_R=20 nm, S_R=76 nm, $\varepsilon_m^L = \varepsilon_m^R = \varepsilon_{Ag}$, $\varepsilon_d^L = \varepsilon_{Al_2O_3}$, $\varepsilon_d^R = \varepsilon_{HfO_2}$.

In Fig. 5, the three modes (a_L=10nm, a_L=30nm, a_L=40nm) always lie to the right side of the light line and remain nonradiative (bound) SP modes throughout the certain frequency range. The mode corresponding to the case a_L=20nm is of particular interest due to the fact that its dispersion relation crosses the light line and a significant portion at lower frequencies lies above the free space light line, which usually splits up nonradiative (bound) and radiative (leaky) regions. For the bound modes, longer propagation lengths take place at lower frequencies owning the dispersion that is close to linear. Mode corresponding to the case a_L=30 nm possesses the longer propagation length than the mode corresponding to the case a_L=40 nm.

Looking at the real dispersions of the modes it can be noticed a band bending at frequencies around ω=7·10^{14} Hz. Correspondingly, a divergence in the imaginary parts is observed. Similar deviations are typical of real-frequency (and complex propagation constant) eigenvalue methods. They are not physical and were already reported elsewhere [39-41].

As it is depicted in Figs. 3-6, all the bounded modes always lie to the right side of the light line and remain nonradiative SP modes throughout the whole frequency range. The case presented in Fig. 6 (a) is of particular interest since its dispersion relation crosses the light line and a substantial portion at lower frequencies lies above the free space light line, which typically separates nonradiative (bound) and radiative (leaky) regions. Consequently, the proposed structure will interact with the material via leaky waves. Moreover, the case depicted in Fig. 6 allows the presence of the Ferrell-Berreman modes which exist at energies near the ENZ of the hyperbolic metamaterial to the left of the light line [42-44].

4. Conclusions

We analyzed the boundary of two metamaterials. Despite the simple geometry, the structure allows for rich phenomena. The comparison of both cases (metamaterials with the same dielectric; metamaterials with different dielectrics) gives insight into the differences of the dispersion diagrams. Our results are significant seeking for a better understanding of

the plasmonic properties of SPs in metamaterial, which are useful to design the various metamaterial-based optoelectronic devices.

Abstract

The paper imparts the architecture of a modified theta shaped double negative metamaterial unit cell that is felicitous for dual band of microwave frequency. To justify the performance of the proposed resonator an analogy is conferred on transmission coefficient, relative permeability, permittivity and refractive index. A correlation is made on the performance after the analysis of unit cell and array structures. The 9 × 9 mm^2 structure has been printed on FR-4 and a correlation is made between the basic unit cell and array structures to validate the performance of the proposed metamaterial. A great transmission coefficient of 13GHz with a 500MHz band gap in the middle is demonstrated for all of these configurations. The effective parameters of the resonators cover C, X, and Ku-band independently with double negative phenomena at X and Ku-band with a frequency range of about 1.1GHz. Due to its auspicious design, double-negative characteristics and the proposed metamaterial has potential to be used for satellite application.

Keywords Metamaterial, Array Structure, Double negative, satellite communication.

1. Introduction

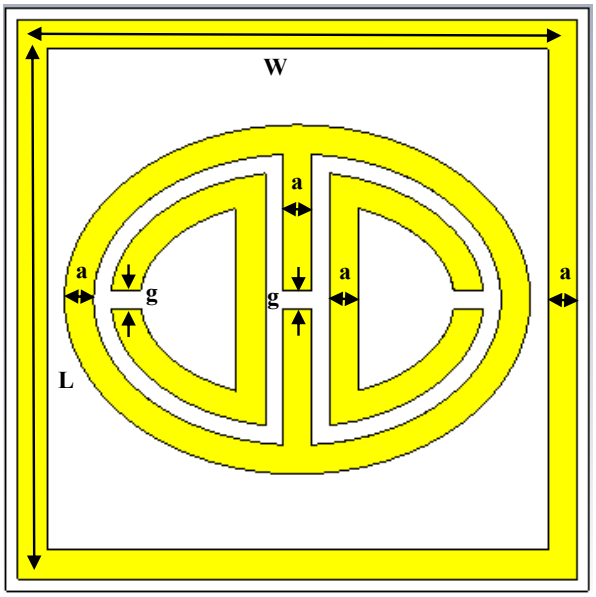
Metamaterials are the special type of materials that are usually not available in nature. They are actually engineered materials, they need to embed periodic unit cell for their formation to create naturally unavailable electromagnetic properties. Moreover, these materials have the power to control the electromagnetic wave beams to show their unorthodox characteristics. These unusual features of the metamaterials totally depend on the geometry of the atomic construction. It has been started from the year 1968, Veselago et al [1] observed unique properties of materials having negative permittivity (ε) and permeability (μ). But it was not appreciated until 2000 when Smith et al. [2] fortunately validated a new unreal with these unconventional properties (both permittivity and permeability were negative) is called left-handed metamaterial. In case of negativity, it has been categorized as Single-negative (either permittivity is negative or permeability is negative), Double-negative (both permittivity and permeability are negative). There is also a term called near-zero refractive index metamaterial (NZRI) where the permittivity and permeability of a material become approximately to zero on a particular range of frequency. Having these captivating electromagnetic phenomena, necessary applications, like SAR reduction [3-4], super lenses, antenna design [5-7], filters [8], invisibility cloaking [9-10], electromagnetic absorber, and electromagnetic band gaps etc can be employed by metamaterials. In some cases, intrinsic negative permittivity is found. But it is really difficult to find the negative permeability with a natural medium. Even artificial structures can hardly obtain the negative permeability. Concurrently, it is really difficult to get the negative refractive indices. Currently, multi-band metamaterial absorbers have become an auspicious application in the detection of explosives, even in bolometers and thermal detectors. Moreover, a very few studies have been made in designing this type of materials [11-14]. Different alphabetic shapes have become popular for particular operations [15]; like, Benosman et al. [16] introduced a double S-shaped metamaterial that showed negative values of η from 15.67 to 17.43GHz. Mallik et al. proposed various U-shaped rectangular array structures left-handed aspect at approximately 5, 6 and 11GHz. A V-shaped metamaterial was presented by Ekmekci et al. the architecture showed double-negative characteristic. Zhou et al. designed an S-shaped 15 × 15 mm^2 chiral metamaterial for X- and Ku-band application. Though the EMR was not higher than 4. For the purpose of application on S and C bands, Hossain et al. [17] design G-shaped DNG for different unit cells and array sizes.

A metamaterial unit cell of modified theta-shaped has been proposed in this paper. The structure covers multiple bands

(L, C, X, and Ku) of frequencies for the transmission coefficient. And for effective parameters, it covers the X and Ku bands with double negative characteristic.

2. Cell Design

The diagram of the prospective modified Theta-shaped unit cell composition is itemized in Fig. 1. Each unit cell comprises with 9mm in length and 9mm in width. All elements have the thickness of 0.35mm. Each Theta-shaped split resonator has the width of 0.5mm with a same split gap. The outer length of the resonator is 9mm where the split of each of the resonators is 0.5mm. The entire patch (made of copper) is developed on a substrate called FR-4. It has a dielectric constant of $\varepsilon r = 4.3$, a dielectric loss-tangent of $\tan\delta\varepsilon = 0.025$. Sides of the substrate are L = W = 9mm and the thickness is t = 1.6mm. Designed parameters of the proposed metamaterial are enlisted in Table 1.



(a)

(b)

(c)

Fig.1: Metamaterial Unit cell: (a) Proposed geometry; (b) Fabricated geometry; (c) Prototype array

A prototype array and a unit cell are fabricated for the purpose of measurement. The area of the array is 36 × 36mm^2. Two waveguide ports are used to propagate the electromagnetic waves to excite the configuration on two opposite direction of Z-axis. PEC and PMC were used along the vertical direction of x and y axis respectively. And for the free-space simulation purposes, a frequency domain solver was utilized. Moreover, for the analysis purpose of these configurations, a tetrahedral mesh was used with a flexible mesh. The normalized impedance was 50 ohms and the system was performed from 1 to 18GHz.

Table 1: Parameters of the unit cell

Parameters	Dimensions (mm)
L	9
W	9
a	0.5
g	0.5

The area of the prototype was 9 × 9 mm,^{2} which was fabricated for the purpose of measurements. By settling the perspective unit cell in between, the waveguides as per the Fig. 2 to actuate the parameters accurately of the metamaterial unit cell. To determine the parameters, we used a vector analyzer commonly known as Agilent N5227A. To calibrate perfectly, an Agilent N4694-60001 was utilized.

3. Results and Discussions

There are plenty of ways to find out the effective parameters of a unit cell like NRW method, DRI, etc. This paper highlights the electromagnetic properties using the real values of ε, μ, and η using S_{11} and S_{21}.

3.1. Analysis of unit cell

As the unit cell is fabricated on a Fr-4 which has an area of 81mm^2, it has been measured within a frequency range of 1 to 18GHz. The simulation was done in the CST microwave studio and the result is compared with the measured one after the fabrication to measure the transmission coefficient (S_{21}). The measured result follows the similar pattern as there is a bit shitting of frequencies in the C-band. The transmission coefficient exhibits a wide band with a coverage of L, C, X, and Ku-band. The first resonance is found in the L-band at frequency 1.63GHz. Then a wide band from 4.68GHz to 17.18GHz with a little band gap of 500MHz. The shifting is occurring due to fabrication error and the free space measurement process.

Fig.2 (b) shows the current distribution of the unit cell at 6.50GHz and 13.5GHz. Due to the antithetical geometry of the structure, a reverse current flow is noticed in the metal fillet of the configuration. Moreover, opposite current flows through the inner and outer surfaces of the resonator creates the stop band at this frequency [18].

Fig.3 (a) shows the magnitude of the transmission coefficient (S_{21}). By using S_{21} and S_{11} parameters, the effective parameters, i.e., effective permeability and effective permittivity can be obtained [19]. Fig.3 (b) and (c) show the result of effective permittivity and effective permeability respectively.
To differentiate the effective permittivity (ε_r) and permeability (μ_r) with S_{11} and S_{21}, the NRW method is applied.

$$\varepsilon_r = \frac{c}{j\pi f d} \times \frac{(1-V_1)}{(1+V_1)} \quad (1)$$

$$\mu_r = \frac{c}{j\pi f d} \times \frac{(1-V_2)}{(1+V_2)} \quad (2)$$

The effective refractive index (η_r) can also be calculated from S_{21} and S_{11} [2]:

$$\eta_r = \frac{c}{j\pi f d} \times \sqrt{\frac{(S_{21}-1)^2 - S_{11}^2}{(S_{21}+1)^2 - S_{11}^2}} \quad (3)$$

Fig.3 (b) shows negative permittivity at resonating points. It shows negativity at 2.60 to 5.16GHz, 6.63 to 9.31GHz and 13.03 to 16.18GHz. Fig.3 (c) exhibits the negative permeability at 7.74 to 13.07GHz and 13.88 to 16.55GHz. At lower frequencies, the current flow matches with the applied field. But in case of higher frequencies, it is not possible for the current to cope up with the applied field when the permeability becomes negative. In the gap, there is a charge produced of a SRR is regulated to a fluctuating magnetic field. Both current and applied field remain in same phase at lower frequencies, but it fails to remain in phase in higher frequencies and as a result, negative permeability produces.
In Fig. 3(d), real and imaginary parts of η are plotted as a function of frequency. The curve shows negativity at 8.13 to 12.14GHz, 13.01 to 15.22GHz and 16.73 to 16.95GHz. Table 2 shows the frequency range of refractive indices with effective parameters of the unit cell at different resonating frequency bands. The refractive index shows negativity when the permittivity and permeability both become negative. Here η shows certain negativity at different bands of frequencies. Hence, the designed unit cell has significant portions, where all the three effective parameters becomes negative. Therefore, this configuration can be allegated as double-negative metamaterial as it has negative peaks at 8.14GHz and 14.01GHz in all the three effective parameters which is shown in Table 2 with bandwidths.

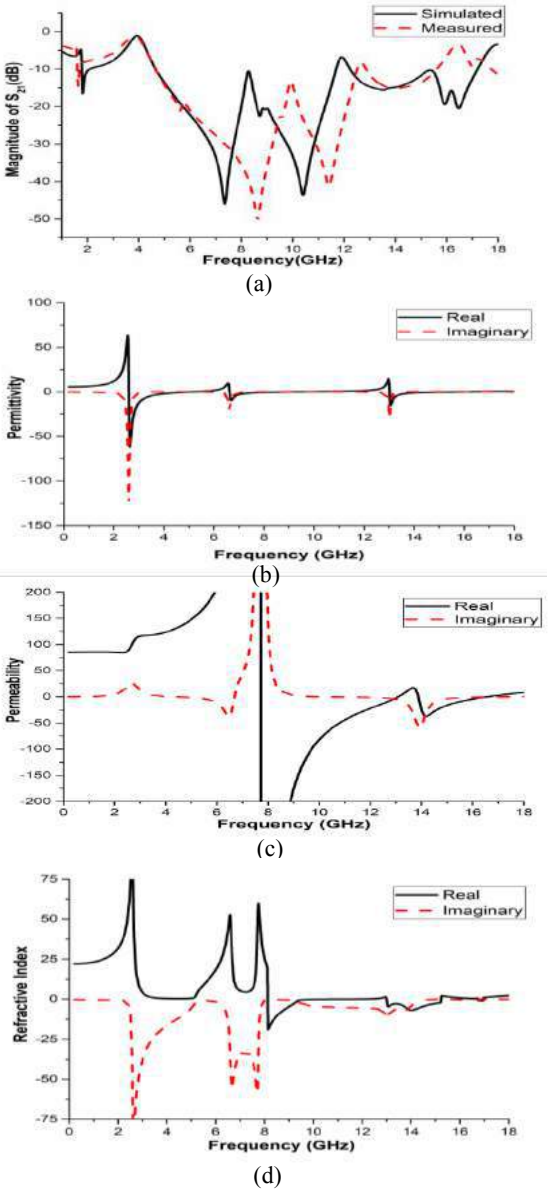

Fig. 3 (a) Measured and simulated results of S_{21} ; Real and imaginary values of (b) effective permittivity (ε) vs frequency; (c) effective permeability (μ) vs frequency; (d) refractive index (η) vs frequency

Table 2: Parameters of the unit cell

Effective parameters	Frequency Range(GHz)	Covered Bands	Values at 8.14 and 14.01GHz
Permittivity (ε)	2.60 to 5.16, 6.63 to 9.31 & 13.03 to 16.18 GHz	S, C, X & Ku	-0.56 & -1.15
Permeability (μ)	7.74 to 13.07 & 13.88 to 16.55GHz	C, X & Ku	-292.49 & -26.21
Refractive Index (η)	8.13 to 12.14, 13.01 to 15.22 & 16.73 to 16.95GHz	X & Ku	-18.32 & -6.99

3.2. Array Analysis

Fig. 4 describes the array formation of the unit structure and unit cell structure which are placed horizontally for 1 × 2 array and both vertically and horizontally on the basic unit structure for higher degrees of arrays on the same Fr-4 substrate. The array structure is measured within the frequency range of 1 to 18GHz. For unit structure, both the patches are placed 0.5mm apart from each other on the substrate. On the other hand, incase of unit cell structure, the gap between the patches is 1mm and the similar approach was used to assess the attainment of the array.

3.2.1. Unit Structure Analysis

Fig.4 (a) shows array formation and (b) shows the transmission coefficient of the array structures. It is apparent that the resonances of the frequencies are found at the same points as the unit cell, but having greater negative magnitudes.

The S21 improves a bit as there is no band gap in between 4.68 to 17.18GHz in case of 1 × 2 array. But it shows a little gap of about 100MHz for 2 × 2 and 4 × 4 array. Fig.4 (c) shows the real values of the permittivity, permeability and refractive index as a function of frequency of array structures.

From Fig.4 (c), it is observed that the negative values for the single unit cell and the array structures are quite similar. The differences among them are the amplitudes or magnitudes and the resonating points shifted a bit to lower frequencies. The negative magnitude decreases in cases of permittivity. But in case of permeability, the negative magnitude increases at resonating points. In case of the refractive index, only the negative qualities are counted. The results of the array structures show similarity with the unit structure. All the effective parameters of these array structures are summarized in table 3. All the arrays show double negative characteristics at 8.14 and 14.01GHz.

Effective parameters	Array Structures	Frequency Range (GHz)	Covered Bands
Permittivity (ε)	1 × 2	1.83 – 4.76, 6.55 – 9.19 & 13.92 – 16.45	L, S, C, X & Ku
	2 × 2	1.78 – 4.61, 6.44 – 9.19 & 12.96 – 16.27	
	4 × 4	1.19 – 4.22, 6.27 – 9.12 & 12.98 – 16.20	
Permeability (μ)	1 × 2	7.71 – 13.01 & 13.92 – 16.57	C, X & Ku
	2 × 2	7.71 – 13.01 & 13.85 – 16.58	
	4 × 4	7.69 – 13.03 & 13.87 – 16.55	
Refractive Index (η)	1 × 2	7.92 – 12.32, 12.98 – 15.56 & 16.63 – 17.18	C, X & Ku
	2 × 2	8.10 – 11.98, 12.94 – 15.24 & 16.73 – 17.11	
	4 × 4	2.48 – 3.76, 8.06 – 12.03, 12.96 – 15.24 & 16.73 – 16.96	

3.2.2. Unit Cell structure Analysis

Fig. 5 shows the design of Unit Cell Structures of 1 × 2, 2 × 2 and 4 × 4 array. Here, the total unit cell is arranged horizontally for 1 × 2 array and for higher formations, the unit cells are placed 0.5mm apart both vertically and horizontally based on their degree. And the structures are operated at the frequency range of 1 to 18GHz. The same procedure is followed to evaluate the unit cell and results are compared with the array structures.

The array formations, effective parameters and the transmission coefficient of the unit cell structures are shown in Fig. 5. Array formations are shown in Fig. 5(a), S-parameter is in Fig.5 (b) and Fig.5 (c) contains the real values of effective parameters.

The demonstration was done between two square unit cells. They are actually two different working cells, but the output was quite identical to the single unit cell structure. And the same procedure is repeated for a higher degree of array formations. It is evident from the figure, at lower frequencies, there is a slight deviation in the effective parameters including transmission coefficient. The resonating points shifts a bit from the basic structure. In case of S_{21}, the effect is a bit higher. There is no resonance in the L-band except 2 × 2 formation with a negligible spike. Moreover, instead of getting the double negative at 8.14GHz, the point shifts to 7.94GHz to show the characteristic. But with the increase with frequencies, the unit cell structures showed good commitment to the basic unit cell. However, the unit cell still carries the double-negative characteristic at some extent.

Fig. 5 (a)Different array formation; (b) S_{21} vs frequency; (c) Effective parameters vs frequency for the 1 × 2, 2 × 2, 4 × 4 array of the unit cell structure.

The transmission coefficient of 13GHz with a 500MHz band gap in the middle is demonstrated for all of these configurations. The effective parameters of the resonators cover C, X, and Ku-band independently with double negative phenomena at X and Ku-band which is similar to basic unit cell. All the effective parameters of these unit cell structures are summarized in table 4

Table 4: Frequency range of effective parameters for unit cell array structures

Effective parameters	Array Structures	Frequency Range (GHz)	Covered Bands
Permittivity (ε)	1 × 2	2.56 – 5.15, 6.59 – 9.28 & 13.05 – 16.41	S, C, X & Ku
	2 × 2	2.55 – 5.15, 6.60 – 9.27 & 13.06 – 16.16	
	4 × 4	2.51 – 5.13, 6.57 – 9.26 & 13.10 – 16.09	
Permeability (μ)	1 × 2	7.73 – 13.06 & 13.92 – 16.55	C, X & Ku
	2 × 2	7.73 – 13.01 & 13.92 – 16.54	
	4 × 4	7.72 – 13.14 & 13.96 – 16.52	
Refractive Index (η)	1 × 2	7.94 – 12.46, 13.01 – 15.58 & 16.61 – 17.12	C, X & Ku
	2 × 2	8.13 – 12.17, 13.07 – 15.25 & 16.77 – 16.86	
	4 × 4	8.12 – 12.21 & 13.07 – 15.28	

4. Comparative Analyses of the configurations

In this paper, total observation is made on S-parameter, effective permittivity, effective permeability, and refractive index. All the results have shown unique, but not contradictory information throughout the methodology. Based on the comparison of 1 × 2, 2 × 2, 4 × 4 arrays and 1 × 2, 2 × 2, 4 × 4 unit structure, it is found that the metamaterial shows double negativity at X and Ku-bands. It has covered 8.13 to 9.31GHz (bandwidth of 1.18GHz) and 13.88 to 15.22 (bandwidth of 1.34 GHz) in basic unit structure. Among these set of results, 8.14 and 14.01GHz is the two frequencies where the double negative character of all sorts of configurations is found. Table 5 shows the covered area and relative bandwidths by the refractive index of different configurations for double negative characteristic.

From the Table 5, it is evident that all the configurations show similar double negative characteristic of the respective frequency range. But more stability is found among basic unit cell, 1 × 2, 2 × 2 and 4 × 4 array with higher bandwidths. Besides 1 × 2, 2 × 2 and 4 × 4 unit cell structures shown fluctuating results with less bandwidth with respect to other configurations.

Table 5: Covered area and relative bandwidths by refractive index of different configurations for double negative characteristic

Structure	Frequency range (GHz)	Band width	Covered Bands	Type of Metamaterial
Unit Cell	8.14 – 9.31 13.80 – 15.22	1.17 1.42	X & Ku	DNG
1 × 2 Structure	7.92 – 9.19 13.92 – 15.56	1.27 1.64	X & Ku	DNG
1 × 2 Unit cell Structure	7.94 – 9.27 13.92 – 15.58	1.33 1.66	X & Ku	DNG
2 × 2 Structure	8.10 – 9.19 13.85 – 15.24	1.09 1.39	X & Ku	DNG
2 × 2 Unit cell Structure	8.13 – 9.27 13.92 – 15.25	1.14 1.33	X & Ku	DNG
4 × 4 Structure	8.06 – 9.12 13.87 – 15.24	1.06 1.37	X & Ku	DNG
4 × 4 Unit Cell Structure	8.12 – 9.26 13.96 – 15.27	1.14 1.31	X & Ku	DNG

5. Conclusions

This paper presents the framework of the modified Theta shaped unit cell and a correlation is contrived on transmission coefficient, relative permeability, permittivity and refractive index. The analyses and the comparisons are made on unit cell, 1 × 2, 2 × 2 and 4 × 4 array structures with 1 × 2, 2 × 2 and 4 × 4 unit cell structures. The transmission coefficient (S_{21}) is calculated and compared with different array formations. The transmission coefficient covered L, C, X and Ku bands for all the configurations. Negative effective parameters are also found in all the structures. However, unit cell, 1 × 2, 2 × 2 and 4 × 4 array structures shown good commitment to the effective parameters. Even the negative values of each of the effective parameters are found on the X and Ku bands at 8.14 and 14.01GHz with a bandwidth of more than 1.20 and 1.32GHz respectively. It certainly represents the dual band double negative characteristic of the proposed compact design. Thus, these structures are valid for the application of dual bands and satellite communication. These can also be a promising choice for double negativity. This modified Theta shaped structure can be an auspicious alternative to new metamaterials, especially in utilizations where metamaterials are the only requirement.

Abstract

In this article, a defected ground structure (DGS) is introduced to design a broad band-stop filter to adjust the resonating characteristics by varying the dimension of the structure. The proposed antenna is embedded into a 50Ω microstrip framework. FR-4 (Lossy) is used as a substrate to design the proposed broad band-stop filter which has a succinct structure. The attainment of the antenna is explored both integrally and experimentally. Here CSRR is introduced in the ground layer. It has been monitored that the level of rejection of the filter in stop band region keeps on going with the introduction of CSRR. This filter is advisable for X-band applications especially on 5.9 to 11.3GHz. It has also been observed by Nicolson-Ross-Weir approach that at the filtering frequency. The effective electromagnetic parameters retrieved from the simulation of the S-parameters imply that metamaterial antenna shows negative refraction bands. This indicates that the proposed antenna has a behaviour to justify the obligation as a Left Handed medium.

Keywords Band-stop filter, Defected ground plane, Left handed medium

1. Introduction

After getting the commercial authorization from Federal Communication Commission (FCC) in February 2002, Ultra-wideband (UWB) applications had become very popular at home and abroad [1]. But this UWB system has to go through probable interferences for WiMax, WLAN and RFID. Thus the use of RF components that operate in multiple bands has become really important to handle this complexity. A lot of researches have been made on the development of filter technology. The context of applications of these filters are included in. In today's world, one of the most essential parameters is confinement among channels in a particular bandwidth. In spite of avoiding possible interferences in a system, Band-stop filter (BSF) is one of the competent arrangements to notify this problem by combining them to the system. In progression, a lot of researches have been done to flourish different kinds of BSF [2].

From last few years, transmission lines have been used with patterned ground structures like spaces, gaps and slots, show interesting characteristics inclusive of band-stop and slow wave phenomena[3-5]. These specially arranged structures are commonly known as slotted ground structure or defected ground structure (DGS) [5]. Park et al. in 1991 proposed this DGS for its improvement quality on filter behaviours and reduction of filter size [6]. Moreover, this DGS has good command over the performance enhancement of stop-band filters, suppression of good harmonics and distinguished periodic system [7]. DGS quenches the response of the effective inductance and capacitance of a microstrip line only by changing the size and shape of it. As a result, the execution of the filter and its circuit can be enhanced. The performance of the filter turned to a different level when matematerials were introduced.

Metamaterials are the special type of materials that are usually not available in nature. They are actually engineered materials, they need embedding periodic unit cell for their formation to create naturally unavailable electromagnetic properties. Moreover, these materials have the power to control the electromagnetic wave beams to show their unorthodox characteristics. These unusual features of the metamaterials totally depend on the geometry of the atomic construction. It has been started from the year 1968, Veselago et al observed unique properties of materials having negative permittivity (ε) and permeability (μ). But it was not appreciated until 2000 when Smith et al. fortunately validated a new unreal with these unconventional properties (both permittivity and permeability were negative) is called left-handed metamaterial. In case of negativity, it has been categorized as Single-negative (either permittivity is negative or permeability is negative), Double-negative (both permittivity and permeability are negative). There is also a term called near-zero refractive index metamaterial (NZRI) where the permittivity and permeability of a material become approximately to zero of a particular range of frequency. Having these captivating electromagnetic

phenomena, necessary applications, like SAR reduction [8], super lenses, antenna design [9], filters [10-11], invisibility cloaking [12], electromagnetic absorber, and electromagnetic band gaps etc can be employed by metamaterials.

Resonant type metamaterials are actually used in filter applications. A variety of sub wavelength resonators are used, such as split ring resonators (SRRs), complimentary split ring resonators (CSRRs), double Slit split-rings resonators (DS-SRRs), double Slit complementary split-rings resonators (DS-CSRRs) [13]etc.
In this paper, a fusion in made by complimentary split ring resonator (CSRR) in the ground plane as defected ground system so that the structure can mostly work in X-band region as broad band-stop band filter.

2. Depiction and configuration

Fig. 1 shows the proposed band-stop filter. The resonating frequency confides on the physical aspects of the structure. The concentration of the structure can be realized depending on the specifications derived from the equivalent circuit Fig. 1 (c) proposed by Woo *et al.* [14]. On the hand, the cut off frequency of this type of filter can be accustomed by maintaining suitable values of the elements of the filter. However, to understand the expected values of lumped filter elements, it is essential to determine the aspects of these transmission lines. The proposed filter is contrived and constructed on a composite material named as glass-reinforced epoxy laminate or FR-4 substrate. This substrate having a height of 1.60 mm and a relative dielectric constant (εr) of 4.4 and loss tangent tan δ=0.02. Defected Ground Structure (DGS) has a direct connection with photonic band gap (PBG). It can be extracted directly from PBG and can be realized when this defected structure is depicted on the ground. This defectiveness in the ground plane interrupts the shield current. This may cause the increment of effective capacitance and inductance in the transmission line [3]. CSRRs are used as DGS under the modified microstrip line. Even resonant frequency can be controlled if the microstrip line and the DGS are modified. This DGS has an influence in implementing compact capacitive coupling to the line is called microstrip DGS. The cut off frequency of the filter depends on the overall slot size. This cut off frequency can be adjusted by varying the slot size. It is essential to reduce the inductance of the strip line if the resonant frequency needs to be shifted up instead of back, or widening the strip line may help to reduce the inductance of the filter. Table 1 shows the parameters of the filter. Commercially available Finite Integration Technique (FIT)-based on Computer Simulation Technology (CST) Microwave Studio software was used to simulate the proposed filter.

3. Results and Discussions

The filter is designed on FR-4 (substrate) with an area of 24×40 mm^2. A parametric study is made on the dimension of the filter to justify the insertion loss. CSRR in the ground plane is used and the results are compared with the convention one. There are plenty of ways to find out the effective parameters of a unit cell like Nicolson-Ross-Weir (NRW) method, direct retrieval method of refractive index (DRI) etc. This paper highlights the electromagnetic properties using the real values of ε, μ, and η using S_{11} and S_{21}.

Fig. 3 shows the parametric study of the filter and a decision is made on return/ insertion loss characteristics. The simulation is made on 5 to 15 GHz that provides a justification of its unorthodox pattern. In the microstrip line, the width places the main role to adjust the inductive effect. Decrease in inductance shifts the resonant to higher frequencies.

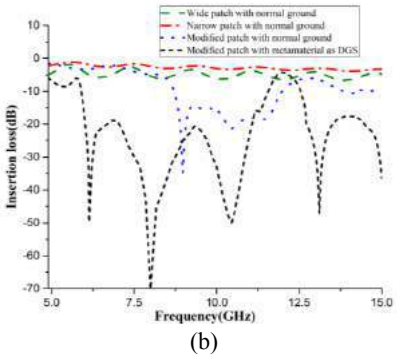
(a)



(b)

Fig. 3 Simulated return/ insertion loss characteristics for different structures (a) return loss & (b) insertion loss

Fig. 3 (a) exhibits the return loss of the structure with various shapes of the microstrip line. Keeping the ground unchanged, the microstrip line has been made three different structures. The microstrip line with modification shows less fluctuating response than the other two. But with the use of DGS, the return loss reaches near zero line or less than -10dB line in the frequency range of 5.9 to 11.3 GHz. The application of CSRR has made the band gap in this frequency range.

Fig. 3 (b) exhibits the insertion loss of the configuration with the same three different microstrip lines. Firstly, the loss is observed by applying normal ground and lately, DGS is applied. The modified microstrip line shows better band gap than the other two, so DGS is applied on the ground of the modified microstrip. The insertion loss curves crosses the -10dB line at 5.3GHz and comes back to zero line at 11.3GHz. The influence of CSRR in the ground plane makes the insertion loss wider.

Fig. 4 shows the flat response of return and insertion losses at about 5.9 to 11.9 GHz. Comparatively a wider stop-band has acquired. Moreover, the proposed structure shows broader and deeper band coverage than traditional stop-band filters [15-16]. There is a bit divergence between simulated and measured values. This difference is predominantly due to few parameters like fabrication, dielectric constant and thickness of the substrate, large simulation frequencies and the effect of SMA [17-18]. It is better to check the manufacturing and the measurement process to get a good deal of return loss characteristics for the structure. However, soldering accuracy of the SMA, quality of the substrate and no rusting in the structure need to be considered.

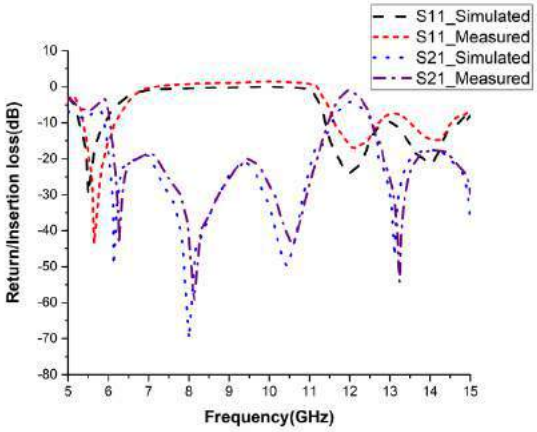


Fig. 4: Simulated and measured return/insertion loss for the proposed band stop filter

3.1. Analysis of Effective parameters

The series of gaps effect the structure for its negative effective permeability. Combining these CSRRs and gaps create a narrow band gap continuously permeability and permittivity emerged close to the resonant frequency [10].

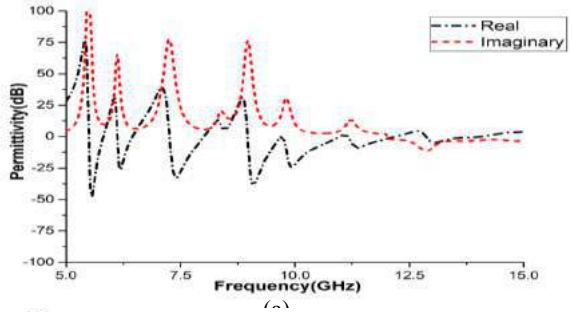
To differentiate the effective permittivity (ε_r) and permeability (μ_r) with S_{11} and S_{21}, the Nicolson-Ross-Weir (NRW) method is applied.

$$\varepsilon_r = \frac{c}{j\pi f d} \times \frac{(1-V_1)}{(1+V_1)} \quad (1)$$

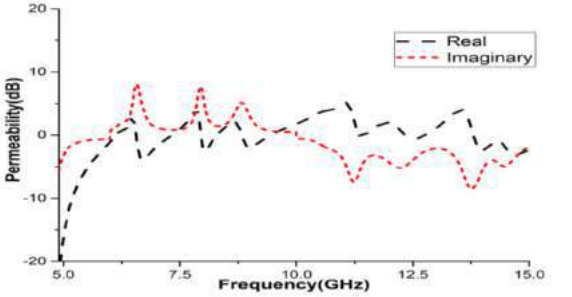
$$\mu_r = \frac{c}{j\pi f d} \times \frac{(1-V_2)}{(1+V_2)} \quad (2)$$

The effective refractive index (η_r) can also be calculated from S_{21} and S_{11} [2]:

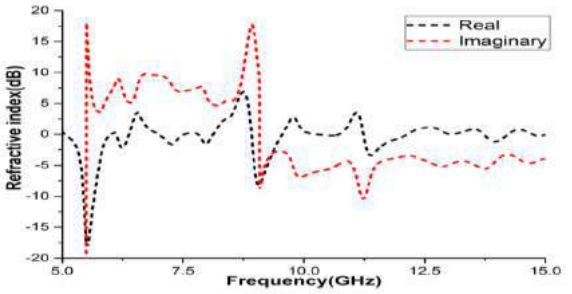
$$\eta_r = \frac{c}{j\pi f d} \times \sqrt{\frac{(S_{21}-1)^2 - S_{11}^2}{(S_{21}+1)^2 - S_{11}^2}} \quad (3)$$



(a)



(b)



(c)

Fig. 5 (a) Effective permittivity (ε) vs frequency; (b) effective permeability (μ) vs frequency; (c) refractive index (η) vs frequency

Fig.5 (a) shows negative permittivity at resonating points. It shows negativity at 5.49 to 5.81GHz, 6.12 to 6.44GHz, 7025 to 8.01GHz, 8.97 to 10.97GHz, 11.17 to 12.02GHz and 12.86 to 14.08GHz. Fig.5 (b) shows the negative permeability at 5 to 6.11GHz, 6.56 to 7.31GHz, 7.97 to 8.29GHz, 8.84 to 9.44GHz, 11.34 to 11.47GHz, 12.34 to 12.75GHz and 13.80 to 15GHz. At lower frequencies, the current flow matches with the applied field. But in case of higher frequencies, it is not possible for the current to make a go of it with the applied field when the permeability becomes negative. In the gap, there is a charge produced of a CSRR is regulated to a fluctuating magnetic field. At low frequency, the current remains in phase with the applied field, but it fails to remain in phase in higher frequencies and as a result, negative permeability produces.

In Fig. 5(c), real and imaginary parts of η are plotted as a function of frequency. The curve shows negativity at 5.05 to 6.00GHz, 6.11 to 6.38GHz, 7 to 7.52GHz, 7.82 to 8.11GHz, 8.93 to 9.54GHz, 10.25 to 10.73GHz, 11.23 to 12.14GHz, 13.73 to 14.22GHz and 14.74 to 15 GHz. Table 2 shows the frequency range of refractive indices with effective parameters of the filter at different frequency bands. The refractive index shows negativity when the permittivity and permeability both become negative. Here η shows certain negativity at different bands of frequencies. Hence, the designed filter has significant portions where all the three effective parameters becomes negative. Therefore, this band-stop filter can be claimed as double-negative metamaterial as it has negative peaks at 5.51, 7.29, 7.97, 9.05, 11.37 and 13.93GHz in all the three effective parameters which is shown in Table 2 with bandwidths.

Table 2: Parameters of the unit cell

Effective parameters	Frequency Range(GHz)	Covered Bands
Permittivity (ε)	5.49 to 5.81, 6.12 to 6.44, 7025 to 8.01, 8.97 to 10.97, 11.17 to 12.02 & 12.86 to 14.08GHz.	C, X & Ku
Permeability (μ)	5 to 6.11, 6.56 to 7.31, 7.97 to 8.29, 8.84 to 9.44, 11.34 to 11.47, 12.34 to 12.75 & 13.80 to 15GHz.	C, X & Ku
Refractive Index (η)	5.05 to 6.00, 6.11 to 6.38, 7 to 7.52, 7.82 to 8.11, 8.93 to 9.54, 10.25 to 10.73, 11.23 to 12.14, 13.73 to 14.22GHz & 14.74 to 15 GHz.	C, X & Ku

4. Conclusions

This paper presents the framework of the broad band stop filter using modified microstrip line and defected ground structure. Implementation of CSRR in the ground plane creates a constant and flat impedance bandwidth of almost 5.4GHz (5.9 to 11.3 GHz). To justify the performance of the proposed filter an analogy is conferred on transmission coefficient, relative permeability, permittivity and refractive index. The effective parameters of the filter cover C, X, and Ku-band independently with double negative phenomena at C, X and Ku-band. Due to its auspicious design, double-negative characteristics and the proposed structure has potential to be used as Broad band stop filter

Abstract

A miniaturized dual band antenna is presented for using GPS L1/GS communication systems. This antenna structure consists of a radiating patch with four mender line resonant elements, and a modified ground plane, which provides a dual band covering from 1.55 GHz to 1.64 GHz frequency. The inductances and capacitances developed due to the ground plane and patterned radiating patch leads to the behavior of the metamaterial. The proposed antenna designed on Rogers's 4350B material substrate with dimension of 25.4 mm × 25.4 mm× 0.70 mm. The proposed antenna shows good omni directional radiation pattern, considerable gain level, and reasonable S11 for using in the GPS L1/GS communication systems.
This is the layout specification and template definition for a paper to be submitted to META Conference.

1. Introduction

Owing to the rapid growth of wireless communication technology, miniature antenna plays a significant role for small size multifunctional devices. In recent days, all communication devices need to be small in size, compact, lightweight, in short should be portable. Moreover, portable devices obligatory to operate dual frequency band applications to use in different areas or countries[1].

Recently, demand of satellite based portable communication devices are increasing noticeably, especially vehicle tracking, mobile communication portable satellite station, weather forecasting etc. A considerable number of patch antenna have been developed targeting better performance for multiple frequency band applications due to lower performance of wired antennas. A low profile, compact, Antenna size reduction with multiband operation capability is still interesting topic for communication engineering researchers. A considerable research effort is given to antenna miniaturization to integrate with small form factor multi frequency devices without compromising the overall performance. There are several techniques have extensively studied by many researchers, such as using reactive impedance substrate [1], artificial magnetic conductor [2], EBG substrate [3], Metamaterials [4-7], Multilayer dielectric substrates [8], etc. Use of ceramic material substrate is one of the effective techniques for antenna miniaturization. Due to higher dielectric constant of the ceramic material substrate, the overall size of antenna can be reduced significantly without compromising the overall performance [9]. Many antenna technology researchers have comprehensively examined the use of ceramic material substrate for miniature antenna design in their article. A miniature antenna was designed using thick truncated textured Ceramic Substrate with the dimension of 14 mm×13.6 mm at 1.88 GHz resonant frequency and obtained 3.5 MHz of bandwidth [10]. A 25 mm×10 mm ×4 mm multiband dielectric resonator antenna designed for multi-standard mobile handheld devices [11]. A miniaturized patch antenna designed with 25.4 mm × 25.4 mm × 6.35 mm dimension using low temperature co-fired-ceramic (LTCC) substrates [12]. On the other hand, Metamaterial-inspired electrically small antennas were proposed in [13] and further developments in the corresponding electric monopole-based electrically small antenna designs have been obtained and confirmed experimentally. Although there is no bulk metamaterial involved in the performance enhancements of these antennas, their radiating elements represent a single unit cell of a metamaterial structure, which leads to the metamaterial-inspired terminology [14, 15]. However, in terms of antenna size reduction or bandwidth enhancement there are still needs to put more research effort for miniaturization with better performance to meet the ever increasing demand for dual band applications.

In this article, a compact (25.4 mm × 25.4 mm×0.762 mm) electrically small, low profile dual band antenna is presented. Multifunctional compact planar versions are introduced by appropriately four meander line elements. These antenna can be used for dual band [GPS L1 and Global star (GS)] linear polarization application. The performance characteristics of the proposed dual band antenna is investigated by Finite Element Method based 3D electromagnetic simulator ANSYS Ansoft High Frequency Structure Simulator (HFSS).

2. Antenna Design

Due to the popularity of satellite positioning and communications, a highly compact, multifunctional antenna that can communicate with satellites to accommodate both voice and data exchanges, while providing GPS

functionality, is of great interest for portable communication device applications. For this perspective, a dual-band GPS L1 (1575.42 MHz) and Global Star (GS, 1610–1621 MHz) electrically small, planar antenna was designed and developed. The proposed dual band antennas geometric layout is presented in Figure 1 (a) top and (b) bottom which is printed on an Rogers 4350B dielectric substrate material with thickness 0.70 mm, dielectric constant 3.66, loss tangent 0.004 and 0.017 copper thickness. The basic architecture of the proposed dual band antenna consists of the radiating patch, a partial ground plane and a coaxial feed-line. The proposed dual band antenna is ported to a 50 Ω SMA connector for signal transmission. To achieve dual band characteristics, the radiating patch consists of some slotted structure with four meander line structure where M1 and M3 meander line elements are responsible for lower band 1.575 (GPS L1 1.575) and M2 and M4 elements is responsible for GS band (1.615 GHz). This can be clearly understand from the surface current distribution of the radiating patch shown in Figure 2 where M1 and M3 are more exciting for the lower band and M2 and M4 are exciting for upper band. The ground plane of the proposed antenna is consists of two near field parasitic elements which is act as single driven elements in the other side of the substrate. By exciting top and bottom driven elements through coaxial fed, both dipoles are the same except for the gaps between the capacitive loads, i.e., the capacitances formed by the gaps between the ends of the arrows. Because of the differences in the resulting capacitances, two independent resonant frequencies were obtained. However, to avoid any unnecessary structural overlaps and to keep the parasitic elements in a one-layer layout, the meander lines were introduced on their legs to increase the overall inductance while allowing a decrease in the requisite capacitances provided by their gaps and still maintaining the desired operating frequency. The choices of the dimensions of the elements were varied according to the usual principles, e.g., thinner traces and longer meander-line segments produce more inductance, and smaller gaps produce more capacitance. A square copper elements also introduced in the center of the radiating patch for widening the total bandwidth. Their final values were optimized with HFSS by studying multiple design iterations and their behaviors. The dimensions of the proposed antenna structure are then optimized using the HFSS simulation software. The final dimensions are: L=25.4 mm, W=25.4 mm, L1= 2.86 mm, L2=2.86 mm, L3=4.57 mm, L4=4.18mm, L5= 1.18 mm, L6=5.23 mm, W1=2.5 mm, R1=8.1 mm.

3. Results and Discussions

Fig. 3 shows the simulated reflection coefficient of the proposed dual band antenna. It can be observed from the figure that the proposed antenna achieve -10dB S_{11} (Reflection coefficient) bandwidth from 1.55 GHz to 1.65 GHz which is totally cover the GPS L1 band (1.575 GHz) and GS band (1.615 GHz). The simulated gains and radiation efficiency of the proposed antenna against frequency are shown in Fig. 4. And Fig. 5. At GPS L1 frequency, the corresponding peak gain and radiation efficiencies were 1.44 dB and 92 % respectively. On the other hand, at the GS frequency, the peak gain and radiation efficiencies values were 1.45 dB and 93% respectively. Fig. 6 illustrates the far-field radiation pattern of the proposed antenna at 1.575 GHz and 1.615 GHz, including the xz plane (H-plane) and yz planes (E-plane). It can be seen that omnidirectional radiation pattern can be observed on xz plane and nearly omnidirectional radiation pattern on the yz plane can be observed over the whole operating frequency bands Figure 7 illustrates the 3D radiation pattern of the proposed antenna of the GPS and GS band frequency. The maximum directivity values were 1.72 dB at GPS L1 band and 1.73dB at GS band, respectively.

4. Conclusions

An Omni-directional antenna with dual band characteristic for used in GPS and GS system has been proposed. The designed antenna consists of a radiating patch with four meander line parasitic elements and two Egyptian axe like dipoles to create required dual band frequency. The design antenna faces the -10dB reflection coefficient requirement from 1.55 GHz to 1.64 GHz. The overall antenna dimension is $0.133\lambda \times 0.133\lambda \times 0.004\lambda$ at 1.575 GHz. From the simulated results, it can be shown that the proposed antenna exhibits the dual band characteristic for the GPS L1 and GS band frequency. Reflection coefficient, Gain, radiation pattern and radiation efficiency, directivity of the proposed antenna are analyzed and optimized by using finite element method based 3D-fullwave electromagnetic simulator HFSS. The proposed antenna can be a competitive solution for the current needs to be adopted with small multi technology wireless devices compare to other available dual band antennas.

Abstract

In the last decade, various works have demonstrated that a class of artificial material called metamaterials (MTM) can synthesize μ-negative (MNG) media capable of evanescent-wave focusing which largely enhances the magnetic coupling between coils, which is the basic mechanism of Inductive Power Transmission (IPT) systems. In the present work, MTM-enhanced coupling in IPT systems is examined through analytical and numerical results, which are validated by experimental data. Adopting a transmission-line based approach to describe the general MTM-enhanced IPT system, it is evidenced that MNG MTMs can be interpreted as a negative impedance from a circuital point of view.

1. Introduction

The exploitation of evanescent waves in the near field for power transfer purpose has gained a lot of interest recently. In order to prevent radiation, the drivers are high-Q electrically small antennas (ESA). Most of their energy remains stored in the surrounding near field and power transfer occurs primarily via induction. Nonetheless, such inductive power transmission is efficient only for distances smaller than the diameter of the antennas being also quite sensible to misalignment. Electromagnetic MTM slabs presenting effective negative permeability can be used as near-field lenses to improve the overall efficiency of such inductive power transmission systems by enhancing the inductive coupling between the antennas. It has been called MTM-enhanced coupling [1] [2].

This paper describes a transmission-line based approach of the interaction between a MNG MTM and a magnetic link. By introducing the concept of *virtual magnetic transmission line* (VMTL) to describe the magnetic circuit and by calculating an equivalent virtual impedance to represent the MTM slab, the gain mechanism of those lenses can be regarded as a non-Foster impedance matching. Foster's reactance theorem states that any lossless passive one-port network has a reactance (or susceptance) derivative that increases with frequency [3]. According to [4], non-Foster circuits can provide negative resistance, negative inductance and negative capacitance (meaning that their slope varies decreases with frequency). As it will be further shown, a passive MNG MTM behaves as a band-limited negative impedance described by a negative resistor in series with a negative inductor. The negative inductance implies on reduction of the amount of net energy stored in the magnetic circuit while the negative resistance implies on potential gain across the MTM.

This work is organized as follows: In section 2, a generalized theory of transmission lines is presented in order to include a magnetic coupled system. In section 3, an equivalent virtual impedance for the proposed MTM slab is obtained. In section 4, it is demonstrated by means of analytic calculations and numerical results that a magnetic link can be satisfactorily described as virtual transmission line and that the gain introduced by the MTM is due to improvements in the impedance matching between the drivers. The results are supported by experimental evidence.

2. Generalized theory of transmission lines

2.1. Physical and virtual transmission lines

Most of the classical literature on transmission line (TL) concentrates exclusively on electric transmission lines (ELTL) or the guidance of electromagnetic energy using two or multiple electric conductors (two-wire TL, coaxial cable, stripline and so on). Only recently, more general concepts of TLs have been proposed. According to [5], a time-varying magnetic flux can guide EM fields as electric currents in conventional TLs. In [6], it is proposed a generalization for TL theory by introducing the concept of *virtual TLs*.

Since electric and magnetic fluxes have the same dimension of electric and magnetic charges, respectively, a time-varying flux acts as a sort of "virtual current" driving the fields.

It can be easily shown that a time-varying flux is a current:

$$j\omega\psi_m = j\omega \iint \boldsymbol{B}\cdot d\boldsymbol{s} = \iint j\omega\boldsymbol{B}\cdot d\boldsymbol{s} = \iint \boldsymbol{J}_{m,d}\cdot d\boldsymbol{s} = I_{m,d} \quad [V] \qquad (1)$$

According to the Collins Dictionary [7], the word *virtual* means *"sonnearlyntrue that for most purposes it can be regardednasntrue",n"havingnthenessencenornreffectnbutnotnthen appearancenornformnof"* or *"beingnsuchnpracticallynorninn*

effect, although not in actual fact or name". Thus, as fluxes produce *virtually* the same effect as physical charges concerning guidance, the phenomena of electric and magnetic induction can be effectively described through TL equations by taking the displacement currents as *virtual currents*, the fluxes as *virtual charges* and the reluctance to the flux of the medium as *virtual impedances*.

Hence, physical TLs are defined as the ones where EM fields are guided by means of conduction currents, and virtual TLs, as the ones where EM fields are guided by means of displacement currents.

2.2. Propagation equations for virtual magnetic transmission lines

The virtual magnetic transmission line (VMGTL) is defined as a magnetic circuit formed between two insulated drivers (no physical charge is flowing from one driver to the other) coupled by an intervening quasistatic magnetic field. The transmitting driver is the magneto-motive force (MMF) source generating the time-varying magnetic flux (magnetic displacement current) that links the terminals. The receiving driver is the transducer connected to the load that "converts" the virtual magnetic charges (the magnetic flux) to physical ones (see Fig. 1).

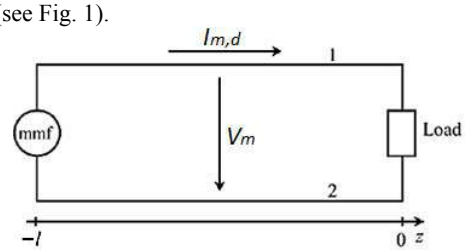

Figure 1: Schematic of a virtual magnetic transmission line.

The total MMF of the virtual line is a real magnetic potential V_m because fluxes going in opposite directions possess inverted magnetic potentials. Consequently, there must be a uniform magnetic field stored between them:

$$MMF = \psi_m \mathcal{R}_m = \int_a^b \boldsymbol{H} \cdot d\boldsymbol{l} = V_m \quad [A] \tag{2}$$

As it is shown in Fig. 2, power flow in a VMGTL is the product of this magnetic field stored between the fluxes and the electric field generated by the time-varying flux in the form of electric-field circulation [8]:

$$P = j\omega \mathcal{R}_m \psi_m^2 = V_m I_{m,d} \quad [W] \tag{3}$$

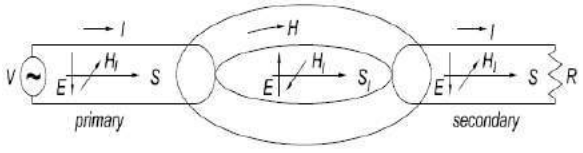

Figure 2: The transversal magnetic field component is responsible for power flow, not the magnetic field parallel to the flux.

Making the simplifying hypothesis that the magnetic flux is mostly confined in a magnetic circuit of fixed transversal section, the virtual TLs can be said to obey propagation equations in terms of potential and current similar to the ones followed by classical ELTLs:

$$\frac{d}{dz} V_m(z) = \left(\frac{\mathcal{R}'_m}{j\omega} + G'_e + j\omega C' \right) I_{m,d}(z) = Y_m I_{m,d}(z) \tag{4}$$

$$\frac{d}{dz} I_{m,d}(z) = (G'_m + j\omega L') V_m(z) = Z_m V_m(z) \tag{5}$$

where Z_m, Y_m, $\mathcal{R}'_m$, G'_e, G'_m, L' and C' denote the series impedance, the shunt admittance and the magnetic reluctance, the electrical conductance, the magnetic conductance, the inductance and the capacitance per unit length, respectively.

Its characteristic impedance Z_0 is given by:

$$Z_0 = \frac{I_{m,d}(z)}{V_m(z)} = \sqrt{\frac{Z_m}{Y_m}} = \sqrt{\frac{G'_m + j\omega L'}{\frac{\mathcal{R}'_m}{j\omega} + G'_e + j\omega C'}} \tag{6}$$

The term $\frac{\mathcal{R}'_m}{j\omega}$ can be said to be a virtual admittance because it neither stores nor dissipate any real power. Like the radiation resistance of an antenna, which is also a virtual impedance [9], it has no relationship with the thermal equilibrium of the circuit that is generating the flux.

The complex propagation constant γ, the load reflection coefficient Γ and the input impedance Z_{in} are given by:

$$\gamma = \sqrt{Z_m Y_m} = \sqrt{\left(\frac{G'_m}{j\omega} + L' \right) \left(-\frac{\mathcal{R}'_m}{\omega^2} + \frac{G'_e}{j\omega} + C' \right)} \tag{7}$$

$$\Gamma = \frac{Z_L - Z_0}{Z_L + Z_0} \tag{8}$$

$$Z_{in} = Z_0 \frac{Z_L + Z_0 \tanh(\gamma l)}{Z_0 + Z_L \tanh(\gamma l)} \tag{9}$$

where Z_L is the load impedance.

The magnetic potential and the virtual current can be identified and converted into the physical electric potential V_e and the physical electric current I_e in the terminals through:

$$V_m(-l) = V_m^{in} = I_e^{in} \tag{10}$$

$$I_{m,d}(-l) = I_{m,d}^{in} = V_e^{in} \tag{11}$$

$$V_{m,v}(0) = V_m^{out} = I_e^{out} \tag{12}$$

$$I_{m,d}(0) = I_{m,d}^{out} = V_e^{out} \tag{13}$$

Note that the magnetic and electric potentials and currents are dimensionally inverted.

Since VMGTLs support the transverse electromagnetic (TEM) mode [5], propagation is described by a one-

dimensional Helmholtz equation [10]. Its generic solution is given by:

$$I_m(z) = I_m(0)e^{-\gamma z}(1 + \Gamma e^{2\gamma z}) \quad (14)$$

$$V_m(z) = \frac{I_m(0)}{Z_0}e^{-\gamma z}(1 - \Gamma e^{2\gamma z}) \quad (15)$$

2.3. Propagation equations for virtual magnetic transmission lines in free space

If there is no ferromagnetic material channeling the flux from the source to the load, the propagation equations of the virtual line must be adapted to compensate the flux leakage. Supposing that the reflection coefficient Γ must increase inversely with the coupling between the terminals of the TL:

$$I_m(z) = I_m(0)e^{-\gamma z}\left(1 + \frac{\Gamma_m}{\kappa_m}e^{2\gamma z}\right) \quad (16)$$

$$V_m(z) = \frac{I_m(0)}{Z_0}e^{-\gamma z}\left(1 - \frac{\Gamma_m}{\kappa_m}e^{2\gamma z}\right) \quad (17)$$

where κ_m is the magnetic coupling coefficient:

$$\kappa_m = \frac{L_m}{\sqrt{L_1 L_2}} \quad (18)$$

3. Equivalent virtual impedance for a μ-negative metamaterial

Table 1: The constitutive parameters of the MTM slab

L_{cell}	$240\ nH$
f_0	$32.4\ MHz$
$C = \frac{1}{\omega_0^2 L}$	$100pF$
Q_{cell}	245
Cell number	49
Periodicity	2.3 cm

The proposed MTM to synthesize a MNG slab is the same model exploited in [1]. Its main characteristics are presented in Table 1.

The Lorentz model can be used to estimate the relative permeability μ_r of the MTM [11]:

$$\mu_{r,MTM} = 1 + \frac{F\omega^2}{\omega^2 - j\omega\xi - \omega_0^2} \quad (19)$$

where F is the coupling coefficient between adjacent cells of the lattice and ξ is the damping ratio of the system.

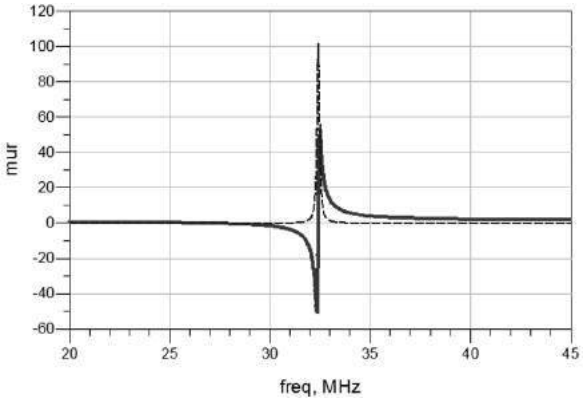

Figure 3: Estimation of the real (solid) and imaginary part (dash) of μ_r.

As it can be seen in Fig. 3, μ_r becomes negative around the resonance frequency ($f_0 = 32.4\ MHz$):

$$\mu_{r,MTM_{analytical}} = -51 - j101.6 \quad (20)$$

The equivalent inductance of the MTM can be determined from its effective parameters:

$$L_{MTM} = \mu_{r,MTM}\mu_0 a = \left(1 + \frac{F\omega^2}{\omega^2 - j\omega\xi - \omega_0^2}\right)\mu_0 a \quad (21)$$

Then, the MTM equivalent virtual impedance is given by:

$$Z_{m,v}(\omega) = jX_{MTM}(\omega) = j\omega L_{MTM}(\omega) \quad (22)$$

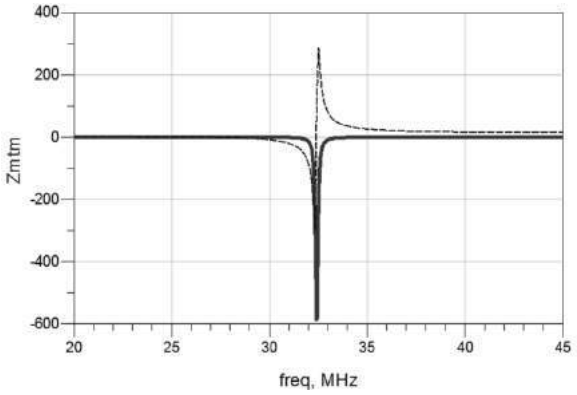

Figure 4: MTM equivalent impedance Z_{MTM} as a function of frequency.

Since the slope of Z_{MTM} does not increases monotonically with the frequency, it can be said to possess a band-limited non-Foster behavior. As it is shown in FIG, the MTM is perceived as negative resistance and a negative reactance around the resonance ($Z_{MTM} \in \mathbb{R}^-$). At the range of sub-resonance frequencies, it is completely invisible to the virtual line ($Z_{MTM} = 0$). And at the over-resonance one, it is seen as a positive reactance ($Z_{MTM} \in Im^+$).

As a negative resistance it acts in the sense of enhancing (restoring) the magnetic current (and consequently the magnetic flux) of the virtual line:

$$\frac{d}{dz}I_{m,d}(z) = -|Re\{Z_{MTM}(\omega_0)\}|V_{m,v}(z) \quad (23)$$

As a negative reactance, it becomes equivalent to a negative inductor and converts the stored energy in the magnetic field into the complementary electric one, reducing the total reactance of the circuit and enhancing the electric potential. On the other hand, as a positive reactance the MTM becomes equivalent to an inductor and stores energy in the surrounding magnetic field. The energy stored by the MTM from higher frequency modes is the energy it uses to amplify the resonance mode.

4. Application

The proposed free-space VMGTL consists of two magnetically coupled loop antennas of radius $r = 5\,cm$ made of copper wire with diameter $p = 1\,mm$ assisted by the MTM described in section 3. The loops operate far from self-resonance. It is assumed that the electrical resistance of wires, the capacitance C and the radiation resistance of the antennas as well as the internal resistance of the source are all negligible. The secondary driver is connected to a load $R_L = 50\,Ohms$. The drivers are separated by a distance $D = 15\,cm$. The amplitude of the tension source is $V_{e,c}^{in} = 1\,V$. The source loop is assumed to have a small internal resistance $R_{source} = 0.5\,Ohms$.

The analytical results are a direct application of the TL model for coupled systems presented in section 2. The numerical results were achieved by the FDTD method on Agilent EMPro and CST studio. The experimental data were obtained using a Vector Network Analyzer.

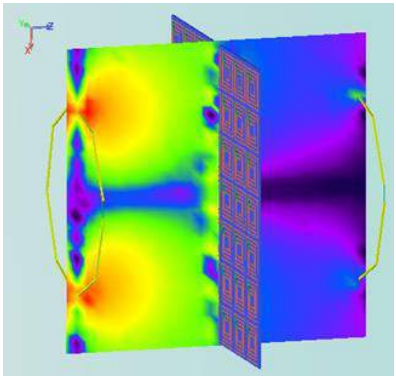

Figure 5: Magnitude of H_x out of the resonance at the plane XZ

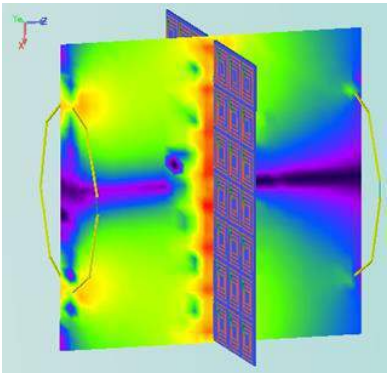

Figure 6: Magnitude of H_x at the resonance at the plane XZ

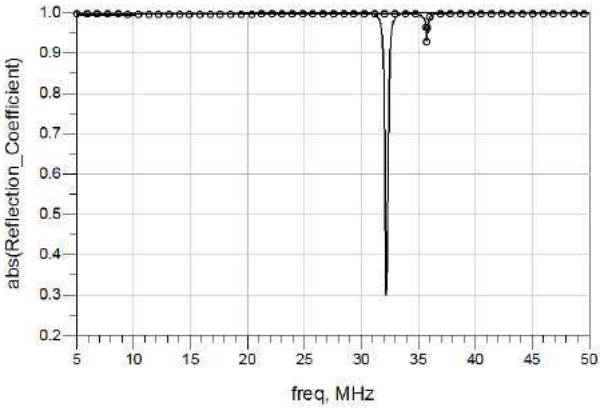

Figure 7: Analytical (solid) and numerical (circle) results for the magnitude of Γ with the MTM slab

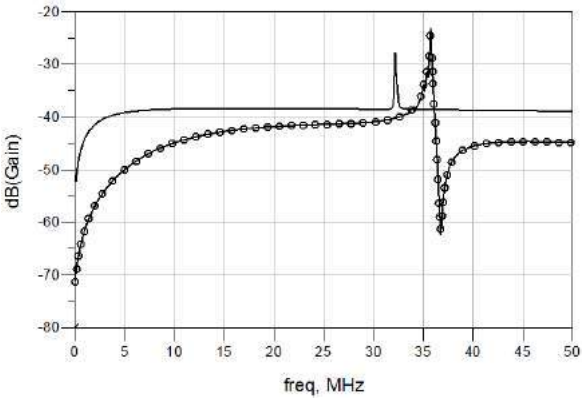

Figure 8: Analytical (solid) and numerical (circle) results for the gain G with the MTM slab inside of the magnetic link

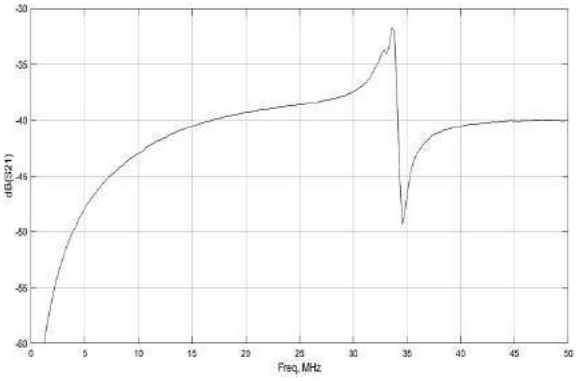

Figure 9: Experimental result for the gain G with the MTM slab

5. Discussion and conclusion

As it is shown in Fig. 5 and Fig. 6, there is a component H_x of the magnetic field inside the link because of the magnetic potential difference V_m between the incoming and the ongoing fluxes trespassing the drivers. It can be clearly seen that the distribution of H_x (thus, the distribution of V_m) is quite improved along the line when the MTM is activated, making the system to behave more similarly to a confined VMGTL with improved transmission. The improvement of the potential distribution along the magnetic link is equivalent to improve the impedance matching of the virtual line as shown in Fig 7.

Table 2: Comparison between the predicted gains and the experimental one

	Gain
Analytical	10 dB
Simulated	15 dB
Experimental	9 dB

As it can be seen in Table 2, the analytical and experimental results for the MTM gain at the resonance present a greater agreement than the one predicted by the numerical simulation, despite the fact that the curve behavior obtained by simulation is more similar to the one obtained with experiment (see Fig. 8 and Fig. 9). The discrepancy between the analytical and experimental curves comes from the simplifying hypotheses concerning the magnetic flux distribution employed by the model.

Finally, one important aspect of the considered system must be pointed out: the relative position of the MTM to the source does not interfere significantly with the gain, which reinforces that such magnetic link has a TL-like behavior.

Abstract

A new double U-Π shape design, simulation, fabrication and experimental verification of unit cell structure based on a simple configuration was operated in microwave spectra. The proposed structure resonators have magnetic and electric resonances that demonstrate metamaterials properties at different resonance frequency. The finite-difference time-domain (FDTD) based commercially available CST electromagnetic simulator was adopted to investigate the design scattering parameters, effective medium parameters and absorption analysis. The design structure exhibited the resonance frequency within the L-band, C-band, X-band, and Ku-band of the microwave regime. The characteristics and absorption were analyzed using the angular rotation of the structure and different dielectric substrate material. An N5227A vector network analyzer was used for the measurements. The measurement results of the printed prototype were in a better covenant with the simulation results. As a result, the proposed structure enables innumerable application areas such as mobile phones, long-distance radio communications, satellite communications, radar, and space communications.

Keywords: Absorption; Compact; Effective medium ratio; Metamaterials; Multi-band; Planar;

1. Introduction

Metamaterials have attracted noteworthy attention in the past decade due to a number of attractive phenomena not found in nature, such as sub-wavelength focusing, negative refraction, surface wave manipulation, extraordinary transmission, invisible cloaking, super-resolution imaging etc. Negative refractive index metamaterials are engineered materials with negative permittivity (ε less than 0) and permeability (μ less than 0) simultaneously, which have exotic properties in terms of well-known phenomena like Snell's law, and Doppler effect etc. [1]. Due to the interesting properties, the scientific community has been concerned to the metamaterials for strange characteristics and extensive applications in energy harvesting, invisibility clocks [2, 3], filtering, electromagnetic absorber [4] and perfect lenses [5], SAR reduction [6]. A 10×10 mm^2 square split "Z-shape" metamaterials showed Negative refractive index properties at different azimuthal angles, whereas the maximum effective medium ratio (EMR) was 9.1 by Faruque et al. in [7]. A 5×5 mm^2 "Ring-shape" metamaterial was designed by Yang et al. for cloaking effects of frequency range 8-13 GHz. Moreover, the EMR of meta-atom was 6 [8]. Hossain et al. recommended a design structure of 12×12 mm^2 "double C-shape" metamaterial for multi-band operation and reported EMR was 7.44 with negative refractive index from 11.304 to 13.796 GHz [9]. Zhou et al. suggested a "double Z-shape" double negative metamaterial unit cell constructed using coplanar magnetic and electric resonators which obtained an EMR of 4.80 as well as, dimension was 8.5×8.5 mm^2 [10]. Islam et al. recommended a metamaterial unit cell structure with 30×30 mm^2 dimensions and "H-shape" that was applicable microwave regime. The negative refractive indices of the structure were at 0.5 GHz and 0.3 GHz, whereas the EMR was 3.65 [11]. A left-handed "F-shape" metamaterial was designed by Rizwan et al. with 2.3 GHz bandwidth of negative refractive index for K- and Ka-band [12]. Zhou et al. reported a 15×15 mm^2 "S-shape" chiral metamaterial for X- and Ku- band. On the contrary, the EMR of the metamaterial was very small that was less than 4 [13]. However, above authors analyzed Negative refractive index characteristics and compactness but absorption properties did not analyze of their metamaterial. A triple-band metamaterial absorber can be utilized in bolometers, explosives detection and spectroscopic imaging, etc. [14]. Islam et al. [15] proposed multi-band split S-shaped metamaterial structure for absorption analysis, whereas authors obtained maximum 55% absorption. In addition, a paper was proposed by Islam et al. whereas different substrate materials were analyzed for S-band only. Compactness and absorption were not shown in that paper [16]. In this paper, the planar double U-Π shape based metamaterial exhibits, multi resonance at L-, C-, X-, and Ku-bands with different metamaterials properties for

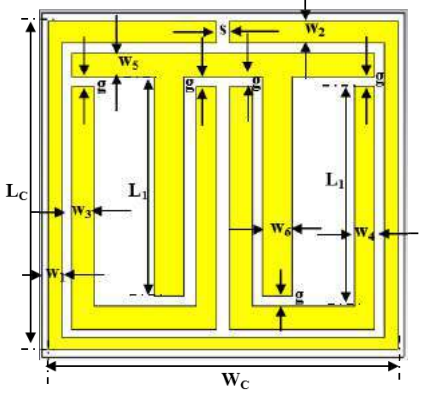
instance, ε-negative, μ-negative and negative refractive index. An absorption, effective medium ratio, and effective medium parameters have been changed by altering the rotation of unit cell and different substrate materials. Moreover, the size of the proposed planar unit cell is 10.5×11 mm^2, which is smaller than the stated metamaterials unit cells in [7, 8, 9, 10, 11, 13] with the terms of EMR. Metamaterial can operate in the sub-wavelength spectra, whether the EMR of the material is greater than 4. Furthermore, the design structure provides high absorption value 99% at 3.79 GHz, 99% at 11.78 GHz, and 96% at 12.24 GHz for RO3010, RT5880 and FR4 substrate materials respectively. It is observed that the absorption of the proposed design is better than the suggested metamaterials unit cells in [17, 18, 19]. To determine the scattering parameters, for example, the reflection coefficient (S_{11}) and transmission coefficient (S_{21}), the CST electromagnetic simulator 2015 was used. The effective medium parameter, for instance, effective permittivity, permeability and refractive index were also retrieved using well-established Nicolson-Ross-Weir method.

2. Design, Numerical simulation, and Measurement

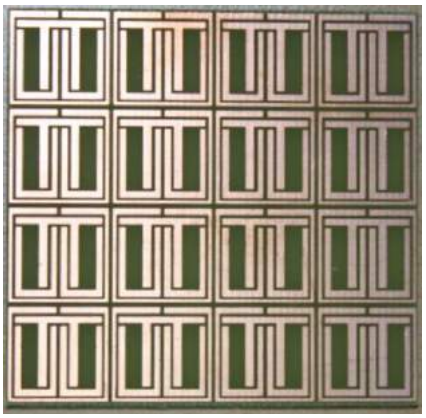
The suggested design consists of two U shape and one Π shape resonators with single split square resonator which was employed to attain unconventional characteristics of metamaterials that were usually not found in nature. The proposed metamaterial structure and structural parameters are shown in Fig. 1(a). The substrate material is low cost FR4 lossy material. All elements of the resonators are made of copper with conductivity of 5.8×10^7 S/m and the thickness of copper resonators are 0.035 mm that is printed on a substrate with standard relative permittivity ε= 4.3 as well as loss tangent δn= 0.025. The parameters of the structure are Lc=10 mm, Wc=10.6 mm, W_1=0.4 mm, W_2=0.65 mm, W_3=0.7 mm, W_4=0.6 mm, W_5=0.7 mm, W_6=0.9 mm, L_1=6.7 mm, g=0.3 mm, s=0.4 mm.

In this paper, the finite-difference time-domain method based CST simulator is implemented to examine this design structure. The electric field and magnetic field have been polarized along the x-axis and the y-axis, respectively, whereas z-axis has been utilized for electromagnetic wave travelling. The boundary conditions of perfect magnetic conductor (PEC) and the perfect electric conductor (PMC) are utilized along the x-axis and y-axis, individually, and two waveguide ports are placed on the positive and negative z-axis. In addition, the periodic boundary conditions with the wave guide port are used in the simulation. The schematic diagram of the proposed design is illustrated in Fig. 1(a). To determine the transmission coefficient and the reflection coefficient in simulation a frequency domain solver is employed. The frequency range 1-15 GHz was used to simulate and measure the design structure.

A fabricated prototype is shown in Fig. 1 (b). The prototype comprises 4×4 arrays of the unit-cell of copper materials and the size of the prototype are 44×42 mm^2. The measurement has been performed with two waveguide in the free-space environment. To allow the incident electromagnetic wave travelling over the prototype that was positioned between the two waveguide in the identical plane, similar to the simulation geometry. In addition, the scattering parameters have been measured by the PNA network analyzer (N5227) where the frequency range of the device is 10 MHz-67 GHz.



(a)



(b)

Figure 1: (a) The proposed metamaterial structure, (b) The fabricated array of structure.

Furthermore, a calibration kit (Agilent N4694-60001) was utilized to calibrate the network analyzer. That is why, the measurements were completed precisely. The Nicolson-Rose-Weir (NRW) method was utilized to determine the medium parameters like effective permeability (μ) and permittivity (ε) from simulated scattering parameters such as transmission coefficient (S_{21}) and reflection coefficient (S_{11}). The direct refractive index method was applied to calculate the effective refractive index (n) from the simulated complex S-parameters. The absorption of the design structure was determined using the following equation, $A(\omega) = 1–R(\omega)–T(\omega)$, where $T(\omega)$, $R(\omega)$, and $A(\omega)$ are the transmittance, reflectance and absorption, respectively. Absorption depends on the scattering parameters, for instance, $|S_{21}|^2 = T(\omega)$, and $|S_{11}|^2 = R(\omega)$. However, from the absorption equation, it can be seen that minimizing the scattering parameters which can maximize the absorption of the metamaterials.

3. Results and Discussions

In this paper, scattering parameters, effective medium parameters, effective medium ratio and absorption of design structure with angular rotation and different type of substrate materials were analyzed..

3.1. Analysis of design structure with angular rotation

The numerical and experimental result of planar double U-Π shape compact metamaterial has been presented. The numerical and measured reflection coefficient (S_{11}), and transmission coefficient (S_{21}) of the design structure has been demonstrated in Fig. 2. It shows the cover band of the resonance frequencies that designates L-, C-, X-, and Ku-bands applications.

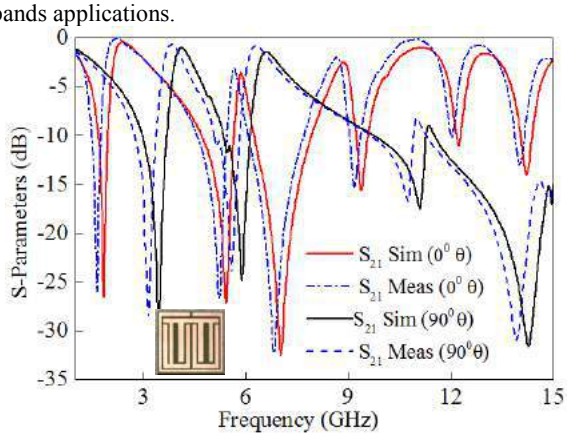


Figure 2: Numerical and measured S-parameters of design structure.

From Fig. 2, the numerical and experimental results are showing good agreement with each other. The measured results have shown the same band comparing with numerical results in Fig. 2. On the contrary, the scattering parameters of measured results have been marginally shifted towards the lower frequency and increase small amount of the magnitude comparing with simulation results. The small amount difference has been occurred for the several fabrication tolerance and open-space measurement procedure. Fig. 3 (a) exhibits the values of the relative negative permittivity 1.658-2.148 GHz, 3.464-5.676 GHz, 5.844-7.37 GHz, 8.84-9.218 GHz, 10.394-11.766 GHz, 12.494-13.012 GHz, and 14.538-14.86 GHz for 0^0 angular rotation. In contrast, 2.512-3.828 GHz, 4.402-6.124 GHz, 6.572-9.456 GHz, 7.622-15 GHz for 90^0 angular rotation of design structure of metamaterial. The electric and magnetic dipole moment can keep route with the applied electromagnetic field at lower frequency. On the other hand, the dipole moment cannot content with the applied field. As a consequence, the fluctuation of scattering parameters have been occurred at higher frequencies. Fig. 3 (b) displays the values of the relative negative permeability 7.93-14.958 GHz and 7.622-15 GHz for 0^0 and 90^0 angular rotation of design structure, respectively. The negative properties of the permittivity and permeability has been altered a small amount as a result of the polarization effect on the interior construction of metamaterial structures. Fig. 3 (c) describes the relative negative refractive index 3.324-5.186 GHz, 6.068-6.726 GHz, 7.636-13.614 GHz, 14.048-15 GHz, and 2.372-3.114 GHz, 4.57-5.382 GHz, 5.564-5.606 GHz, 6.824-8.952 GHz, 11.038-11.388 GHz, 14.146-15 GHz for 0^0 and for 90^0 angular rotation of the design structure.

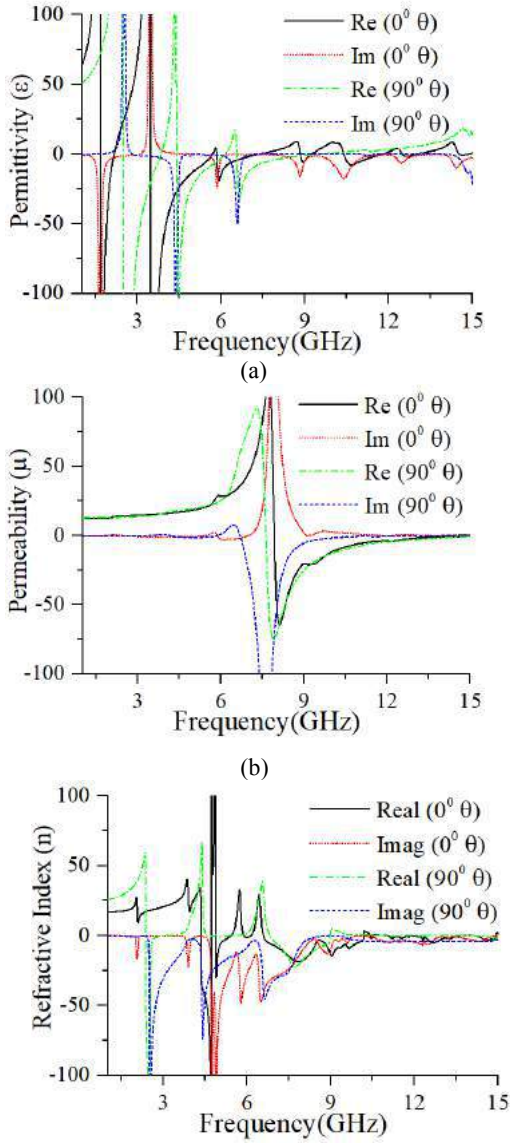

Figure 3: (a) Permittivity (b) permeability and (c) refractive index values of the angular rotation of 0^0 and 90^0 of the design structure.

The curves of the effective refractive index become negative when the curves of the permittivity and permeability are negative, simultaneously. The design structure of material has shown metamaterial properties ε-negative at 1.82 GHz, ε-negative at 5.42 GHz, μ-negative at 9.37 GHz, and negative refractive index at 12.24 GHz that have designated L-, C-, X-, and Ku-bands in the microwave region.

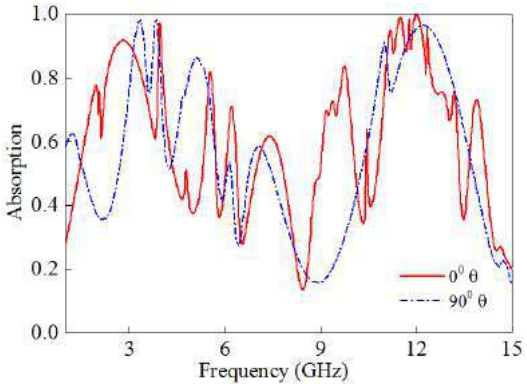

Figure 4: Absorption values of the angular rotation of 0^0 and 90^0 of the design structure.

It is observed from Fig. 4 that the absorption value of design structure are 49% at 1.82 GHz, 73% at 5.42 GHz, 47% at 9.37 GHz, and 96% at 12.24 GHz, respectively for 0^0 angular rotation. On the other hand, the values of the absorption are 95% at 3.42 GHz, 60% at 5.86 GHz, 86% at 11.11 GHz, and 30% at 14.43 GHz, respectively for 90^0 angular rotation of the structure. The absorption value is high while the transmittance value is near zero. However, the reflectance value is less in that point. The angular rotation of the design structure along the propagation direction of electromagnetic wave has changed the resonance frequencies and absorption values due to alter the material properties.

Table 1 describes the overall properties of the structure like EMR, resonance frequencies and metamaterial classification, and absorption for 0^0 and 90^0 angular rotation. The design structure shows the higher EMR at 0^0 angular rotation compares to 90^0 angular rotation. In addition, the absorption value, 96% at resonance frequency, 12.24 GHz for 0^0 angular rotation compares to 90^0 angular rotation of the proposed structure.

Table 1: The values of effective medium parameters, metamaterials properties, and absorption at different resonance frequencies for 0^0 and 90^0 angular rotation of proposed structure.

Rotation angle(θ)	EMR	Resonance frequencies	Metamate-rials properties	Absorption (%)
0^0	14.99	1.82	ENG	49
		5.42	ENG	73
		9.37	MNG	47
		12.24	NRI	96
90^0	7.97	3.42	ENG	95
		5.86	ENG	60
		11.11	MNG	86
		14.43	NRI	30

3.2. Analysis of design structure with different substrate materials

Three types of substrate materials, for example, FR-4(lossy), rogers RO3010(lossy) and rogers RT5880(lossy) have been used as a substrate material in the design structure. In numerical analysis as well as practical implementation, 1.6 mm thick FR4 substrate with permittivity 4.3 and loss tangent 0.025 as well as thermal conductivity 0.3 W/K/m has been utilized. The thickness, electric permittivity, thermal conductivity, loss tangent of rogers RO3010 substrate material are 1.6 mm, 10.2, 0.66 W/K/m and 0.0022. Moreover, the rogers RT5880 substrate material comprises thickness= 1.6 mm, electric permittivity= 2.2, thermal conductivity = 0.2 W/K/m, and loss tangent=0.0009. Three different types of substrate material have been used to observe the metamaterial characteristics, EMR, and absorption in microwave spectra.

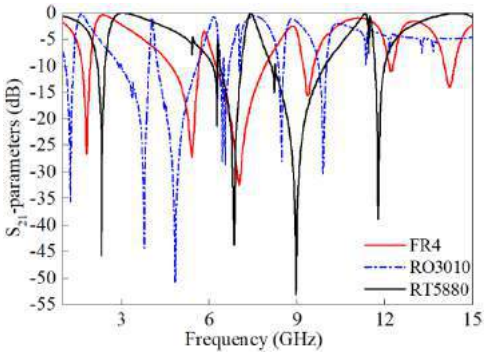

Figure 5: Transmission coefficient of the design structure for different substrate material

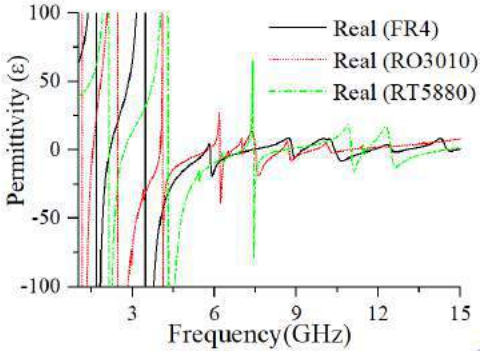
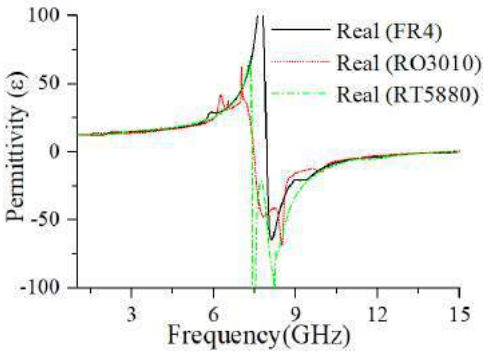
Fig. 5 states the transmission coefficient value in dB for different substrate materials like FR4, rogers RO3010, and rogers RT5880. The transmission dip, number of resonance frequency and value of the resonance frequency of the structure have been changed due to different electric properties of the material. In this frequency range, rogers RT5880 has shown the maximum dip. On the other hand, the minimum dip has been obtained by FR4 substrate material. However, rogers RO3010 has displayed the lowest fundamental resonance frequency which has increased the EMR of the structure.



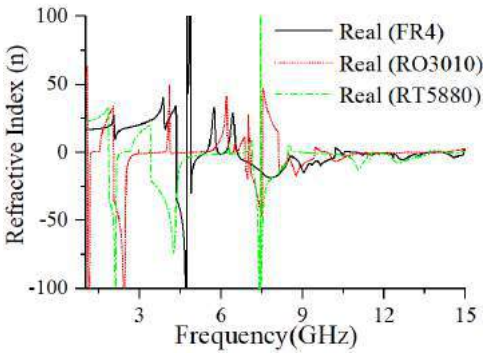
(a)

Fig. 6 (a) displays the ranges of the relative negative permittivity 1.658-2.148 GHz,3.464-5.676 GHz,5.844-7.37 GHz, 8.84-9.218 GHz, 10.394-11.766 GHz, 12.494-13.012 GHz, and 14.538-14.86 GHz; for FR4 substrate in the proposed design. Moreover, 1.154-1.532 GHz, 2.456-3.996

GHz, 4.094-5.746 GHz, 6.208-6.656 GHz, 7.496-8.448 GHz, 8.728-9.624 GHz, and 10.198-10.898 GHz for rogers RO3010 substrate. Furthermore, 2.12-2.694 GHz, 4.304-7.006 GHz, 7.412-8.588 GHz, 11.01-11.542 GHz, and 12.452-14.44 GHz for rogers RT5880 substrate of design structure of metamaterial.



(b)



(c)

Figure 6: (a) Permittivity (b) permeability and (c) refractive index values of the angular rotation of 0^0 and 90^0 of the design structure.

The electric and magnetic dipole moment can keep route with the applied electromagnetic field at lower frequency. On the other hand, the dipole moment cannot content with the applied field at higher frequencies. As a result, the fluctuation of effective parameters like permittivity has been occurred more at higher frequencies. Fig. 6 (b) shows the range of the relative negative permeability 7.93-14.958 GHz, 7.468-14.314 GHz, and 7.398-14.608 GHz for FR4, rogers RO3010, and rogers RT5880 substrate materials, correspondingly. Fig. 6 (c) designates the relative negative refractive index 3.324-5.186 GHz, 6.068-6.726 GHz, 7.636-13.614 GHz, 14.048-15 GHz; 1.07-1.21 GHz, 2.036-3.744 GHz, 4.122-4.808 GHz, 6.306-6.418 GHz, 6.88-6.978 GHz, 7.076-7.496 GHz, 8.112-9.428 GHz, 9.89-12.13 GHz, 12.172-12.998 GHz, 13.278-13.46 GHz, 13.67-13.964 GHz; 1.868-2.316 GHz, 3.408-6.25 GHz, 6.292-6.824 GHz, 7.132-8.434 GHz, 8.966-11.514 GHz, 11.78-13.628 GHz, 14.286-14.804 GHz for FR4, rogers RO3010, and rogers RT5880 substrate materials, individually. The negative properties of the permittivity, permeability, and refractive index has altered a bit accordingly of the polarization effect on the materials properties of the structures.The design structure of material has a metamaterial property like single negative, double negative that are shown in Table 3.

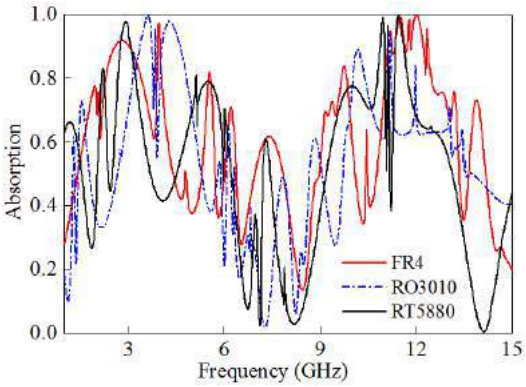


Figure 7: Absorption values of the FR4, rogers RO3010, and rogers RT5880 substrate materials of the design structure.

It is seen from Fig. 7 that the absorption value of design structure are 49% at 1.82 GHz, 73% at 5.42 GHz, 47% at 9.37 GHz, and 96% at 12.24 GHz, respectively for FR4 substrate material. Moreover, the values of the absorption are 22% at 1.25 GHz, 99% at 3.79 GHz, 89% at 4.84 GHz, 35% at 6.45 GHz, 6% at 8.45 GHz, and 50% at 9.90 GHz, correspondingly for rogers R03010 substrate material. Furthermore, absorption values are 63% at 2.33 GHz, 50% at 6.26 GHz, 15% at 8.97 GHz, and 99% at 11.78 GHz, individually for rogers RT5880 substrate material. The absorption value is high while the reflectance value is low. The high absorption value is 99% at 3.79 GHz for rogers R03010 and 99% at 11.78 GHz for rogers RT5880 substrate material. Due to different material properties, the absorption rate has been different at different frequencies.

Table 2: The values of effective medium parameters, metamaterials properties, and absorption at different resonance frequencies for FR4, rogers RO3010, and rogers RT5880 substrate materials of proposed structure.

Substrate type	EMR	Resonance frequencies	Metamate-rials properties	Absorption (%)
FR4	14.99	1.82	ENG	49
		5.42	ENG	73
		7.02	ENG	17
		9.37	MNG	47
		12.24	NRI	96
R03010	21.82	1.25	ENG	22
		3.79	ENG	99
		4.84	ENG	89
		6.45	ENG	35
		8.45	MNG	6
		9.90	NRI	50
RT5880	11.71	2.33	ENG	63
		6.26	ENG	50
		8.97	MNG	15
		11.78	NRI	99

Table 2 designates the overall properties of the structure for instance, EMR, resonance frequencies and metamaterial characteristics, and absorption of different substrate material. The design structure displays the high EMR (21.82) for rogers RO3010 substrate material compares to FR4 and RT5880 substrate material. Additionally, the high absorption value, 99% at resonance frequency, 3.79 GHz for rogers RO3010 compares to FR4 substrate of the proposed structure. It is seen from Table 2, rogers RO3010 substrate material is suitable, in terms of high absorption value and compactness of the design structure.

4. Conclusions

A new design of double U-Π shape compact metamaterial structure was suggested for multi-band, for instance, L-, C-, X-, and Ku-band applications in this paper. This design structure based on rogers RO3010 substrate exhibited 99% absorption with high EMR (21.82) at 3.79 GHz. The CST electromagnetic simulator was utilized to determine the absorption, EMR and metamaterials characteristics. The suggested metamaterials are appropriate for amateur radio, GPS, GSM, radar and satellite communications, long-distance radio telecommunications, space communication and radar terrestrial broadband. A comparative analysis also carried out on the basis of the angular rotation of the unit cell and different substrate material. The open-space measurement method was applied to validate the results of the prototype of the structure. Therefore, the metamaterial structure was compact in size, high absorption and follows better EMR which were more suitable in microwave spectra.

Abstract

In this manuscript, a new modified hexagonal unit cell structure with wideband negative refractive index metamaterial structure was worked in microwave regime. The proposed structure was designed of two symmetrical metallic patterns printed on the both sides of an FR4 dielectric substrate. The finite-difference time-domain (FDTD) based commercially available CST microwave studio was adopted to investigate scattering parameters of the design. The design structure was analyzed by two orientations with respect to the incident plane wave. For normal wave incidence, the suggested structure displays wideband negative refractive index (3.18 GHz) and (0.9 GHz) with a higher effective medium ratio (17.26) that was indicated small electrical size of the structure, whereas for parallel wave incidence, wideband negative refractive index (2.45 GHz), (1.22 GHz) and (1.93 GHz) bandwidth with a higher effective medium ratio (28.01) was obtained. The negative refractive index was verified by simulation and measurement for quad-band applications. Furthermore, the effective medium ratio (λ/a) of the proposed wideband negative refractive index metamaterial was considerably improved compared to previous suggested multi-band metamaterials.

Keywords: Double-incident, Effective medium ratio, Metamaterial, Quad-band, Negative refractive index, Wideband;

1. Introduction

The composite materials that are called metamaterials, designed to exhibit exotic electromagnetic phenomena not available by natural materials, offer many fascinating ways of handling light and have been intensively examined. The artificial periodic structures comprised of sub-wavelength constituent elements that build the structure perform as an effective medium with negative values of permittivity ($\varepsilon < 0$) and permeability ($\mu < 0$) at the frequencies of interest. The properties of such media were already studied by Veselago over 45 years ago [1]. Negative refractive index materials, i.e., Negative Index Metamaterials (NIMs) are artificial metanmaterials with effective negative permittivity and permeability simultaneously, which have unusual properties in terms of familiar phenomena like Snell's law, Cherenkov radiation, and Doppler effect etc. [1, 2]. Because of these unusual properties of the metamaterials, it can be used many vigorous applications such as antenna design [3], electromagnetic absorption reduction [4], invisibility cloaking [5], absorber design [6], etc. Until now, very few of NIMs designed and tested to perceive an effective negative refractive index materials. On the other hand, most of such NIMs is perceived by the overlapping of effective negative electric permittivity and effective negative magnetic permeability of the materials that are responsible of a metallic wire and engineered magnetic resonator, respectively [7]. The negative electric permittivity perceived by plasma behavior of metallic wire has foremost disadvantages, such as the problem in scheming a NIMs with improved effective medium ratio, for example, the operating wavelength to unit cell size and the subject of strong spatial dispersion [8]. In addition, the refractive negative index has been perceived by artificial S-type resonators and Ω-shaped man-made structure [9, 10]. However, mentioned NIMs have a significant shortcoming for the innovative practical applications due to the single band operation. In addition, in terms of the direction of applied electromagnetic (EM) waves, there are three types of EM incidence are possible, such as parallel, normal and double incidence. The earlier metamaterials are established on the classical incident planar electromagnetic (EM) waves which is parallel to the substrate, like ELC–HSLR pair structure [11], nonlinear metamaterials [12] as well as MTSRR-wire pair structure [13]. The second Metamaterials are also established on the incident planar EM waves that are normal to the substrate, for instance, multiple SSRR pair structure [14] and double C-shaped structures [15]. In case of the third one, the negative refractive index is parallel to both. However, very few researchers are focusing on this way to perceive the metamaterils. On the contrary, very little research has been achieved it. Zhou et al. and Zhu et al. [16, 17] who exhibit multi-bands NIMs founded on double Z-shape pair structure and multiple dendritic cells. It has been displayed the negative refractive index multi-bands for

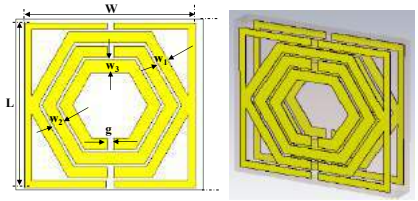
perpendicular and parallel incidences. Recently, metamaterials for multiband application with negative refractive index and miniaturized sizes are an encouraging research field and a few researchers are focused on such metamaterials. "Π-shape" metamaterial suggested by Islam et al. [18] that was applicable for electromagnetic invisibility cloaking operation in X-band and achieved near zero refractive index of 2 GHz wideband. The effective medium ratio was 3.58 whereas the structure size of the "Π-shape" was 10×10 mm. "Double Z-shape" metamaterials that comprised the electric and magnetic resonators suggested by Zhou et al. in 2015 [16] This structure was built by metal strips of two orthogonal z-shape that exhibited different resonance peak such as 7.3 GHz, 8.1 GHz, and 9.4 GHz, respectively. However, this structure was shown EMR of 4.83 and 4.97 due to the parallel and normal incidence of EM wave. Cumali Sabah recommended a design structure of triangular shape with metal strip for dual-band operation and reported EMR was 7.35 with NIMs properties [19].

In this paper, a new double-incidence miniaturized quad-band NIM with an improved EMR has been introduced. The design structure of metamaterials covers L-, S-, C-, and X-bands with resonance frequencies 1.64 GHz at -18.23 dB, 3.67 GHz at -29.98 dB, 7.90 GHz at -12.55 dB, and 9.41 GHz at -31.94 dB, respectively. The negative refractive indices of the proposed structure are 3.36-3.52 GHz (0.16 GHz bandwidth), 5.34-5.52 GHz (0.18 GHz bandwidth), 5.63-8.69 GHz (3.06 GHz bandwidth), 9.71-10.55 GHz (0.84 GHz bandwidth), and 11.84-13.90 GHz (2.06 GHz bandwidth) for the normal incidence. Moreover, the bandwidths of negative refractive indix due to the parallel incidence of an electromagnetic wave are 1.91-7.33 GHz (5.42 GHz bandwidth), and 12.56-14.30 GHz (1.74 GHz bandwidth). In addition, the dimension of the proposed unit cell is smaller than the reported metamaterials unit cells in [11,12, 13, 14, 16, 19] in respect of EMR. The NIMs characteristics of the suggested structure were tested by numerically and experimentally. The NIM structure is suitable for multi-band applications, for instance, GPS, mobile phones, weather radar, surface ship radar, long-distance radio telecommunications, satellite communications and, space communications from the normal incidence and parallel incidence with the same dimension as well as same structure.

2. Methodology

2.1. Physical geometry of metamaterials

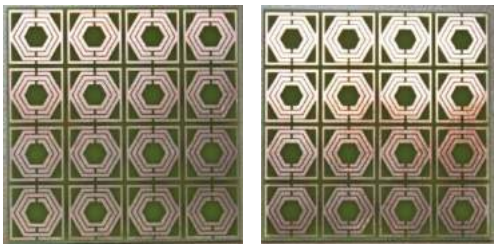
The proposed engineered NIM metamaterial structure has composed the same design structure on the substrate of both sides. The frontside and backside of a dielectric slab are a planar modified hexagonal copper metal structure. A combination of multiple hexagonal shaped split ring resonators with meander line was employed to attain unconventional characteristics of metamaterials that were usually not found in nature. The numerical analysis has been performed using commercially available CST microwave studio. In numerical analysis as well as practical implementation, 1.6 mm thick FR4 substrate with permittivity 4.3 and loss tangent 0.025 as well as permeability 1 has been utilized. All elements of the modified hexagonal resonators are made of copper with electric conductivity of 5.8×107 S/m, thermal conductivity 401 W/K/m, Rho of 8930 kg/m^3, Diffusivity 0.000115141 m^2/s, Young's modulus of 120 KN/mm^2 and the thickness of copper resonators, 35 μm. The elements of all the artificial structure are captured inside a cubic lattice of dimension 10×9.6 mm^2. The design structures are considered the incidence of uniform plane wave propagating along z-direction for normal incident as well as the y-direction for parallel incident. The parameters of the structure are L=9.8 mm, W=9.8 mm, W_1=0.7 mm, W_2=0.8 mm, W_3=0.8 mm, g=0.4.



(a) (b)

Figure 1: The proposed engineered structure (a) front side and (b) perspective with both side.

To observe the double incidence operation of the structure, primarily, the z-axis EM plane wave propagation was performed, and then the y-axis EM plane wave propagation was implemented. The schematic diagram of the proposed engineered structure is illustrated in Fig. 1. To determine the transmission coefficient and the reflection coefficient in simulation a frequency domain solver is utilized and 1001 frequency samples were reserved.



(a) (b)

Figure 2: The fabricated array of proposed engineered structure (a) front side and (b) back side.

A fabricated prototype is shown in Fig. 2. The fabricated sample encloses 5 × 4 arrays of the structure of copper materials and the dimension of the fabricated sample are 55 × 42.5 mm^2. The measurement has been performed with two waveguides in the free-space environment. Besides, the scattering parameters have been measured by the PNA network analyzer (N5227) where the frequency range of the device is 10 MHz-67 GHz. Moreover, a calibration kit (Agilent N4694-60001) was utilized to calibrate the network analyzer. Furthermore, in case of calibration purposes, measurement has been performed with and without of the

prototype. That is why; the measurements have been completed precisely.

2.2. Effective Scattering and medium parameters Calculation

The Nicolson-Rose-Weir method was utilized to retrieve the parameters of the material. The magnetic permeability, $\mu = \mu_0\mu_{eff}$ and the dielectric permittivity, $\varepsilon = \varepsilon_0\varepsilon_{eff}$, the impedance is defined as $Z = \sqrt{\frac{\mu_r}{\varepsilon_r}} Z_0$,

The S-parameters are represented as the addition and subtraction terms as given in equations 1 and 2.

$$v_1 = S_{21} + S_{11}, \quad (1)$$

$$v_2 = S_{21} - S_{11}, \quad (2)$$

The transmission coefficient (S_{21}) and reflection coefficient (S_{11}) are the scattering parameters of the metamaterials. Metamaterials that have finite thickness, $k_{real}d \leq 1$ and complex wave number, $K = \frac{\omega\sqrt{\mu_r\varepsilon_r}}{c} = K_0\sqrt{\mu_r\varepsilon_r}$, to obtain effective magnetic permeability (μ_{eff}), dielectric permittivity (ε_{eff}), and effective refractive index (n_{eff}) are written as follows:

Effective permeability, $\mu_{eff} = \frac{2c}{j\omega d} \times \frac{(1-v_1)}{(1+v_1)}$ (3)

Effective permittivity, $\varepsilon_{eff} = \frac{2c}{j\omega d} \times \frac{(1-v_2)}{(1+v_2)}$ (4)

Refractive index, $n_{eff} = \frac{2c}{j\omega d} \times \left\{ \frac{(S_{21}-1)^2 - S^2{}_{11}}{(S_{21}+1)^2 - S^2{}_{11}} \right\}^{1/2}$ (5)

Where, d, c, and ω are used as the thickness of the substrate, the velocity of light and the angular frequency. The above equations are utilized to determine the effective medium parameters.

3. Results and Discussions

The values of the effective dielectric permittivity, effective magnetic permeability and effective refractive index are verified to characterize the proposed engineered materials. Engineered structure with different type of EM wave propagation, i.e., normal incidence and parallel incidence have been analyzed in this paper.

3.1. Analysis of the Normal Incidents of EM wave

The electric and magnetic field have been polarized along the x-axis and the y-axis, respectively, whereas z-axis has been utilized for electromagnetic wave travelling for normal incident. The PEC and PMC boundary conditions are employed alongside the x-axis and y-axis, individually, and two waveguide ports are placed on the positive and negative z-axis. The numerical and experimental result of the modified hexagonal engineered structure was offered. The numerical and measured reflection coefficient (S_{11}), and transmission coefficient (S_{21}) of the unit-cells were shown in Fig. 3. It illustrates the mathematical values of the four frequency ranges of resonance frequencies are 1.57-1.7 GHz, 3.24-3.95 GHz, 6.44-8.02 GHz and 8.94-11.51 GHz, that designates L-, S-, C, and X-bands applications.

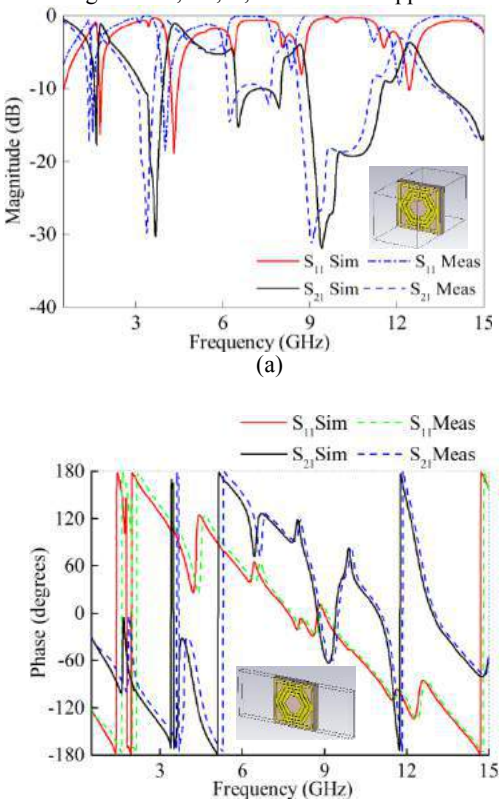


Figure 3: (a) Magnitude (b) phase of simulated and measured S-parameters of engineered structure.

From Fig. 3, the simulation and experimental results for the magnitude and phase of the design structure are showing good agreement with each other. The corresponding magnitude and phases are plotted in Fig. 3(a) and 3(b). Matching occurs at 1.64 GHz, 3.67 GHz, 7.90 GHz, and 9.41 GHz. The value of reflection is highest, whereas the value of transmission is nearly zero at the resonance frequencies. The phase of the transmission and reflection response has a jump at the same frequency which carries a signature of existence the metamaterial's resonance. The experimental results have revealed the same band comparing with simulation results in Fig. 3 (a) and 3(b). On the other hand, the scattering parameters of experimental results have been slightly lifted towards the lower frequency and reduced small amount of magnitude comparing with simulation results. The small amount of difference has been occured for the several fabrication tolerance and open-space measurement procedure. Fig. 4 exhibits the distributions of instantaneous surface current and magnetic field of the resonant four peaks, for instance, 1.64 GHz, 3.67 GHz, 7.90 GHz and 9.41 GHz, where its expose epsilon negative metamaterial, epsilon negative metamaterial, double negative metamaterial and mu negative metamaterial respectively. The flow of the direction of the current on the frontal metallic slabs was

reversely paralleled to the back one. This current produces a heavy charge gathering at the regions where the two opposite flowing currents meet each other and form four magnetic dipoles that show negative magnetic resonances under normal incidence of electromagnetic wave. At 1.64 GHz, the distributions of magnetic field have concentrated on the areas of split gap of middle ring and around the middle ring. Hence, the first epsilon negative is subjected by the magnetic resonance of the areas.

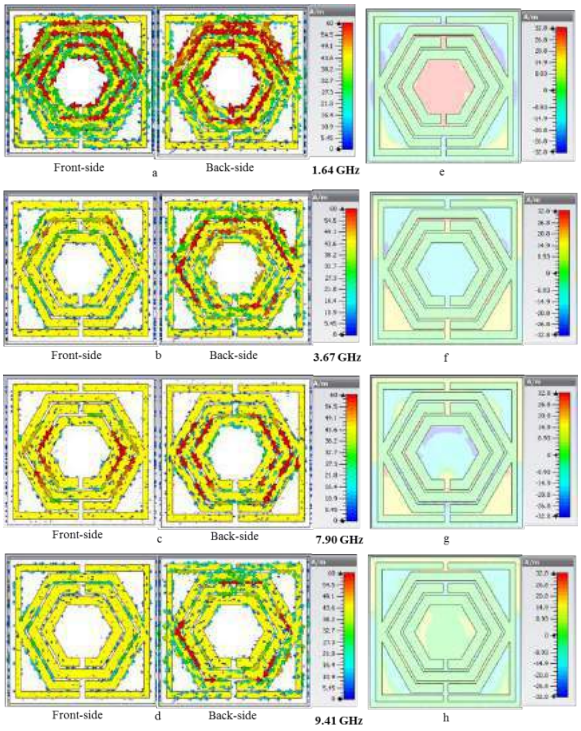

Figure 4: Instantaneous surface current and magnetic field distribution for nermal incidence of EM wave.

Moreover, at 3.67 GHz, the magnetic field's is concentrated in the regions of the left-side, right-side and upper-side of the substrate. Therefore, the second epsilon negative is prevailed by the regions of the magnetic resonance. Furthermore, at 7.90 GHz, the magnetic field's is concentrated in the regions of the left-side, right-side and lower-side of the substrate. So, the double negative is dominated by the magnetic resonance of the areas. Additionally, at 9.41 GHz, the magnetic field's is concentrated in the regions of the left-side and right-side of the substrate. Thus, the mu negative is conquered by the regions of the magnetic resonance. Fig. 5(a) and 5(b) demonstrate the retrieval effective permittivity, $\varepsilon = \varepsilon' + i\varepsilon''$, and effective permeability, $\mu = \mu' + i\mu''$, respectively. Fig. 5(a) shows the real values of the effective negative permittivity, 1.59-1.72 GHz, 2.56-4.05 GHz, 4.60-7.92 GHz, 8.01-8.69 GHz, 12.17-12.56 GHz and 14.86-15.00 GHz for the normal incidence of the EM along the design structure of metamaterials. The real values of the effective negative permeability, 6.21-6.39 GHz, 7.26-8.74 GHz, and 9.10-14.43 GHz, for the propagation direction along the z-axis (normal incidence) of design structure of metamaterials are shown in Fig. 5(b).

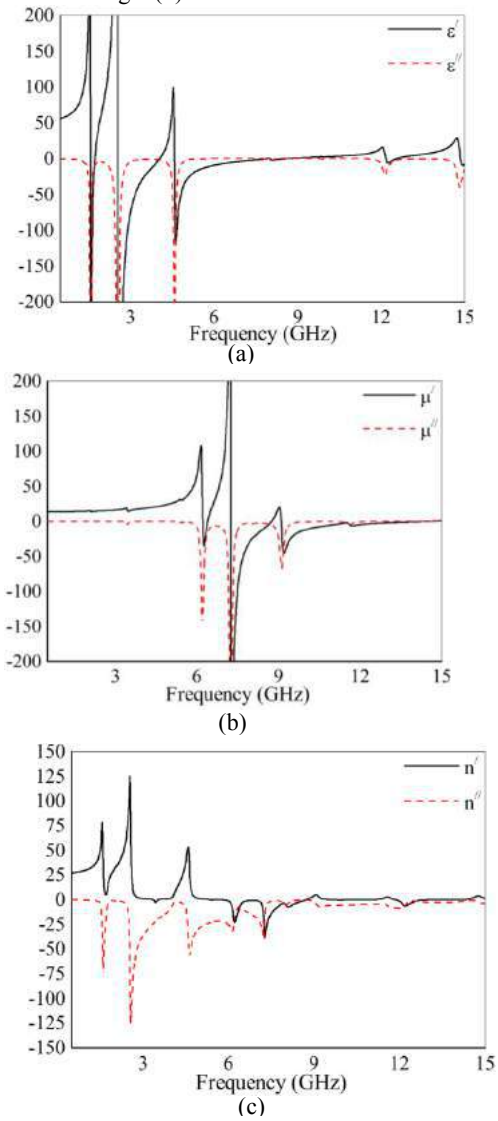

Figure 5: (a) Permittivity (b) permeability (c) Refractive index values of real and imaginary curves for normal incidence of EM.

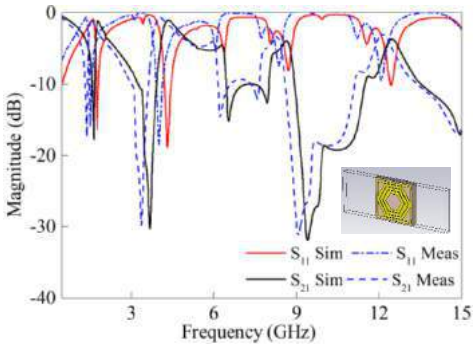
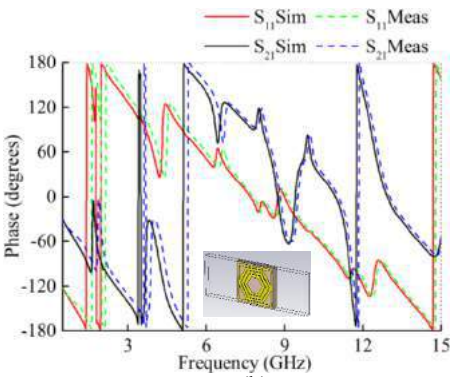
The negative properties of the permittivity and permeability has altered by a tiny amount due to the polarization effect on the internal construction of metamaterials structures. Anisotropic materials comprise unequal lattice structure that handles the applied electromagnetic field due to the polarization of dipole moment inside materials. Hence, the variety of design structure also alters the properties of the effective permittivity and permeability of the metamaterials. The effective refractive index, $n = n' + in''$, are demonstrated in Fig. 5(c). It can be seen that the magnitude of the real values of the effective negative refractive index are in 3.36-3.52 GHz, 5.34-5.52 GHz, 5.63-8.69 GHz, 9.71-10.55 GHz and 11.84-13.90 GHz of the design structure of metamaterials. The curves of the effective refractive index

become negative when the curves of the permittivity and permeability are negative, simultaneously. The design structure of metamaterials has revealed double negative properties at region of 6.21-6.39 GHz, 7.26-7.92 GHz, 8.01-8.69 GHz, and 12.17-12.56 GHz. It can be considered that the losses are insignificant in those frequency ranges, which designates four efficient pass band.

3.2. Analysis of the Parallel Incidents of EM wave



(a)



(b)

Figure 6: (a) Magnitude (b) phase of simulated and measuredS-parameters of the structure.

For the parallel incidence, the incident condition was fulfilled by applying PMC and PEC are applied along the y- and z-direction, individually, and two waveguide ports are placed on the positive and negative x-direction. The amplitudes of the real and imaginary values of scattering parameters are shown in Fig. 6(a). Fig. 6 depicts the simulated and measured reflection coefficient (S_{11}), and transmission coefficient (S_{21}) of the artificial material for the direction of EM planar wave propagation along the x-axis.. Fig. 6 (a) demonstrates the values of the dip of the resonances at 1.01 GHz, 3.47 GHz, 6.17 GHz, and 9.81 GHz frequencies, that designates L-, S-, C-, and X-bands applications. The value of transmission is lowest, on the contrary, the value of reflection is nearly zero at the resonance frequencies. The phase of the transmission and reflection follows same phenomena as described in Fig. 3. The distributions of instantaneous surface current and magnetic field of the resonant four peaks are shown in Fig. 7, for instance, 1.01 GHz, 3.47 GHz, 6.17 GHz and 9.81 GHz, where its depict mu negative metamaterial, double negative metamaterial, negative refractive index metamaterial and mu negative metamaterial respectively.

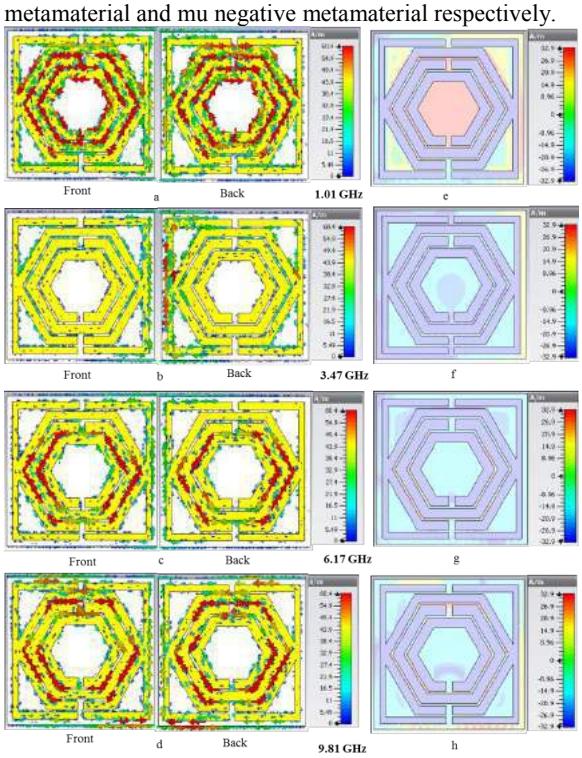


Figure 7: Instantaneous surface current and magnetic field distribution for nermal incidence of EM wave.

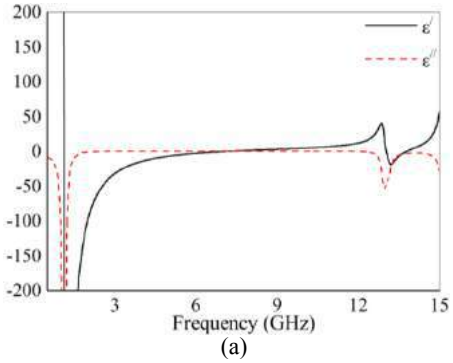
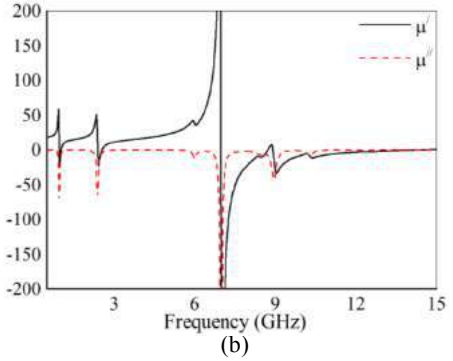
The flow of current on the facial metallic pieces is anti-paralleled to the backward or following one, hence, generating a heavy charge buildup at the areas. As a result, four magnetic dipoles formed due to opposite current flow that show negative magnetic resonances under the parallel incidence of EM wave. At 1.01 GHz, the distributions of magnetic field have concentrated on the areas of split gap of inner and middle ring with the surroundings. Hence, the mu negative is exposed by the regions of the magnetic resonance. Moreover, at 3.47 GHz, the magnetic field's is concentrated in the regions of the upper-side and lower-side of the slabs. Therefore, the dual negative is subjugated by the regions of the magnetic resonance. Furthermore, at 6.17 GHz, the magnetic field's is concentrated in the regions of the left-side and right-side of the substrate. So, the negative refractive index is prevailed by the regions of the magnetic resonance Additionally, at 9.81 GHz, the magnetic field's is concentrated on the zones of the left-side, right-side, upper-side and lower-side of the substrate. Thus, the mu negative is prevailed by the regions of the magnetic resonance. Fig. 8 (a) represents the real and imaginary curves of retrieval effective permittivity of the artificial material for the propagation of planar EM wave along the x-axis means parallel incidence. It can be seen that a large span of frequencies, for instance,1.12 to 7.26 GHz and 13.03 to 13.78 GHz of negative amplitude have been attained in the microwave spectra.

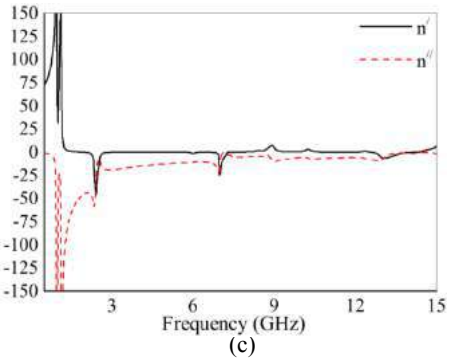


(a)



(b)

Likewise, from Fig. 8 (b), it has been perceived that few negative peaks of the effective permeability are 0.95 to 1.01 GHz, 2.39 to 2.53 GHz, 6.98 to 8.71 GHz, and 8.92 to 14.39 GHz.



(c)

Figure 8: (a) Permittivity (b) permeability (c) Refractive index values of real and imaginary curves for parallel incidence of EM.

Hence, it is apparent that the artificial material exhibits negative magnitude for both permittivity and permeability at the frequency ranges of 2.39 to 2.53 GHz and 6.98 to 7.26 GHz in the microwave region. Generally, the properties of permittivity and permeability are affected by the polarization that are mentioned previous discussion. Therefore, the refractive index curve of the material also affected by the polarization like as permittivity and permeability. The real and imaginary magnitude of the effective refractive index is shown in Fig. 8 (c) for parallel incident of EM wave, where peak resonances are perceived in the S-, C-, and Ku-band in the microwave region. The bandwidths of the effective refractive index are 1.91-7.33 GHz (5.42 GHz) and 12.56-14.30 GHz (1.74 GHz) for parallel incident of EM wave that indicates the wideband applications of the structure.

Table 1: Comparison of performance with other multi-band metamaterials.

Composition Technique	MHSRR-MHSRR pair	Pair of ELC–HSLR	Orthogonal Z-shaped metallic strip pair	Nonlinear Metamaterial	Pair of MTSRR-wire	Pair of multiple SSRR	Pair of TSRR-wire

Table 1 reveals the comparisons of the incident direction of EM wave, the number of frequency bands, applicable regime, EMR, number of resonance frequency and complexity of the structure of the proposed design. It is seen that EMR of the proposed NIM structure is the uppermost when compared to other suggested metamaterials. Proposed structure has a quad-band, good selectivity, simple construction, and decent characteristics with dual incidence.

4. Conclusions

A new design of miniaturized quad-band negative refractive index operating under the normal and parallel incidence proposed in this manuscript. The metamaterials properties of the suggested structure tested in numerically and experimentally. The FDTD based Computer Simulation Technology was used for the numerical analyses and a vector network analyzer (N5227A) was used for the measurements. For an EM wave of normal incidence, the structure revealed metamaterials properties with wideband negative refractive index (3.18 GHz). In addition, for an EM wave of parallel incidence, the structure has exhibited metamaterials properties with wideband negative refractive index (2.45 GHz). These differences occurred due to changes in the boundary conditions. The proposed NIM considerably improved EMR as compared to other multi-band metamaterials. Furthermore, the proposed structure was appropriate for mobile phones (GSM), microwave communications, radar and satellite communications.

Abstract

A tri-band fractal meta-surface absorber composed of metallic branches of tree connected with a straight metal strip has been presented in this paper for high absorption application. The proposed tree-shape structure shows resonance in C-, X-, and Ku-band and left handed characteristics in 14.15 GHz. The dimension of the tree-shaped meta-surface single unit cell structure is 9×9 mm^2 and the effective medium ration is 5.50. In addition, the designed absorber structure shows absorption above 84%, whereas the absorber structure printed on epoxy resin fiber substrate material. The FIT-based CST-MWS has been utilized for the design, simulation, and analysis purpose. Fabrication is also done for the experimental validation.

1. Introduction

Meta-surface absorbers, as a branch of metamaterials, with the sub wavelength scale unit cell, currently provoke extensive interests since the first experimental demonstration. The necessity of having low-profile absorbers in microwave frequency is growing rapidly, as a result actuated the researcher toward the development of metamaterial based absorbers. These metamaterial absorbers are formed by the periodic extension of unit cell. On receiving the incident wave, these unit cells get excited due to simultaneous occurrence of electric and magnetic resonances in their structure. High absorption can be achieved by minimizing the reflectance and transmittance as well as impedance must be well matched. Due to ultra-thin dielectric layer thickness, high absorption, and simple design procedure, meta-surface absorbers have been broad applications in the fields of microwave, terahertz, infrared, and optical frequencies. Some metamaterial and metamaterial based absorbers having absorptivity in a single frequency band, dual frequency band, and triple frequency band has been reported in this paper. In 2003 R. W. Ziolkowski successfully developed a capacitor loaded strips and split ring resonators metamaterial that displayed negative permittivity and permeability both at the X-band frequency [1]. After the successfully invention of metamaterial the researcher was being motivated to develop the metamaterial based absorber for high absorption, simple design procedure, cost effective, miniature in size, etc. As a result, first perfect metamaterial absorber was demonstrated by Landy and his colleagues in 2008, which was a classic sandwiched structure composed of a split ring resonator, a dielectric substrate, and a metallic cut wire achieved its peak absorption of 88% in 11.50 GHz [2]. An ultra-wideband metamaterial absorber was presented above 90% absorption and the wide bandwidth from 7.85 to 12.25 GHz (X-band). The structure was designed by composed of two concentric circular split rings imprinted on a metal backed dielectric substrate [3]. In addition, a z-shaped left handed metamaterial for wide band applications was presented, which applicable for C- and X-band application and miniature in size of 10×10 mm^2 but there were no absorption properties had been investigated [4]. Further, a compact square split z-shape metamaterial was presented with left handed features in 8.50 GHz, wide bandwidth of 5.67 GHz for S-, C-, X- and Ku-band application. Besides, the presented meta-atom was investigated in 15^0, 30^0, 45^0, 60^0, 75^0 and 90^0 angular rotations in xy-plane [5]. A left handed metamaterial consisted of a single-sided tree-shaped fractal structure, features triple magnetic resonances and one electric resonance apart from the lower metal plasma response was introduced. Moreover, the resonance points had a value of 2.2, 3.3 and 5.6 dB were clearly observed, respectively in 7.98, 8.68 and 9.0 GHz [6]. An ultrathin and miniaturized FPMA structure was investigated for RCS reduction and the absorption was <90% from 3.17 to 3.22 GHz, whereas the size of the absorber was 0.1λ×0.1λ [7]. Moreover, a fractal shaped square absorber had been proposed and exhibited absorption of 99.1% and 99.7% respectively in 4.17 and 11.16 GHz [8]. Further, a microwave metamaterial absorber was designed that resonance at C-, X- and Ku-band with double negative characteristics as well as the absorption peaks were respectively, 82%, 67%, and 93% in 6.22, 8.76, and 13.05 GHz in [9]. A microwave metamaterial absorber composed of delicate periodic patterned structures and a metallic background plane was separated by a dielectric substrate suggested by Wang and his colleagues. The designed absorber shown absorption peaks were respectively in 28.21, 39.59, 52.78, and 58.63 GHz with the absorption of 99.47%, 99.94%, 99.05%, and 99.55% [10]. An absorber consisted of closed-ring resonator with a metallic patch inside it, and the resonator and the patch were diagonally connected by a metallic arm, shown dual resonance in C-band and broadband absorption in X-band. The absorber

had the peak absorptivity of 95.7%, 99%, and 98.9% in 4.69, 5.19, and 7.15 GHz, for C-band and absorptivity of 99.81% and 99.77 % was obtained in 8.94 and 10.68 GHz for X-band [11]. A wearable microwave metamaterial absorbing for dual resonances in 9.0 and 9.80 GHz and two absorptivity peaks <90%, composed of two square ring resonators with different sizes, a backing ground plane, and a flat substrate with a 1.0 mm thickness in 2016. However, the proposed WMMA has a high absorptivity regardless of the polarization angle of the EM waves and the deformation effect [12]. In [13] Islam et al. proposed a new multi band split S-shape metamaterial for absorption analyses that shown resonance at S-, X- and Ku-bands in microwave spectra. The absorption spectra for the proposed was 45% achieved at S-band. Moreover, after reducing the coupling capacitance in the z-axis absorption was reaching up to 55%, but in the y-axis absorption was extended up to 47%. In [14] a symmetrical circular fractal metamaterial absorber had been proposed for tri-band absorption for both TE and TM polarisations and absorption of 98.7%, 99.4%, and 99.5% respectively in 2.29, 4.28, and 11.71 GHz [14]. A broadband metamaterial absorbing in terahertz frequency range that was made up by two circular split rings, a dielectric substrate and a metallic ground to achieve absorption from 0.85 to 1.926 THz with the absorptivity beyond 90% at normal incidence and the bandwidth was 1.076 THz [15].

In this paper, the proposed fractal meta-surface absorber is completely new by the tree-shaped structure for high absorption application. The designed structure is quite different from the previously designed meta-surface structure. Most of the famous structure was square-, circular-, ring-, or alphabetical-letter shaped, but the proposed fractal meat-surface structure is totally different like a tree-shape structure with lots of branches. The unit cell of the proposed meta-surface structure contains metallic branch tree-shaped fractal metal printed on FR-4 material. The dimension of the tree-shaped structure is 9×9 mm2 and applicable for tri-band (C-, X-, and Ku-band) application. The results of the simulated resonance peaks are in 6.20, 8.13, and 12.23 GHz, whereas the measured transmittances resonance peaks are respectively, 6.06, 7.98, 11.94 GHz. Moreover, the absorption peaks are above 73%, 64% and 84% respectively in 6.50, 8.73, and 14.40 GHz for the designed absorber structure. Besides, the surface impedance of these fractal structures is -2-48i. The paper is organized as follows: in section 2, fractal meta-surface absorber design procedure with specification is described, the methodology and the retrieval of the effective permittivity, permeability and refractive index are explained in section 3, in section 4 measurement procedure and the obtained results are analysed and the paper is concluded by section 5.

2. Fractal Meta-Surface Structural Design

The top view of the proposed fractal meta-surface structure with optimized geometric dimensions is shown in figure 1(a-c). Each single unit cell of the proposed meta-surface structure contains metallic branch tree-shaped fractal metal printed on a 1.60 mm thick epoxy resin fibre substrate material (εr = 4.25 and tanδ = 0.02). However, 'A', 'B', and 't' are respectively the FR-4 substrate material width, length and height. Besides, 'L1', 'W1', and 'd' is the fractal shape length, width and the width of copper metal.

The metal (copper) has a width (d) of 0.50 mm and thickness (h) of 0.035mm, (b) Fabricated single unit cell structure, (c) Fabricated array structure of the proposed fractal meta-surface absorber.

3. Methodology and Retrieval of Parameters

The finite integration technique has been adopted for all design, simulation, and numerical investigations. This is a spatial discretization technique to solve electromagnetic

field problems numerically in the frequency domain. Basically, in this approach Maxwell's equations are applied in integral form of a set of staggered grids. The utilization of a stable dual orthogonal grid with a precise time integration technique leads the computation process. The technique covers full range of electromagnetic application and a basis for commercially available computer simulation technology microwave studio electromagnetic simulator. Two boundary conditions are commonly used for the computation of meta-surface parameters: periodic boundary condition and perfect electromagnetic conductor boundary condition. Periodic boundary conditions are usually applied for simulating a part of the mass framework by modelling its small part to the absence of proper surface. The perfect electromagnetic conductor boundary condition is the generalization of perfect electric conductor and perfect magnetic conductor. For the simulation of the proposed fractal meta-surface absorber EM-waves are propagating along the z-axis, whereas the x- and y-axis are respectively considered as a perfect electric conductor and perfect magnetic conductor boundaries. The frequency domain solver with tetrahedral mesh have been utilized for the simulation and the impedance has been set to 50Ω. However, the retrieving procedure of the effective medium parameters is given as follows [16],

$$Reflection\ Coefficient,\ S_{11} = \left\{ \frac{R_1\left(1-e^{-2j\theta}\right)}{1-R_1^2 e^{-2j\theta}} \right\} \quad 1$$

$$Transmission\ Coefficient,\ S_{21} = \left\{ \frac{e^{-2j\theta}\left(1-R_1^2\right)}{1-R_1^2 e^{-2j\theta}} \right\} \quad 2$$

$$Permeability,\ \mu_r \approx \left[\frac{2c(1-S_{21}+S_{11})}{j\omega d(1+S_{21}-S_{11})} \right]$$

$$Permeability,\ \mu_r \approx \left[\frac{c(1-S_{21}+S_{11})}{j\pi f d(1+S_{21}-S_{11})} \right] \quad 3$$

$$Permittivity,\ \varepsilon_r \approx (\mu_r + j\frac{2cS_{11}}{\omega d})$$

$$Permittivity,\ \varepsilon_r \approx (\mu_r + j\frac{cS_{11}}{\pi f d}) \quad 4$$

$$Refractive\ Index,\ n_r \approx \left[\frac{2c}{j\omega d}\left\{ \frac{\left(S_{21}-1\right)^2 - S_{11}^2}{\left(S_{21}+1\right)^2 - S_{11}^2} \right\} \right]^{1/2}$$

$$Refractive\ Index,\ n_r \approx \left[\frac{c}{j\pi f d}\left\{ \frac{\left(S_{21}-1\right)^2 - S_{11}^2}{\left(S_{21}+1\right)^2 - S_{11}^2} \right\} \right]^{1/2} \quad 5$$

In addition, the total inductance of the designed structure can be calculated from the equation,

$$L_T = \mu_0 t^2 \left\{ \frac{\sqrt{A^2+B^2}}{3\pi\sqrt{L_1^2+W_1^2+t^2}} + \frac{\sqrt{L_1^2+W_1^2}}{\sqrt{t^2+d^2}} \right\} \quad 6$$

The total capacitance can be calculated from the equation,

$$C_T = \varepsilon_0 \left\{ \frac{\pi(A+B)}{2(L_1+d)} \ln \frac{(L_1+W_1)}{\pi(t+d)} \right\} \quad 7$$

Perfect absorption takes place when the effective impedance of the absorber matches with the impedance of the free space. This condition ensures the zero reflection and transmission of the incident wave. Effective impedance is strongly related with the effective permeability and permittivity of the proposed absorber structure.

$$Impedance,\ Z_{eff} = \sqrt{\varepsilon_r / \mu_r} \quad 8$$

where 'd' is the thickness of the substrate, 'Z_{eff}' is the normalize impedance, 'ω' is the angular frequency, 'c' is the velocity of light, 'S_{11}' is the reflection coefficient, and 'S_{21}' is the transmission coefficient. In addition, the free-space permeability of $4\pi\times10^{-7}$ H/m and permittivity of 8.85×10^{-12} F/m. From the developed equation 6 & 7, the calculated transmittance resonance peaks is 6.18, whereas the simulated and the measured transmittance resonance peaks are respectively in 6.20 GHz and 6.06 GHz. Therefore, the resonance frequency is calculated by,

$$f_r = \frac{1}{2\pi\sqrt{L_T C_T}} \quad 9$$

The total inductance and capacitance describes the resonance points of the proposed meta-surface structure. The variation of any geometrical parameters corresponding to the change of the total inductances and capacitances causes the shift of the resonant frequencies. This analysis provides us a quantitative prediction of residual resonant frequencies whenever a magnetic or electric resonant frequency is given and in turn affords a good guideline for individual control over these resonances. The electromagnetic wave incident on the absorber structure and the absorption can be calculated from the following equation,

$$Absorption,\ A(f) = \left\{ 1 - \left|S_{11}\right|^2 - \left|S_{21}\right|^2 \right\} \quad 10$$

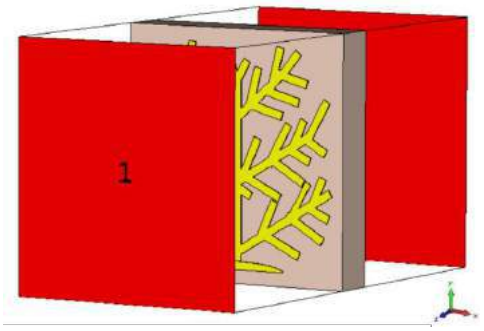

Figure 2: Simulation set-up of the designed fractal meta-surface absorber in the CST-MWS.

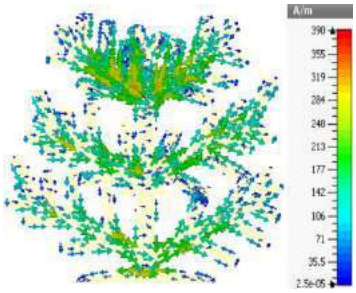
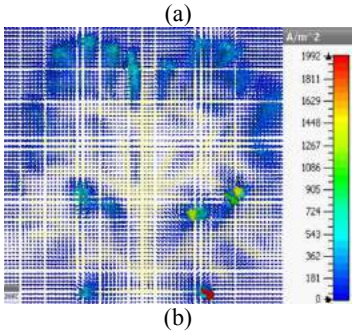
4. Experimental Measurement & Result Analysis

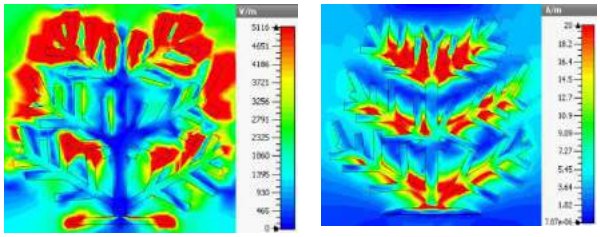
A 153×198-mm^2 (17×22 unit cells) array structure has been fabricated for measurement (shown in figure 1(c)). The fabricated tree-shape fractal meta-surface is placed between the horn antennas and the EM-waves are propagated along z-directions to an incident on the fabricated structure, similar to the simulation set-up (shown in figure 2). Antennas are placed far enough from each other to provide far-field conditions. Since the backward side of the structure is covered by a metal, there will be no transmission. Therefore, only the reflection measurements are carried out to evaluate the absorption coefficient. To measure the scattering and effective medium parameters, an Agilent N5227A vector network analyser was connected to the antennas. In addition, an Agilent N4694-60001 device was used to calibrate the vector network analyser (VNA-N5227A) to ensure accuracy of the network analyser in the case of measurement. For the current distribution analysis, the current is flowing inner direction from every branch of the tree-shape structure. At the resonance points the intensity of the current is the highest, whereas the stop bands are created at the null point by the minimization of the current by flowing opposite direction shown in figure 3(a,b). Besides, current loops behave to resemble several independent magnetic dipoles whose dipole moments drill through these loops and are anti-parallel to the external magnetic field. The electric field distributing in the substrate board of proposed fractal structure is plotted at electric and magnetic resonance in figure 3(c-d). The inductive net electric dipole moments yield when current flows on the tree-shaped metal patterns and are anti-parallel to the incident electric fields, providing the negative permittivity. Although th gap is capable of providing a capacitance, it is unable to excite the oscillation of current and play the role of accumulating charges whose dipole moments are anti-parallel to electric fields.



(a)



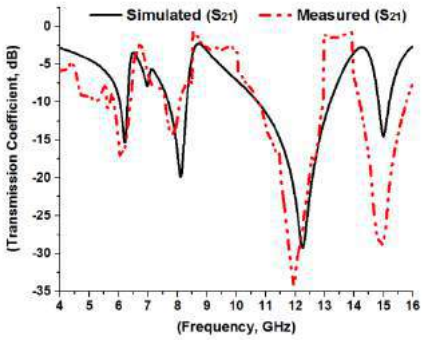
(b)



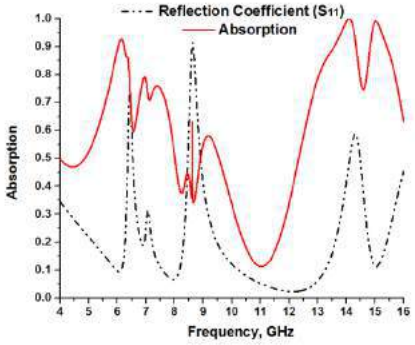
(c) (d)

Figure 3: (a) Surface current distribution, (b) Current density, (c) Electric field, (d) Magnetic field of the proposed fractal meta-surface in 11.94 GHz.

Figure 4(a-b) depicts, the amplitude of the transmission (S_{21}) coefficient and the absorption peaks. In figure 4(a) the simulated transmittance resonances are in 6.20, 8.13, and 12.23 GHz and the amplitude of those simulated peaks are respectively, -15.19, -19.62, and -29.06 dB. Besides, the measured transmittance resonances with the magnitude are respectively, 6.06 GHz (magnitude of -17.10 dB), 7.98 GHz (magnitude of -13.16 dB), 11.94 GHz (magnitude of -34.25 dB), and 15.01 GHz (magnitude of -28.40 dB). Here, the measured and simulated transmittances are a little bit shift due to the fabrication tolerance in figure 4(a). From figure 4(b) the absorption peaks of the proposed fractal meta-surface absorber are more than 73%, 64% and 84% respectively, in 6.50, 8.73, and 14.40 GHz in the case of reflection (S_{11}) coefficient resonance frequencies.



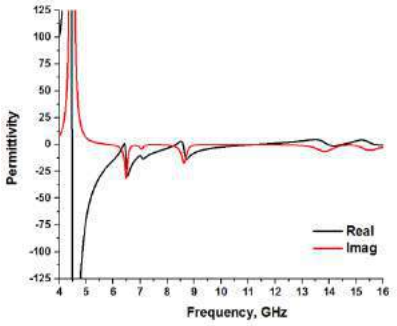
(a)



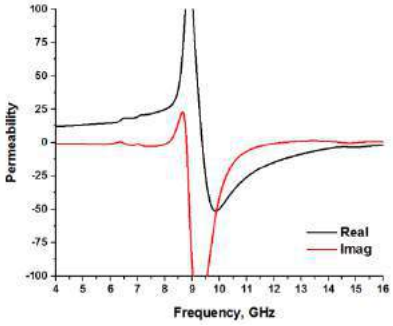
(b)

Figure 4: Amplitude of the proposed meta-surface: (a) Reflection and Transmission coefficient, (b) Absorption.

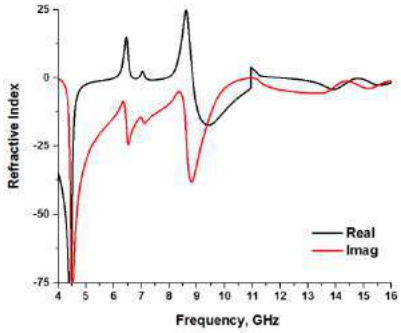
The amplitude of the effective medium parameters (permittivity, permeability, and refractive index) is shown in figure 5(a-c). The effective permittivity exhibits the negative peaks in 6.50 and 8.68 GHz and the values are respectively, (-28.24-22.03i), and (-12.31-12.98i) in figure 5(a). In figure 5(b) the real value of negative permeability curves shows a negative region from 9.38 to 16.0 GHz and the negative refractive index of real magnitude from 4.0 to 7.90 GHz, 8.87 to 10.94 GHz, and 12.0 to 16.0 GHz in figure 5(c). If the permittivity and permeability are simultaneously negative, then refractive index is also negative. Moreover, in 14.15 GHz the proposed meta-surface absorber exhibits the real value of the permittivity, permeability and refractive index parameters are respectively -1.23, -3.95, and -3.43. However, for the negative magnitude of effective medium parameters in 14.15 GHz the meta-surface absorber structure can be called as a left handed meta-surface. In addition, in 9.95 GHz the reactance impedance (or surface impedance) is (-2-48i) shown in figure 5(d).



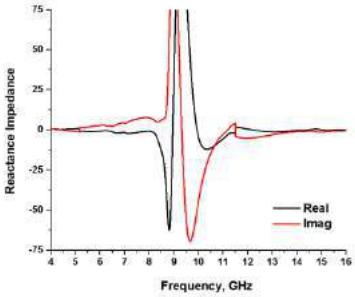
(a)



(b)



(c)



(d)

Figure 5: Amplitude of the proposed fractal meta-surface: (a) Permittivity, (b) Permeability, (c) Refractive index, (d) Reactance impedance.

Further analysis is done with the fractal shape by propagating the electromagnetic waves through the absorber in x-axis displayed in figure 6(a). The resonance of the transmittance (S_{21}) in 8.99 GHz (magnitude of -25.75 dB) is presented in figure 6(b). The permittivity exhibits negative real values from 5.89 to 6.61 GHz and 10.09 to 14.95 GHz in figure 6(c). In addition, surface impedance for x-axis wave propagation is also shown in figure 6(d), which is almost similar highest negative peaks like the z-axis wave propagation.

5. Conclusion

A left handed meta-surface absorber inspired by tree-shaped fractal structure with tri-band resonances have been numerically and experimentally analysed in this paper. The resonance of the proposed design is explained by current distribution and field's pattern. The meta-surface structure is compact in size and the absorption in above the 84%. The EM-wave pass through the proposed structure along z-axis. In addition, the impact of the EM-wave on resonance if the EM-wave propagation along x-axis is also investigated here. However, it is obtained that the proposed structure has wider absorption bandwidths as well as better absorption levels in microwave frequency. Besides, for tri-band (C-, X-, and Ku-band) resonance the proposed fractal meta-surface is applicable for high absorption, detection, satellite communication and sensing applications.

Abstract

This article presents a two-dimensional four-component composite, which consists of a periodic arrangement of coated eccentric cylinders embedded in an elastic medium. The engineered composite can generate negative effective mass density due to local resonances. The multiple interaction of the local resonators is studied using a pseudo-incident wave method with the composite subjected to inplane harmonic elastic waves. Then, the dynamic behaviour of the metamaterial system is comprehensively analyzed and the phenomenon of wave attenuation of the systems is presented. This study can provide an initial step of investigating periodic elastic metamaterial systems with eccentric resonators.

1. Introduction

Metamaterials are generally classified as engineered materials exhibiting unique electromagnetic, optic or mechanical properties, such as negative refractive index, negative effective mass, negative effective modulus, which are not readily observed in nature and quite desirable for many engineering applications. Unlike the traditional materials, these unique properties of the metamaterials are not from their chemical compositions, but from the delicately designed sub-wavelength structures.

The concept of metamaterials with negative properties can be traced back to 1968 when the negative refractive index generated by the simultaneously negative permittivity and negative permeability in the electromagnetic materials was theoretically proposed [1]. Subsequently, this novel concept was experimentally justified with delicately built microstructure [2]. Then, the ideas of superlenses overcoming the diffraction limit [3], invisible cloak for electromagnetic waves [4], had been further proposed or demonstrated.

Inspired by the development of electromagnetic metamaterials, research community has placed considerable attention on the study of acoustic/elastic metamaterials [5, 6]. One of the most prominent properties of metamaterials with negative effective mass and/or negative effective modulus is their wave attenuation ability, especially in the low frequency ranges, which usually requires the conventional material to have structures with a spatial period of similar size to the wavelength of the incident wave. The engineered microstructures, as the essence of the acoustic/elastic metamaterials, have intrigued intensive interests. Silicone rubber coated lead spheres have been periodically embedded in epoxy matrix to form an elastic metamateiral system with negative effective mass density, which experimentally showed the sound wave blocking ability by breaking the Bragg limit [7]. The coated cylinders serve as the local resonant inclusions. The relative motion between the local resonant inclusions and the matrix will generate an effective mass density, which is different from the static mass density based on the volume average of the the components of the system. When the inclusions resonate, interesting interactions between the scattered waves from the resonators and the incident wave occurs, inducing negative effective property [8, 9, 10, 11]. Similar phenomenon has been observed with a fluid matrix [12]. Then, this kind of system configuration has become a classic approach to obtain negative effective mass density with wave attenuation ability [13]. To investigate the underlying mechanism of the acoustic/elastic metamaterials and develop a methodology to predict band gaps, mass-spring models have been developed to proposed a new point of view on the elastodynamic equation of the composite materials [14, 15, 16].

There have been a number of efforts in the development of acoustic/elastic metamaterials with greater wave attenuation performance. Multilevel local resonators have been considered to extend the widths of the band gaps to some extent [17, 18]. Graded resonators also have been implemented to obtain flexible tailoring of the attenuation property over the desired frequency ranges [19]. Elliptical inclusions has been chosen to break the geometric symmetry of the resonators and split the attenuation peaks into separate ones, widening band gaps [20]. The rotational motion of the elliptical resonators can contribute to the band gaps in the low frequency ranges, which is vital for wave attenuation application. However, the irregular shape makes the analytical analysis impractical.

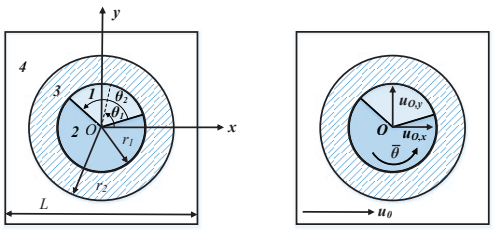
A two-dimensional elastic system with periodic eccentric local resonators embedded in the host matrix is proposed and analyzed in this study, based on a semi-analytical method. To evaluate the dynamic behaviour the system when subjected to inplane harmonic elastic waves, the single coated cylinder solution is firstly developed as the building block and then the solutions of the system with multiple interaction between cylinders are formed by using pseudo-incident wave technique [21]. With the wave field

calculated, the effective mass density of the system, which can turn negative under specific frequencies, has been determined based on the boundary effective medium theory [22]. The effective mass density is mainly dominated by the translational motion and the rotational motion of the coated cylinders [23, 24]. The effect of the rotational motion is substantial, especially in the low frequency range. The dynamic behaviour of the system has been studied and the wave attenuation phenomenon of the metamateria system has been illustrated at the frequencies with negative effective mass.

2. Formulation of the problem

Consider a two-dimensional four-component composite material model consisting of a collection of hard cylinders embedded in an elastic matrix with soft coating. In the composite model presented, the basic building block of the representative cell is shown schematically in Fig.1, where the matrix medium is labelled as 4, the coating medium is labelled as 3, and the two mediums of hard cylinders are labelled as 1 and 2 with density ρ_1 and ρ_2 respectively. The inner and outer radii of the coating layer are denoted as r_1 and r_2 respectively, as illustrated in Fig.1(a). The sector with central angle θ_2 is filled with medium 1. The angle between the angular bisector of θ_2 and the horizontal direction is defined as θ_1. The length of the square cell is L.

In this study, mediums 1 and 2 possess high stiffness to make the cylinders rigid compared to the soft coatings and have different densities to realize eccentric resonators, generating unique and interesting phenomena. As illustrated in Fig.1(b), when subjected to an incident longitudinal wave with displacement amplitude u_0, translational and rotational motions of the coated cylinders will be induced. $u_{O,x}$ and $u_{O,y}$ represent the displacements of the centroid, O, in x and y directions respectively. The rotational angle of the cylinder is denoted as $\bar{\theta}$ in Fig.1(b).



(a) (b)

Figure 1: (a) The configuration of the representative cell, (b) the loading and its corresponding response.

For this two-dimensional metamaterial system, its harmonic response is mostly controlled by the properties of the representative cell.

2.1. The single representative cell

2.1.1. Analysis of the rigid eccentric cylinder

From the geometrical features shown in Fig.1, the following relations can be readily obtained as

$$M_{12} = \frac{1}{2}\theta_2\rho_1 r_1^2 + \frac{1}{2}\left(2\pi - \theta_2\right)\rho_2 r_1^2, \tag{1}$$

$$r_G = \frac{4r_1\left(\rho_1 - \rho_2\right)\sin\left(\theta_2/2\right)}{3\left[\theta_2\left(\rho_1 - \rho_2\right) + 2\pi\rho_2\right]}, \tag{2}$$

where M_{12} is the mass of the cylinder and r_G is defined as the distance between the centroid O and center of mass G of the cylinder. The moment of inertia of the cylinder around its centroid O is

$$I_O = \left\{ \begin{array}{l} \int_0^{r_1}\int_{\theta_1-\theta_2/2}^{\theta_1+\theta_2/2} \rho_1 r^3 d\theta dr \\ + \int_0^{r_1}\int_{\theta_1+\theta_2/2}^{2\pi+\theta_1-\theta_2/2} \rho_2 r^3 d\theta dr \end{array} \right\}. \tag{3}$$

Based on the parallel axis theorem, the moment of inertia of the cylinder around the centre of mass G will be

$$I_G = I_O - M_{12}{r_G}^2. \tag{4}$$

For any point in the outer boundary of the rigid cylinder, its displacements in polar coordinate can be expressed as

$$u_r^{(1,2)}|_{r=r_1} = u_{O,x}\cos\theta + u_{O,y}\sin\theta, \tag{5}$$

$$u_\theta^{(1,2)}|_{r=r_1} = -u_{O,x}\sin\theta + u_{O,y}\cos\theta + r_1\bar{\theta}. \tag{6}$$

The acceleration components of the centre of mass G are in the form of

$$a_{G,x} = -\omega^2 u_{O,x} + \omega^2\bar{\theta} r_G\sin\theta_1 + \omega^2\bar{\theta}^2 r_G\cos\theta_1, \tag{7}$$

$$a_{G,y} = -\omega^2 u_{O,y} - \omega^2\bar{\theta} r_G\cos\theta_1 + \omega^2\bar{\theta}^2 r_G\sin\theta_1. \tag{8}$$

It can be easily observed from equations (7) and (8) that the rotational motions of the eccentric resonators make the system nonlinear. The motion of the rigid cylinders can be determined by the displacements of its center of centroid, $u_{O,x}$ and $u_{O,y}$, and its rotational angle $\bar{\theta}$.

2.1.2. Analysis of the coating

In the coating, the general form of the equation of motion without body force can be written as

$$\left(\lambda_3 + 2\mu_3\right)\nabla\left(\nabla\cdot\vec{u}\right) - \mu_3\nabla\times\nabla\times\vec{u} + \rho_3\omega^2\vec{u} = 0, \tag{9}$$

where ρ_3 is the density of medium 3, λ_3 and μ_3 are the Lamé constants of medium 3. The displacement components in equation (9) are coupled. In order to avoid high-order partial differential equations, displacement potentials are introduced to express the components of the displacement vector with satisfying uncoupled wave equations. For medium 3, the displacement potentials can be expressed as

$$\phi_3\left(r,\theta\right) = \sum_{n=-\infty}^{+\infty}\left\{ \begin{array}{l} J_n\left(K_{L3}r\right)A_n^{(1)} \\ + H_n^{(1)}\left(K_{L3}r\right)A_n^{(2)} \end{array} \right\} e^{in\theta}, \tag{10}$$

$$\psi_3(r,\theta) = \sum_{n=-\infty}^{+\infty} \left\{ \begin{array}{l} J_n(K_{T3}r)\, A_n^{(3)} \\ + H_n^{(1)}(K_{T3}r)\, A_n^{(4)} \end{array} \right\} e^{in\theta}, \quad (11)$$

where $J_n(\cdot)$ and $H_n^{(1)}(\cdot)$ are the n^{th} order Bessel function and Hankel function of the first kind, respectively. The coefficient A_n can be determined by the boundary conditions in the interfaces. The longitudinal wave number K_{L3} and shear wave number K_{T3} are given by

$$K_{L3} = \omega \sqrt{\frac{\rho_3}{(\lambda_3 + 2\mu_3)}}, \quad (12)$$

$$K_{T3} = \omega \sqrt{\frac{\rho_3}{\mu_3}}. \quad (13)$$

Then, the displacement components of the particles in the medium 3 can be expressed in term of the displacement potentials illustrated in equations (10) and (11), as

$$u_r^{(3)} = \frac{\partial \phi_3}{\partial r} + \frac{1}{r}\frac{\partial \psi_3}{\partial \theta}, \quad (14)$$

$$u_\theta^{(3)} = \frac{1}{r}\frac{\partial \phi_3}{\partial \theta} - \frac{\partial \psi_3}{\partial r}. \quad (15)$$

The stress components, $\sigma_{rr}^{(3)}$ and $\sigma_{r\theta}^{(3)}$, will be

$$\sigma_{rr}^{(3)} = \lambda_3 \nabla^2 \phi_3 + 2\mu_3 \left[\frac{\partial^2 \phi_3}{\partial r^2} - \frac{1}{r^2}\frac{\partial \psi_3}{\partial \theta} + \frac{1}{r}\frac{\partial^2 \psi_3}{\partial r \partial \theta} \right] \quad (16)$$

$$\sigma_{r\theta}^{(3)} = \mu_3 \left\{ \begin{array}{l} 2\left(\frac{1}{r}\frac{\partial^2 \phi_3}{\partial r \partial \theta} - \frac{1}{r^2}\frac{\partial \phi_3}{\partial \theta} \right) \\ + \left(\frac{1}{r^2}\frac{\partial^2 \psi_3}{\partial \theta^2} + \frac{1}{r}\frac{\partial \psi_3}{\partial r} - \frac{\partial^2 \psi_3}{\partial r^2} \right) \end{array} \right\} \quad (17)$$

Then, the motion in the soft coating is completely controlled by the material parameters of medium 3 and the coefficient A_n.

2.1.3. Analysis of the matrix

Subjected to an incident harmonic wave, scattered wave will be generated due to the interface between the matrix and the coating. Then, the wave field in the matrix can be considered as the superposition of the incident wave field and the scattered wave field as

$$w^{(4)} = w^{in} + w^{sc}. \quad (18)$$

The displacement potentials in the matrix will be

$$\phi_4(r,\theta) = \sum_{n=-\infty}^{+\infty} \left\{ H_n^{(1)}(K_{L4}r)\, B_n^{(1)} \right\} e^{in\theta}, \quad (19)$$

$$\psi_4(r,\theta) = \sum_{n=-\infty}^{+\infty} \left\{ H_n^{(1)}(K_{T4}r)\, B_n^{(2)} \right\} e^{in\theta}, \quad (20)$$

where $H_n^{(1)}(\cdot)$ is the n^{th} order Hankel function of the first kind and B_n are the undetermined coefficients. The corresponding longitudinal and shear wave number, K_{L4} and K_{T4} are

$$K_{L4} = \omega \sqrt{\frac{\rho_4}{(\lambda_4 + 2\mu_4)}}, \quad (21)$$

$$K_{T4} = \omega \sqrt{\frac{\rho_4}{\mu_4}}. \quad (22)$$

The displacements and stresses of the scattered field in the matrix, u_r^{sc}, u_θ^{sc}, σ_{rr}^{sc} and $\sigma_{r\theta}^{sc}$, can be obtained by following the same procedures in the previous section. From the discussion above, the total displacements in the matrix will be

$$u_r^{(4)} = u_r^{in} + u_r^{sc}, \quad (23)$$

$$u_\theta^{(4)} = u_\theta^{in} + u_\theta^{sc}. \quad (24)$$

Then, the total stresses of $\sigma_{rr}^{(4)}$ and $\sigma_{r\theta}^{(4)}$ in the matrix have the form of

$$\sigma_{rr}^{(4)} = \sigma_{rr}^{in} + \sigma_{rr}^{sc}, \quad (25)$$

$$\sigma_{r\theta}^{(4)} = \sigma_{r\theta}^{in} + \sigma_{r\theta}^{sc}. \quad (26)$$

2.1.4. Analysis of the boundary conditions

There are two interfaces in the unit cell. For the interface between the rigid cylinder and elastic coating, the displacement continuity yields

$$u_r^{(1,2)}|_{r=r_1} = u_r^{(3)}|_{r=r_1}, \quad (27)$$

$$u_\theta^{(1,2)}|_{r=r_1} = u_\theta^{(3)}|_{r=r_1}. \quad (28)$$

From Newton's second law of motion, the equations of motion of the rigid cylinder can be obtained as

$$Ma_{G,x} = \int_0^{2\pi} \left(\sigma_{rr}^{(3)} r_1 \cos\theta - \sigma_{r\theta}^{(3)} r_1 \sin\theta \right) d\theta|_{r=r_1}, \quad (29)$$

$$Ma_{G,y} = \int_0^{2\pi} \left(\sigma_{rr}^{(3)} r_1 \sin\theta + \sigma_{r\theta}^{(3)} r_1 \cos\theta \right) d\theta|_{r=r_1}, \quad (30)$$

$$I_G\alpha = \int_0^{2\pi} \left\{ \begin{array}{l} \sigma_{r\theta}^{(3)} r_1^2 - \sigma_{rr}^{(3)} r_1 r_G \sin(\theta - \theta_1) \\ - \sigma_{r\theta}^{(3)} r_1 r_G \cos(\theta - \theta_1) \end{array} \right\} d\theta|_{r=r_1}, \quad (31)$$

where the angular acceleration of the rigid cylinder, α, is given by

$$\alpha = -\omega^2 \bar{\theta}. \quad (32)$$

The displacement and stress continuity formula also can be applied to the interface between the elastic coating and the matrix. Then, the following relations can be obtained as

$$u_r^{(3)}|_{r=r_2} = u_r^{(4)}|_{r=r_2}, \quad (33)$$

$$u_\theta^{(3)}|_{r=r_2} = u_\theta^{(4)}|_{r=r_2}, \quad (34)$$

$$\sigma_{rr}^{(3)}|_{r=r_2} = \sigma_{rr}^{(4)}|_{r=r_2}, \quad (35)$$

$$\sigma_{r\theta}^{(3)}|_{r=r_2} = \sigma_{r\theta}^{(4)}|_{r=r_2}. \quad (36)$$

To reduce the complexity of the expression of the incident wave $w^{in}|_{r=r_2}$ in local polar coordinate system, an integration method with limited number of collocation points

along the outer interface has been used [25], which can be written as

$$\int_0^{2\pi} w^{in}|_{r=r_2} e^{-in\theta} d\theta \approx \sum_{j=1}^{P} \int_{\theta_j}^{\theta_{j+1}} f_j(\theta)\, e^{-in\theta} d\theta, \tag{37}$$

where P is the number of the collocation points, $f_j(\theta)$ is the linear interpolation function of $w^{in}|_{r=r_2}$ between the angular coordinates θ_j and θ_{j+1}. These angular coordinates for uniformly distributed collocation points are

$$\theta_j = \frac{2\pi\,(j-1)}{P},\ \theta_{j+1} = \frac{2\pi j}{P}. \tag{38}$$

The collocation point density, δ, has been defined as

$$\delta = \frac{\lambda_i P}{2\pi r_2}, \tag{39}$$

where $\lambda_i = \lambda_{L4}$, the longitudinal wave length in medium 4 for longitudinal incident wave or $\lambda_i = \lambda_{T4}$, the transverse wave length in medium 4 for transverse incident wave. Then, with the coefficient vectors defined as

$$\{A\} = \left\{A_{-S}^{(1)} \quad A_{-S}^{(2)} \quad A_{-S}^{(3)} \quad ... \quad A_{S}^{(2)} \quad A_{S}^{(3)} \quad A_{S}^{(4)}\right\}^T, \tag{40}$$

$$\{B\} = \left\{B_{-S}^{(1)} \quad B_{-S}^{(2)} \quad ... \quad B_{S}^{(1)} \quad B_{S}^{(2)}\right\}^T, \tag{41}$$

$$\{C\} = \left\{u_{O,x} \quad u_{O,y} \quad \bar{\theta}\right\}^T, \tag{42}$$

$$\{D\} = \left\{A \quad B \quad C\right\}^T, \tag{43}$$

those coefficients can be calculated as

$$\{D\} = [Q]\,[W], \tag{44}$$

with S being the highest order of the series expansion in equations (10), (11), (19) and (20). $[Q]$ is the known transformation matrix and $[W]$ is comprised of the displacements and stresses due to the incident wave at the collocation points along the interface. After that, the wave field of the system will be readily solved.

This approach, however, can only apply to linear system. It should be mentioned that the rotational motions of the resonators make the system nonlinear, which can be observed from equations (7) and (8). To build a set of linear equations as described in equation (44), $\bar{\theta}^2$ has been replaced with $\beta\bar{\theta}$ to linearize the composite system and then the acceleration components of the mass centre of the cylinder can be rewritten as

$$a_{G,x} = -\omega^2 u_{O,x} + r_G\omega^2\bar{\theta}\,(\sin\theta_1 + \beta\cos\theta_1), \tag{45}$$

$$a_{G,y} = -\omega^2 u_{O,y} + r_G\omega^2\bar{\theta}\,(-\cos\theta_1 + \beta\sin\theta_1). \tag{46}$$

The initial value of parameter β is set as 0 and then calculate the steady-state rotational angle $\bar{\theta}$, which replaces β to calculate the next value of $\bar{\theta}$ until the difference between $\bar{\theta}$ and β is within a specific threshold value.

For the single cell problem, matrix $[Q]$ provides direct transformation from the values of the incident wave at the collocation points to the coefficients A_n, B_n and the motion parameters of the cylinder in matrix $[C]$. From the discussion above, the wave field of the composite system with a single cell can be readily calculated.

2.2. Interaction of multiple cells

For multiple resonators included in the system, pseudo-incident wave method can be introduced to study the dynamic interaction [21]. Then, every coated cylinder in the system can be regarded as a single inhomogeneity subjected to a pseudo incident wave, which consists of the original incident wave and the unknown scattered wave from other cylinders, as shown in Fig.2. Consider N interacting coated cylinders and the pseudo incident wave of the i^{th} cylinder, w_i^{ps}, can be expressed as

$$w_i^{ps} = w^{in} + \sum_{k=1,k\neq i}^{N} w_k^{sc}, \tag{47}$$

with w^{in} being the original incident wave and w_k^{sc} being the displacement due to the scattered wave from k^{th} inhomogeneity. Then, the relation between different inhomogeneities can be established, based on the continuity conditions along the interfaces.

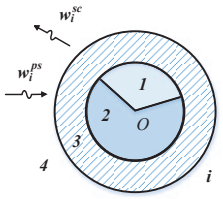


Figure 2: Wave interaction between the matrix and the coating of the i^{th} cell.

Based on the analytical solutions of a single inhomogeneity and the pseudo incident wave method, a set of linear equations for the expansion coefficients can be obtained as

$$\begin{bmatrix} [I]_1 & -\left[\bar{Q}\right]_1[M]_{12} & \cdots & -\left[\bar{Q}\right]_1[M]_{1N} \\ -\left[\bar{Q}\right]_2[M]_{21} & [I]_2 & \cdots & -\left[\bar{Q}\right]_2[M]_{2N} \\ \vdots & \vdots & \vdots & \vdots \\ -\left[\bar{Q}\right]_N[M]_{N1} & -\left[\bar{Q}\right]_N[M]_{N2} & \cdots & [I]_N \end{bmatrix} \bullet \begin{bmatrix} \left\{\bar{D}\right\}^{(1)} \\ \left\{\bar{D}\right\}^{(2)} \\ \vdots \\ \left\{\bar{D}\right\}^{(N)} \end{bmatrix} = \begin{bmatrix} \left[\bar{Q}\right]_1\left[\bar{W}\right]_1 \\ \left[\bar{Q}\right]_2\left[\bar{W}\right]_2 \\ \vdots \\ \left[\bar{Q}\right]_N\left[\bar{W}\right]_N \end{bmatrix}, \tag{48}$$

where matrices $[M]_{kj}$ relate to the effects of the j^{th} inhomogeneity on the k^{th}, matrices $\left\{\bar{D}^{(k)}\right\}$ are the vector composed of the expansion coefficients of the scattered wave

from the k^{th} inhomogeneity given by equation (43), matrices $\left[\bar{W}\right]_k$ represent the displacements and stresses at the collocation points at the interface of the k^{th} inhomogeneity due to the original incident wave, matrix $\left[\bar{Q}\right]_k$ stand for the known transformation matrix from the solution of the single k^{th} inhomogeneity, matrices $[I]_k$ are the identity matrices with a dimension of $(2S+1)$.

Then, the expansion coefficients and kinetic parameters of the rigid cylinders in vectors $\left\{\bar{D}\right\}$ can be determined by solving equation (48), from which the displacement and the stress of the wave field in the matrix and in the soft coating can be readily calculated.

3. Results and discussion

Consider the in-plane problem of the metamaterial system, consisting of 45 distributed eccentric coated cylinders with 5 rows and 9 columns, which are subjected to a harmonic longitudinal wave with excitation frequency ω. The longitudinal incident wave can be generally expressed in the polar coordinates as

$$u_r^{in} = u_0 \cos(\theta - \theta_0) e^{iK_{L4} r \cos(\theta - \theta_0)}, \tag{49}$$

$$u_\theta^{in} = -u_0 \sin(\theta - \theta_0) e^{iK_{L4} r \cos(\theta - \theta_0)}, \tag{50}$$

with u_0 being the displacement amplitude of the incident wave field and the incident wave propagation angle $\theta_0 = 0$. For the geometric parameters shown in Fig.1, $r_1 = 5 \times 10^{-3}$ m, $r_2 = 7.5 \times 10^{-3}$ m, $L = 2.1 \times 10^{-2}$ m and $\theta_2 = \pi/3$. The angles θ_1 of the coated cylinders are in the form of $m\pi/20$ with m as random integers. The materials used are listed in Table 1.

Table 1: Material Parameters.

	Material	Density (Kg/m^3)	λ (Pa)	μ (Pa)
1	Gold	19500	1.62E11	2.70E10
2	Aluminium	2700	5.87E10	2.60E10
3	Silicone rubber	1300	6.00E5	4.00E4
4	Epoxy	1180	4.43E9	1.59E9

In the multiple scattering computation, the highest order of the series expansion in the displacement potentials discussed, S, is set as 30. Also, the collocation point density δ is selected as 1000 for high accuracy.

3.1. Effective mass density

In this study, a square area with 9 cells in the centre of the system has been considered as the targeted element. From the boundary effective medium theory [22], the surface motion of this element, responding to the stimulations exerted by the outside waves, can be calculated in the form of effective displacements, forces on its boundaries. Then, the relation between the net force applied to the element and the average acceleration can be built to calculate the effective mass density.

Due to the symmetry of the system, the effective mass density can be obtained as

$$\rho_e = -\frac{F_{e,x}}{\omega^2 a^2 u_{e,x}}, \tag{51}$$

where a is the length of the element, ρ_e is the effective mass density, $u_{e,x}$ is the effective displacement of the cell in the x direction and it can be expressed as

$$u_{e,x} = \frac{1}{2a}\left(\int_{-a/2}^{a/2} u_x dy|_{x=a/2} + \int_{-a/2}^{a/2} u_x dy|_{x=-a/2}\right), \tag{52}$$

with the centre of the element as the origin of the coordinate system used. Similarly, $F_{e,x}$, the effective force applied to the element in the x direction, can be expressed in the form of

$$F_{e,x} = \left\{ \begin{array}{l} \int_{-a/2}^{a/2} \sigma_{xx} dy|_{x=a/2} - \int_{-a/2}^{a/2} \sigma_{xx} dy|_{x=-a/2} \\ + \int_{-a/2}^{a/2} \sigma_{xy} dx|_{y=a/2} - \int_{-a/2}^{a/2} \sigma_{yx} dx|_{y=-a/2} \end{array} \right\}. \tag{53}$$

3.2. Dynamic behaviour of the metamaterial system

The frequency-dependent mass density is a vital property of elastic metamaterials. The effective mass density of the system designed in the low frequency range has been illustrated in Fig.3. For comparison, the corresponding composite system with uniform resonators have been introduced with the same cylinder density and other parameters.

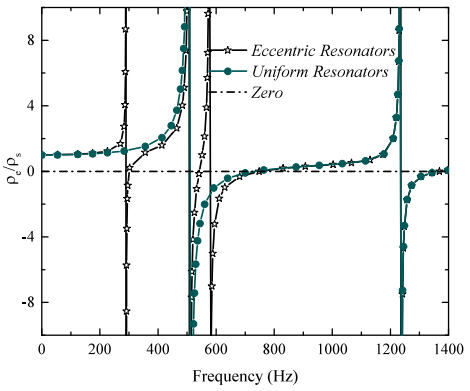

Figure 3: The effective mass density of the system with eccentric resonators and uniform resonators.

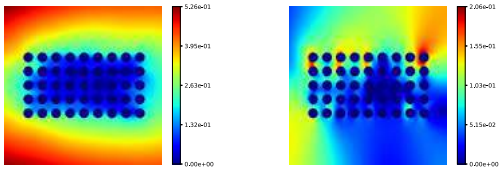
It can be easily observed from Fig.3 that there are four resonances in the low frequency range for the eccentric model. The resonances considered can be regarded as oscillations, in which the rigid cylinders serves as the heavy mass and the silicone rubber provides the soft spring. The

first one is the rotational resonance of the rigid eccentric cylinder, occurring at a very low frequency. The frequency range with negative mass density is relatively narrow. The second one is the translational resonance of the cylinder in the θ_1 direction and its corresponding natural frequency coincides with that of the uniform model as expected. For the third resonance, the translational direction of the cylinder is perpendicular to that of the second resonance. The fourth one is the resonance inside of the rubber coating with relatively small translation of the cylinders. It is more about the properties of the coating and the corresponding overall dynamic response of the eccentric model is almost the same with that of the uniform model. In other words, when r_G turns positive from 0, the uniform model will change into the eccentric model. The first resonance mode of the uniform model is split into three modes, as illustrated in Fig.3. The total width of the frequency ranges with negative mass density for the eccentric model is almost equal to that of the uniform model. However, the eccentric model can realize negative mass density at lower frequencies, which is crucial for the related applications.

It should be mentioned that the geometric parameters shown in Fig.1 and the material properties of the components listed in Table 1 can place a substantial influence on the overall dynamic response of the elastic metamaterial system.

For elastic metamaterials with negative mass density, one of their most prominent abilities should come to wave attenuation. The normalized wave displacement amplitudes (u/u_0) of the metamaterial systems have been illustrated in Fig.4, 5, 6 and 7 for the four frequencies from the first four band gaps of the system respectively. For better observation, the displacement inside of the rigid cylinders and elastic coating are not plotted.



(a) (b)

Figure 4: For $f = 290.46$ Hz, (a) the normalized amplitude of the displacement component in the longitudinal direction, (b) the normalized amplitude of the displacement component in the transverse direction.

It can be directly observed that the wave displacement amplitudes attenuate substantially inside of the metamaterial system. To better evaluate the vibration isolation ability of the system, the normalized displacement amplitudes has been plotted in Fig.8 along the line, which is located in the middle of second and third rows. Fig.8 clearly shows that the normalized displacement amplitudes in the longitudinal direction decrease along the line and reach their minimum values in the middle part. After that, these values begin to increase due to the boundary effect. The normalized displacement amplitudes in the transverse direction are much smaller than those in the longitudinal direction, following a similar changing trend. It should be mentioned that more eccentric resonators can be added to this metamaterial system to further enhance its wave attenuation ability and wave can not propagate through at the frequencies with negative mass density.

Photonic crystals

An experimental study of self-guided unidirectional waveguides by a chain of gyro-magnetic rods

Abstract-We experimentally studied the tunability of an unidirectional waveguides of magnetic photonic crystals(MPCs) which is a straight-line chain with gyro-magnetic rods. By changing the constitution parameters, we could achieve tunable one way transmission (OWT) characteristics. We studied the influence of normalized radius *R* and lattice constant *a* on band width and center frequency of OWT band.

Magnetic photonic crystals (MPCs) have been the focus in recent years for their amazing characteristics[1-3]. Recently a new type of one way waveguide has been proposed which is just a chain of gyro-magnetic rods, this flexible one way waveguide could be arbitrarily bended or curved[4].We theoretically and experimentally investigated the tunability of OWT in this MPCs chain under different constitution parameters in this paper.

First we calculated the band structures of this chain MPCs through multiple-scattering method (MSM)[5], the calculating results of band structure is shown in Figure 1. The chain sample is placed in the parallel-plate waveguide surrounded by absorbers. We specially designed the megnets to fully magnetize the sample. The MPCs chain is stimulated by a probe located at the end of the chain edge and the transmitted signal is detected at another end by Agilent vector network analyzer.

The OWT is originated from (magnetic surface plasmon MSP). The measured results are shown in Figure 2 and Figure 3, the measured results are in good accordance with the band results. Both results showed that we could tune the bandwidth and center frequency by modifying the configuration parameters, the larger normalized radius *R* of the ferrite rods(*R*=*r*/*a, r* is the real radius of ferrite rod) , the wider OWT band, and the higher center frequency. And if we fix the normalized radius, both width and center frequency of the OWT band will decrease with increasing lattice constant. The study illustrates this flexible structure could be widely applied such as tunable isolaters or tunable filters.

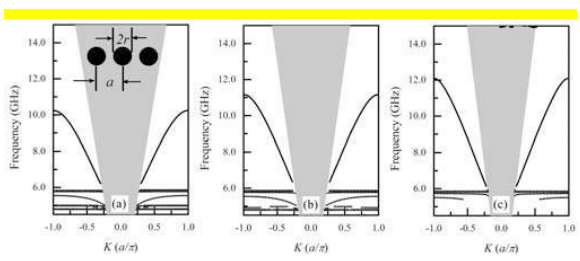

Figure 1: Scheme of MPC chain, and its MSP frequency range with different normalized radius under same magnetic field. (a) MPC chain with *r*/*a*=0.16, (b) MPC chain with *r*/*a*=0.22, (c) MPC chain with *r*/*a*=0.28

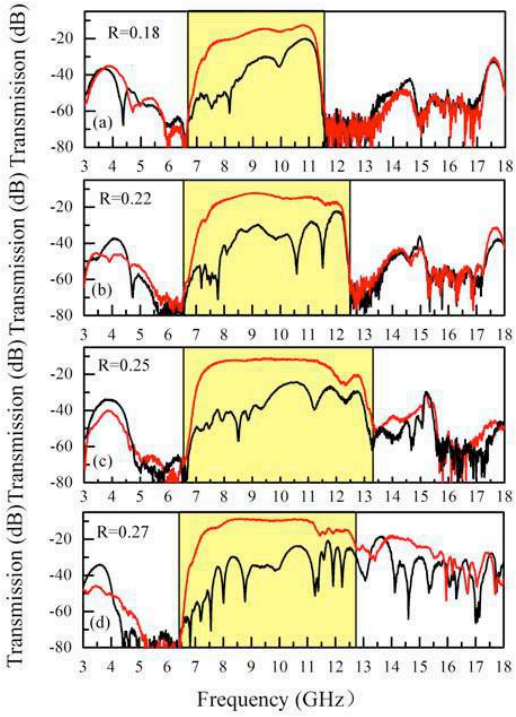

Figure 2: Transmission characteristics of MPC chain with different normalized radius. Red line is forward transmission, black line is backward transmission.(a) R=0.18, (b) R=0.22, (c) R=0.25, (d) R=0.27.

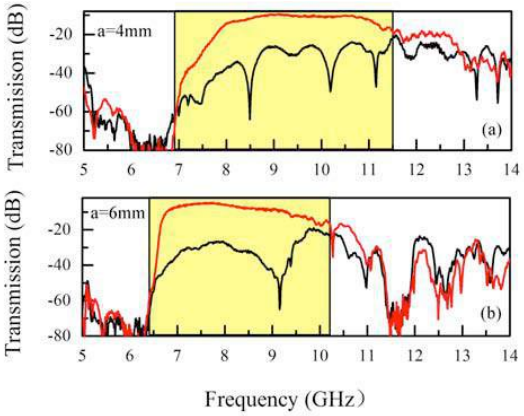

Figure 3: Transmission characteristics of MPC chain with different lattice constant. Red line is forward transmission, black line is backward transmission. (a) a=4mm, (b) a=6mm.

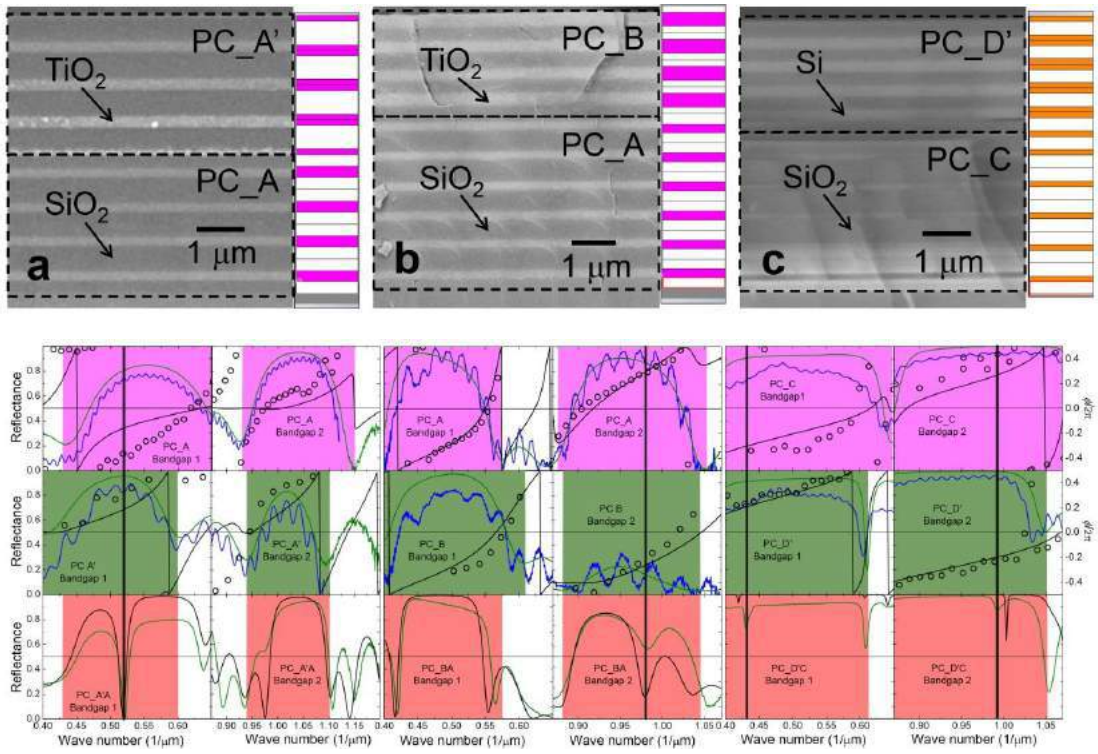
Abstract-Interface states in photonic crystals usually require defects or surface/interface decorations that are susceptible to imperfections. We show here that one can achieve robust interface states through the control of geometrical phase such that interface states can be guaranteed in even or odd, or in all photonic bandgaps of 1D photonic crystals. We verify experimentally the designed interface states in 1D multilayered photonic crystals fabricated by electron beam vapor deposition. We also obtain the geometrical phases by measuring the reflection phases at the bandgaps of the PCs and achieve good agreement with the theory. Our approach could provide a platform for the design of using interface states in photonic crystals for nonlinear optic, sensing, and lasing applications

The existence of interface modes localized at the boundary that separates two materials depend on very much on the details of the system. In principle, one can determine the existence of such interface modes by an explicit calculation or by performing an experiment. However, there are some special cases in which one can predict the existence of interface modes by knowing the properties of the bulk materials. For ideal case there are beautiful mathematical relations that assure the existence of interface modes for periodic media (photonic crystals) if the bulk carries some topological properties that can be labelled by some quantized quantities. A nice example is the geometric Zak phase in 1D crystals [1], which is known to be quantized if the system has inversion symmetry, and which can be used to predict the existence of interface modes [2]. As Zak phases are defined as the integral of "Berry connections" of the bulk bands, one might think that the experimental determination of such a quantity is very difficult. Here, we demonstrate that we can measure the Zak phase of a bulk band simply through the measurement of reflection phases in the band gaps using a thick gap Fabry Perot (FP) interference technique[3], and the measured Zak phases can indeed be used to predict the existence or absence of interface modes. Our results imply we can control the existence of interface modes by controlling the geometric phases of the bulk bands[4]. In our experiment, we can control the interface states' existence in 1st , 2nd or both the band gaps through the designed Zak phase. The results are summarized in below figures. Quantized Zak phases are robust against perturbations, such as fabrication imperfections, enabling the control of the interface states which may find practical applications.



Top Fig. 1: SEM and schematic pictures for 1D photonic crystals.

Bottom Fig. 2: Top and middle rows are reflection spectra (blue and green curves are for samples in FP and bare PC configuration, respectively) and reflection phases (black circles) for the PCs in top Fig. 1 as labeled. The black curves are numerical results for reflection phases calculated using slightly adjusted thicknesses as obtained from the SEM images in top Fig. 1 to account for small difference in layer thickness at the measured areas. The colored regions are bandgaps of the PCs. The last row is reflectance (in green) of the combined PCs. Odd and even columns correspond to bandgaps 1 and 2, respectively. The thick black vertical lines indicate the experimental interface states for the combined PCs. The black curves are calculated reflectance of the combined PCs.

Out-of-plane dispersive photonic band structure of a honey-comb photonic crystal

J. D. Valenzuela-Sau[1], **and R. García-Llamas**[2,*]
[1]Physics Doctorate, Universidad de Sonora, México
[2] Physics Research Department, Universidad de Sonora, México

Abstract-We present an alternative numerical method for calculating dispersive photonic band structures (DPBS). This method can be implemented considering experimental data or an approximate mathematical model for the dielectric constant and for others types of lattices and cross sections. Out-of-plane propagation is considered for a honey-comb photonic crystal given the high interest in graphene like structures.

Using the plane wave method [1], we implement a numerical method for calculating dispersive electromagnetic out-of-plane modes in two-dimensional Photonic Crystals (PCs). The eigenvalues matrix equation (1) is found and solved numerically by using an iteration algorithm to obtain the eigenfrequencies for both, in-plane (stationary) and out-of-plane (propagating) dispersive electromagnetic modes. This method allows us to consider experimental values or a mathematical model for the dielectric constant. Dispersive photonic bands structures (DPBSs) are obtained for a honey-comb array of cylinders of elliptical (circular) cross section. In-plane (out-of-plane) band structure considers perpendicular (oblique) propagation according to the homogeneous axis of the system. Out-of-plane studies have been made [2-4], however, neither of them considers dispersive media. In-plane dispersive PBS was compared with that presented in reference [5] in order to validate this method.

The eigenvalues matrix equation for the out-of-plane modes is,

$$\sum_{m',n'}\left[\varepsilon_2^{-1}(\omega)_{m-m',n-n'}\right]\left[\left(\vec{k}_{m,n}\times\vec{v}_{m',n'}\right)h_{m',n'}-\left(\vec{k}_{m,n}\times\vec{w}_{m',n'}\right)\left|\vec{k}_{m',n'}\right|^2 e_{m',n'}\right]=\frac{\omega^2}{c^2}\left(\vec{v}_{m,n}\left|\vec{k}_{m,n}\right|e_{m,n}+\vec{w}_{m,n}h_{m,n}\right) \quad (1)$$

Where $[\varepsilon_2^{-1}(\omega)]_{m-m',n-n'}$ are the coefficients of the multiplicative inverse of the dispersive dielectric constant, the vectors $\boldsymbol{v}_{m,n}$ and $\boldsymbol{w}_{m,n}$ are two orthogonal polarizations to the propagation wave vector, and $\boldsymbol{k}_{m,n}=k_{x,m,n}\boldsymbol{i}+k_{y,m,n}\boldsymbol{j}+\gamma\boldsymbol{k}$ is the wave vector which contains the Bloch vector, the reciprocal lattice vectors and the oblique propagation component γ.

In Fig. 1 the PBSs of a square lattice of Alumina (Al_2O_3) rods of circular cross section in vacuum are shown. The dispersive and non-dispersive PBSs correspond to the black and blue lines, respectively. The middle of the first band gap is ν =3.58 THz or λ=83.74 μm. The second band gap shifted towards lower frequencies. Dispersive out-of-plane PBSs of a honey-comb PC are in process of being calculated.

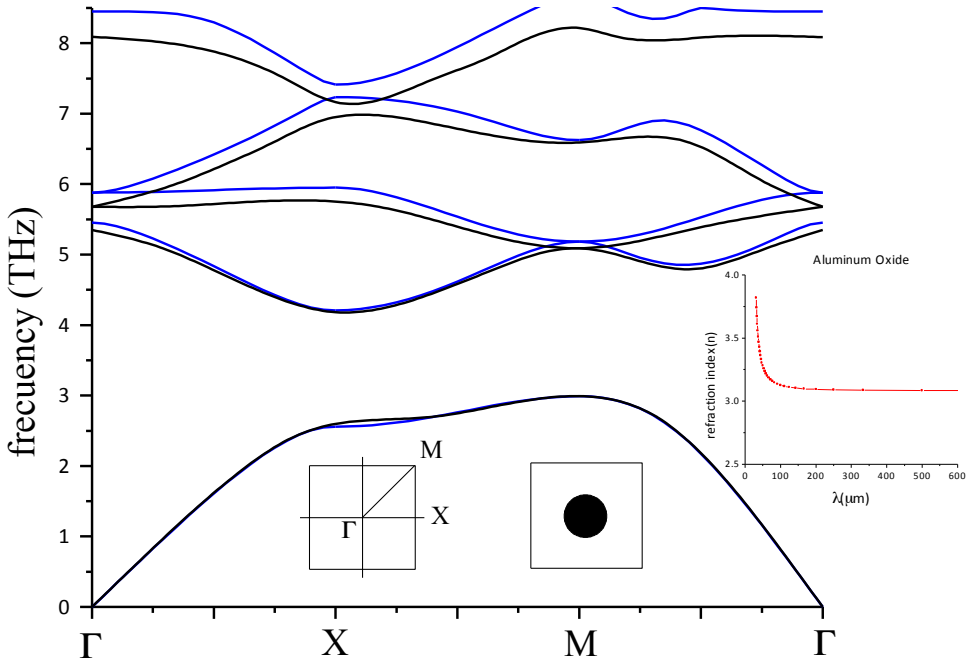

Fig. 1 In-plane photonic band structures of a square lattice of Alumina (Al_2O_3) rods of circular cross section in vacuum. Filling fraction is 0.1256. Dispersive [ε=ε(ω)] (black lines) against non-dispersive [n=3.1256 or ε=9.77] (blue lines) bands are presented. The period of the 2DPC is 31.3819μm. Both PBSs present practically the same band gap between 2.99 and 4.17THz. Inset shows the experimental values of the refraction index (n) of the Alumina as a function of the wavelength (λ) taken from ref. [6] used in this calculation.

Fabrication and Optical Characterization of All-biocompatible Photonic Crystals with Fluorescent Carbon-dots

Taeguen Kim[1], Chaeli Lim[1], Soonil Lee[1,2], and Na Young Ha[1,2*]
[1]Department of Energy Systems Research, Ajou University 16499, Suwon, Korea

Abstract-We fabricated biocompatible polymeric films doped with surface-modified Carbon-dots (C-dots) by drop-casting and introduced periodic nanostructures, i.e., photonic crystals on the surface of the C-dots/polymer films using a nanoimprint lithography. The nanostructured polymeric films doped with the C-dots showed strong enhancement of photoluminescence (PL) efficiencies at the specific spectral region depending on the periodicity of the nanostructured films. These nanostructured C-dots/polymer films can be new biocompatible fluorescent sources and photonic devices.

Fluorescent C-dots have been attractive from high water solubility, chemical stability, facile modification, low photo-bleaching, and excellent biocompatibility. However, the lack of understanding of PL origins in C-dots hinders various photonic applications of C-dots, although much progress is achieved in the synthesis of C-dots [1,2]. Here, to obtain surface-modified C-dots with enhanced PL efficiency, we employed a simple and low-cost microwave synthesis route based on citric acid and urea. For various C-dots synthesized under different urea ratios, physical and chemical properties of C-dots were investigated by using the transmission electron microscope (TEM) and the X-ray photoelectron spectroscopy (XPS) systems. The TEM images showed that C-dots were spherical nanoparticles with a size distribution of 2 - 20 nm in diameter and the average lattice spacing of C-dots was 0.23 nm. In the XPS spectra, we found that the surface amino group of the C-dots increased with increasing the urea ratio. These surface-modified C-dots samples with high density of surface amino groups exhibit high PL efficiencies.

Next, biocompatible polymeric films doped with the surface-modified C-dots were fabricated by drop-casting and one- and two-dimensional periodic nanostructures (photonic crystals) were introduced on the surface of the C-dots/polymer films using a nanoimprint lithography. The nanostructured polymeric films doped with the C-dots showed strong enhancement of PL efficiencies at the specific spectral region depending on the periodicity of the nanostructured films. These nanostructured C-dots/polymer films can be new biocompatible fluorescent sources and photonic devices.

Optical Characterization of Chiral Photonic Crystals on Nanostructured Perfluoropolymer Films

Heetae Ahn[1], Sooyeon Bae[1], Taeguen Kim[1], and Na Young Ha[1,2*]
[1]Department of Energy Systems Research, Ajou University 16499, Suwon, Korea

Abstract-We investigated optical characteristics of cholesteric liquid crystals (CLCs) on periodically-nanostructured perfluoropolymer films. Here, CLCs with periodic helical structures are chiral photonic crystals and nanostructured perfluoropolymer films are used as alignment layers to control orientations of cholesteric helices. The CLCs on the nanostructured films showed not specular but diffusive reflections at the specific spectral region. This nanostructured perfluoropolymer film can provide new possibility to engineer optical characteristics of the CLCs.

CLCs with periodic helical structures of rodlike molecules are chiral photonic crystals that exhibit photonic band gaps (PBGs) for circularly polarized lights with same handedness as CLC helices. In the CLC, the spectral position of the PBG is equal to an optical pitch of the CLC, related to the distance over which the director of molecules undergoes one full turn. Particularly, the CLC systems engineered to obtain broader widths of PBGs or multiple PBGs in the wide spectral region have been studied in various CLC multilayered films and polymer-based composite materials [1].

An amorphous perfluoropolymer poly[perfluoro(4-viny;ox-l-butene)](PPFVB), used in this study, has been used for antireflective coatings due to its low refractive index of 1.34 and high transmittance over a wide spectral region. Also, the PPFVB film has been investigated as a vertical alignment layer because of its strongly hydrophobic surface with low polarity and low polarizability [2].

In this study, we control molecular orientations of cholesteric helices by introducing a nanostructured PPFVB film as an alignment layer and investigate their optical characteristics such as reflectance, spectral position, width, and incident angle dependences of the PBGs. The nanostructured PPFVB films with various periodicities from 300 nm to 800 nm were fabricated by a nanoimprint lithography and characterized by measurements of atomic force microscope image and transmission spectra. The CLCs on the nanostructured PPFVB films showed not specular but diffusive reflections at the PBG region and this behavior did not depend on the periodicity of nanostructured PPFVB films. The present system with diffusive reflections can extend practical applications of CLCs to new photonic devices.

Ultrasensitive optical bio- and gas- sensors based on Photonic Crystal Surface Waves

S. K. Sekatskii

Laboratoire de Physique de la Matière Vivante, IPHYS, BSP, Ecole Polytechnique Fédérale de Lausanne, CH1015 Lausanne, Switzerland
corresponding author: Serguei.Sekatski@epfl.ch

Abstract- We report our recent results on development of ultrasensitive optical bio- and gas-sensors based on a properly designed Photonic Crystal supporting the propagation of bounded Electromagnetic Surface Waves along the Photonic Crystal – medium to be studied interface. In particular, extremely narrow magnetoplasmonic resonances have been observed, and kinetics of interactions of certain antibodies with the surfaces of *intact living bacteria* is measured.

Earlier, we have reported our first results on design and development of ultrasensitive optical bio- and gas-sensor based on a properly designed Photonic Crystal (PC) supporting the propagation of bounded Electromagnetic Surface Waves (ESW) along the PC – medium to be studied interface. These results include ultrasensitive hydrogen detection exploiting surface plasmons propagated along thin (8 nm-thick) Pd layers, launch of surface plasmon in blue (405 nm) and UV spectral ranges along thin gold films and their use for ultrasensitive nitrogen dioxide detection, as well as first experiments with metal-free and label-free optical biosensor. Here we would like to present our newest results in these directions.

A specially designed PC has been constructed and then used to support the surface plasmon propagation along thin *ferromagnetic* cobalt layer, which enabled to combine our approach with the magnetoplasmonics. Unprecedently narrow (equal to 0.02^0 thus corresponding to the surface plasmon propagation length exceeding 0.1 mm) for the field magnetoplasmonic resonance (Transversal Magnetooptical Kerr Effect) with 11% magnitude has been recorded [1]. Note, that for bare cobalt layers, without a specially designed PC, here this would be simply meaningless to speak about surface plasmons (similarly to the aforementioned Pd layers and blue plasmons on gold), because the propagation length is just of the order of the wavelength for all these cases. In other experiments, the *dielectric* layer of ferromagnetic bismuth-substituted iron garnet $Bi_{2,1}Dy_{0,9}Fe_{3,9}Ga_{1,1}O_{12}$ coated by thin gold layer has been used in a similar fashion, and excellent magnetooptical parameters were again demonstrated [2].

For biosensing, we used "bare" (no metal coating) PC – external medium (water) interface, specially treated to chemisorb protein layers, for the study of kinetics of the interprotein interactions. Besides quite large sensitivity, 0.2 pg/mm^2, this approach has additional advantages due to the possibility to excite simultaneously *s*- and *p*-polarized surface electromagnetic waves having very different penetration depths into an external medium. This enables to segregate surface and volume effects, thus drastically increasing both the sensitivity and reliability of the data obtained.

Another advantage of our approach is the appearing possibility also to study interactions involving rather thick (of the order of one micron) objects such as bacteria, viruses, and certain cell organells – option unattainable

for usual surface plasmon resonance-based detectors due to the short penetration depth of such plasmons. We have finished the development of a chitosan-based protocol of PC chip functionalization for bacterial attachment and performed experiments on antibody binding to living bacteria measured in real time by the PC ESW-based biosensor, see Fig. 1. Data analysis reveals specific binding and gives the value of the dissociation constant for monoclonal antibodies IgG2b against bacterial lypo-polysaccharides equal to $K_D = 6.2 \pm 3.4$ nM [3, 4]. *To our knowledge, this is a first demonstration of antibody binding kinetics to living bacteria by an optical biosensor*. Already the first obtained data revealed essential difference with the kinetic data on isolated bacterial membrane. For the latter, the binding constant K_D of monoclonal antibodies WN1 222-5 to isolated LPS membranes *E.coli* R-core types ranged from 10^{-8} to 10^{-5} M, that is essentially larger than measured by us for the whole intact living cells, were reported. We believe that this discrepancy may be caused primarily by different accessibility of the binding sites within the pool of membrane LPS molecules for possible intermolecular interactions, and that this circumstance should be taken into account analyzing the results of studies on isolated bacterial membranes, what is very important e.g. for the assessment of drag efficiency.

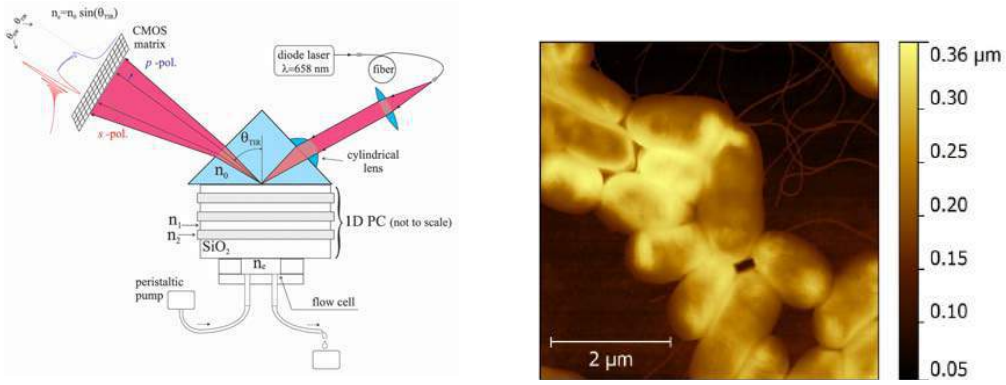

Fig. 1. Left: Schematic of the biosensor. Right: AFM image of (mono)layer of *E. coli* bacteria used as a generic "immobilized receptor layer" in the sensor during the kinetics measurements.

These results pave the way for further sensor and other applications of Photonic Crystal - supported surface waves, and the corresponding perspectives will be discussed.

Abstract-We describe a class of passive optical devices based on chirped photonic crystals that have structural properties are gradually varied along one direction, and are capable to localize and enhance local intensity of the incident light. We have addressed the challenge of realizing 3D chirped photonic crystals by using Direct Laser Write lithography, and report properties of the fabricated prototype structures for infrared spectral range.

In typical optical detectors, a thin p-n junction or other photosensitive layer is embedded in the bulk of absorbing material, and absorptive losses occurring outside the photosensitive region limit sensitivity of the detector (Fig. 1(a), top schematic). The unwanted losses can be reduced by building an optically transparent artificial structure capable to concentrate optical field near the detector, thus boosting its absorption rate and electronic response. Chirped photonic crystals (ChPhC) whose parameters (lattice period or dielectric filling ratio) are smoothly varied along one direction, can be used as field concentrators. At a certain depth inside the ChPhC, where incident waves encounter local photonic band gap (PBG), light propagation becomes slowed down and reversed, leading to field localization and intensity enhancement (Fig. 1(a) bottom schematic and Fig. 1(b)). This principle [1] can be useful for sensitivity enhancement of optical detectors, and was previously experimentally confirmed at microwave frequencies, where fabrication of 3D ChPhCs can be accomplished by simple mechanical machining and assembly, since large ChPhC lattice periods on the order of centimeters are required at these frequencies. However, realization of 3D ChPhCs for optical frequencies presents a significant fabrication challenge, since ChPhC period must be reduced to micrometer and even sub-micrometer range, and therefore has not been attempted before. One of the few 3D structuring techniques capable of high spatial resolution is Direct Laser Write (DLW) lithography [2], which is based on optical exposure of photoresist by a tightly focused beam of an ultrashort laser. Exposure due to non-linear two-photon absorption is induced selectively at the beam focus, while size of the exposed region can be reduced to less than 100 nm by controlling the exposure level. Thus, complex 3D patterns can be drawn by 3D focus scan. Previously, uniform photonic crystals were successfully fabricated using DLW [2]. Figure 1(c) shows Scanning Electron Microscopy (SEM) images of 3D ChPhC samples fabricated in this study. The samples are based on a 3D woodpile architecture, which is modified by introducing a spatial chirp along the woodpile stacking direction by gradually varying the

corresponding lattice period. Two SEM images shown on the left and right of Fig. 3(c) show spatially uniform (non-chirped) and chirped samples, respectively. In the latter image, gradual decrease of vertical lattice period from 0.58μm (at the top) towards 0.38μm (at the bottom) can be seen, while non-chirped sample has the same lattice period of 0.58μm throughout its thickness. Figure 1(d) compares experimental infra-red (IR) reflectance spectra of spatially uniform and chirped photonic crystals measured along the woodpile stacking direction. As can be seen, both structures exhibit reflectance peaks due to PBG. Spectral broadening and lower peak reflectance in the ChPhC sample can be attributed to the presence of spatial chirp. According to numerical simulations, field intensity enhancement by about five times can be expected in the ChPhC sample. DLW technique in principle allows one to embed thin, transparent detectors into the structures, and thus may enable relatively easy implementation efficient light detection schemes in optical detectors. Factors leading to field enhancement at various wavelengths, and practical possibilities to tune the PBG frequency towards telecommunications spectral range will be discussed.

High Quality Photonic Crystal Cavity with low index materials by using Slot Mode

Abstract-We suggest a photonic crystal cavity which confines the photons in low index material for telecommunication wavelength. The photonic crystal consists of periodic Si/SiO□/Si rods. In this cavity, the vertical losses can be reduced by low index slot mode and the horizontal losses can be reduced by photonic bandgap of square lattice photonic crystal slab. For telecommunication wavelength, we can get the highest quality factor 11200 by moving nearest neighborhoods of center defect on suggested photonic crystal structure.

A Si, material used for many electronic devices, has a limit due to its indirect bandgap. Because of its indirect bandgap, we need to another material for example GaAs, as an emitter. However, it is very difficult way to combine Si based electric devices and optical devices that have different lattice structure. We suggest a photonic crystal with low index materials by using slot mode. The vertical loss of cavity can be reduced by low index slot mode and the horizontal loss of cavity can be reduced by photonic band gap of square lattice photonic crystal slab. We used finite-difference time-domain(FDTD) and plane wave expansion(PWE) method to simulation.

In this research, we suggested high quality photonic crystal cavity with low index materials by using slot mode. The photonic crystal has 500 nm lattice constant and 125 nm radius for each cylinder. Each cylinder has a height of 1000 nm, and 10 nm of the center is composed of SiO□ and the rest is composed of Si. (Fig. 1. (a)) The reduced radius defect was positioned at center of entire slab structure for inducing fundamental mode. (Fig. 1. (b))

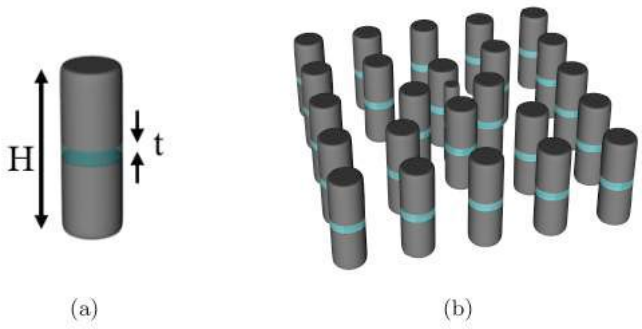

Figure 1: (a) Single cylinder structure. H is height of cylinder. t is thickness of SiO□ slot. (b) Entire photonic crystal structure in air.

For finding proper height of slab, we carried out the FDTD simulation that calculate effective index of Si

plane with height from 200 nm – 1500 nm at 1550 nm wavelength. When the height of plane is higher than 1000 nm of the effective index is saturated to bulk Si (3.47). Thus, we insert SiO□ slot to Si plane with height of 1000 nm. The effective index of combined with Si and SiO□ plane was decreasing while increases thickness of SiO□ slot. For example, when slot thickness is 10 nm, the effective index of combined plane is about 3.30.

Therefore, the 1000 nm Si cylinder with 10 nm SiO□ slot can generate a photonic bandgap. photonic crystal slab has wide bandgap when height of structure approximately 2 - 2.5 times of lattice constant [1]. Therefore, we choose lattice constant of 500 nm when each cylinder has 1000 nm height and the 500 nm lattice constant. Fig. 2. (a) is the photonic band diagram of proposed structure (Fig. 1. (b)) calculated by PWE.

The photonic bandgap was appeared in 1170 - 1690 nm (1620 – 1114 THz) area. The target wavelength (1550 nm) is in the photonic bandgap. Using FDTD simulation, we found the cavity mode appeared in given the defect at center of structure. When the center defect radius is 90 nm and nearest neighborhoods are moved to 70 nm defect toward, we could get the highest Q factor 11200 for 1530 nm wavelength. (Fig. 2. (b))

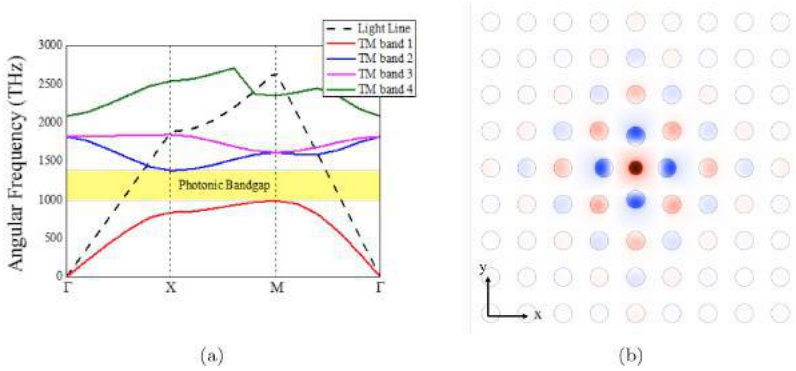

Figure 2: (a) Photonic band structure, cylinder radius = 125 nm, lattice constant = 500 nm. (b) Mode profile of 1530 nm cavity mode, defect radius = 90 nm, nearest neighborhood shift = 70 nm.

We suggested a photonic crystal with low index materials by using slot mode for telecommunication wavelength. We had checked the effective index is approximately 3.3 for height 1000 nm Si cylinder that has 10 nm thickness SiO□ slot. We confirmed that our structure can has enough photonic bandgap when it has square lattice photonic crystal structure. For 500 nm lattice and radius of each cylinder is 125 nm, telecommunication wavelength (1550 nm) was in the photonic bandgap. As a result, when the center defect radius is 90 nm and nearest neighborhoods are moved to 70 nm defect toward, we could get the highest Q factor 11200 for 1530 nm wavelength.

Abstract-We theoretically examine the photonic band structures of an array of quasi-one-dimensional systems where a flat band can exist. Since the interactions in the photonic lattice are not restricted to the nearest neighbor interactions, the flat bands are perturbed by coupling to the dispersive bands, resulting in the avoid crossing nature. The perturbation-induced delocalization is analyzed based on understanding of the life time of localized modes.

Recently, the interest in the flat bands has been remarkably increased in various fields such as condensed matter, optical physics[1-2]. As theoretically predicted by the tight-binding approaches in the condensed matter context, the existence of the flat band is represented by the compact localized states via quantum destructive interferences[2-3], indicating the macroscopic degeneracy. On the other hand, the flat-band formation has been successfully confirmed by realizing the compact localization of light in symmetric cavities of the photonic systems[1,4-5]. While the flat-band modes in either quasi-one-dimensional or two-dimensional photonic lattices have been clearly demonstrated, research on flat bands in an array of quasi-one-dimensional lattices has been unexplored yet because of the existence of unwanted interactions such as next-nearest neighbors coupling, which are simply dismissed in the tight-binding approach. It has been reported that, in bi-layer two-dimensional Lieb lattice, the inter-layer coupling results in the splitting of the flat bands, maintaining their flatness over the in-plane momentum space[6]. In the same context, it is no wonder that the same phenomenon occurs in the case of quasi-one-dimensional lattices: flat bands are still found along the one-dimensional line in the momentum space.

In this work, we consider the more realistic but complicated systems in flat-band photonic lattices, where all possible interactions are taken into account, and examine how the existence of the perturbed flat bands is reflected in optical response spectra and light propagation through the systems. In an array of the quasi-one-dimensional lattices, the one-dimensional flat bands can be still observed whereas two-dimensional flat bands cannot be found. Interestingly, the one-dimensional flat bands exist along both Brillouin zone boundaries, $\Gamma \rightarrow X$ and $\Gamma \rightarrow Y$, at different frequencies (see Fig.1). Anisotropic optical response, obviously, is observed with respect to the propagating direction of the incident waves, and directional dependence of the transmission spectra is also found. Furthermore, it is shown that the presence of perturbations give rise to the delocalization of the flat-band modes, and such delocalization nature is investigated by examining the life time of the perturbed flat-band modes.

By exploring the properties of the perturbed flat band by means of optical response, our results allow for more in-depth understanding of the localization of light in flat-band photonic lattice, which can be easily found

in realistic systems. Anisotropic and directional optical transmission/reflection spectra might be of interest for future optical applications in terms of metamaterials.

Abstract-We have theoretically studied the probability of spontaneous emission rate of the emitter placed in a one-dimensional disordered photonic crystal. It is demonstrated that at high levels of disorder photonic band gap (PBG) is narrowed, and the probability of emission in the center of PBG becomes significantly different from zero, and in the PBG may occur localized states for which the spontaneous emission is significantly enhanced.

Disordered photonic crystals attract interest with the aim of the possibility of light localization [1] in such structures, in analogy with electron localization [2], known as Anderson localization. The aim of this work is to study the influence of disorder on the PBG [3] and the related problem of wave localization in disordered optical media.

We study the probability of spontaneous emission by using S-quantization formalism [4]. We have shown that for a dipole emitter placed in a disordered photonic crystal, the spontaneous emission rate can be enhanced if the frequency corresponds to the optical eigenmode of the structure, and suppression of spontaneous emission can be observed in the case of bandgap, or when the position of the emitter corresponds to a node in the profile of the electric field of the eigenmode. We study the influence of variation of disorder parameter. Particularly, we have demonstrated that at high levels of disorder edge states penetrate into the photonic band gap (PBG), PBG is narrowed, and the probability of emission in the center of PBG becomes significantly different from zero. In addition, in the PBG may occur localized states for which the spontaneous emission can be significantly enhanced.

Abstract-

Slow light photonic crystal (PhC) waveguides tightly compress propagating light and increase interaction times, yet their practical application is largely limited to moderate group indices (n_g <100). This limitation persists because nearly all research has focused on a single lattice type: the triangular lattice. Here, we present kagome lattice waveguides with an intrinsically high group index for slow light away from the band edge. We experimentally observe n_g >150 and reduced propogation losses compared to traditional PhC waveguides.

Two dimensional photonic crystals have been extensively studied because of their ability to tightly confine light to wavelength order dimensions to form high Q cavities and slow light waveguides [1-3], which are of significant interest for applications in interconnects, sensing and strong light-matter interaction [3]. However, the vast majority of 2D photonic crystal work has focused on only a single crystal structure: the triangular lattice. While this geometry has a demonstrated versatility and been used to develop many different devices, it is not ideal for all applications. For instance, waveguides made in the triangular lattice exhibit slow light near the band-edge, where propagation losses are much higher. Even when heavily optimized, the group index (n_g) in such structures is generally limited to ~100 [4].

Rather than further optimizing such waveguides, we investigated whether the crystal lattice itself could be changed to improve slow light in such structures. The kagome lattice consists of a super lattice of missing holes on top of the triangular lattice (Fig. 1a) and supports multiple photonic bandgaps (Fig. 1b). Intuitively, the kagome lattice can be considered to resemble a tight-binding model, compared to the triangular lattice, which is better approximated by a "free photon" (or free electron for electronic crystals) approximation. This leads to larger photonic band gaps and flatter bands in the kagome lattice [5, 6].

A variety of waveguides can be formed by line defects in the kagome crystal lattice, some of which show some cavity-like behaviour in their propagation modes (Fig. 2a). The propagating mode (Fig. 2b) shows clear cavity-like field behaviour, producing slow light (ng > 150, see Fig. 2c) after only rudimentary dispersion engineering. It is important to note that this slow light section of the dispersion curve is away from the band-edge (light blue dispersion curve in Fig. 1b). Furthermore through use of more sophisticated dispersion engineering of these kagome waveguides, we have observed group indices exceeding 300,000 in numerical simulations.

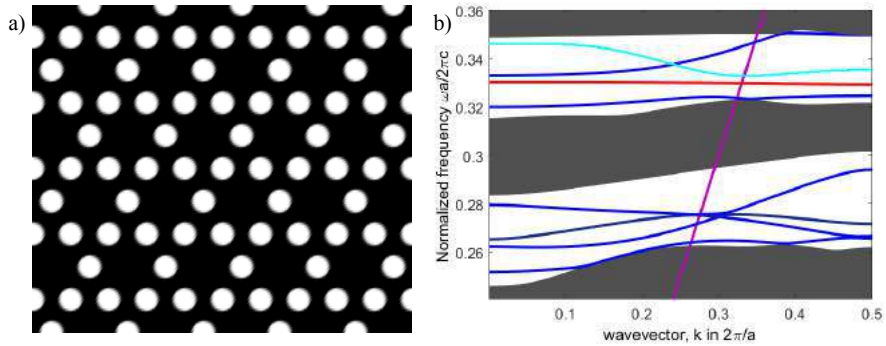

Fig 1: a) Schematic of a bulk kagome lattice. b) Band gaps in dispersion curve of a kagome lattice PhC, with slowlight waveguide modes introduced by a line defect.

We demonstrate that the kagome lattice supports slow light waveguide modes with higher group indices compared to the traditional triangular lattice photonic crystal, even before dispersion engineering. We also consider how the propagation losses in the slow light region are reduced by it being away from the band-edge. We believe that kagome lattice PhCs could thus find practical application for small-footprint, slow light systems as well as providing a medium for fundemental research on slow and stopped light.

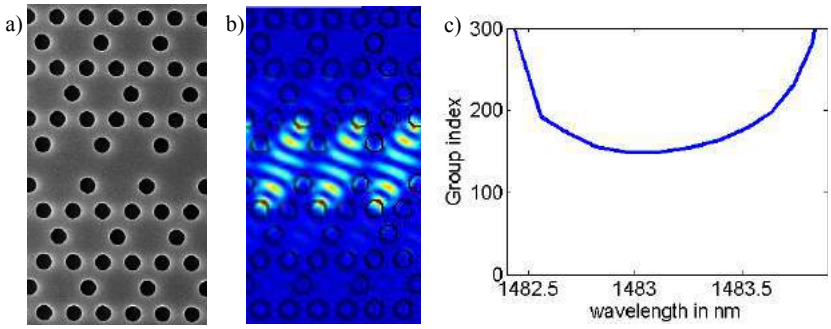

Fig 2: a) Scanning electron microscope image of a kagome lattice waveguide and b) field profile in slow light region, showing cavity-like behaviour of the propagation mode. d) Theoretical group index curve of the mode shown in c).

Abstract - The surface plasmon effect in metallic photonic crystals has been investigated. The band structure graph is the only graph that can be used to explain the characteristics of photonic crystals. In this work the band structure graph has been used to describe these characteristics, which include the surface plasmon effect of photonic crystals. Recently, band structure graphs for frequency-dependent materials have been analyzed by several researchers. The surface plasmon effect has been found for these materials. This article reports the effect of surface plasmons when the relative permittivity is changed from band structure graphs. The numerical results show the magnetic field distribution of waves on the photonic crystals added for each frequency.

1. Introduction

Photonic crystals have been extensively developed since the prediction and investigation of Yablonovitch and John[1], [2]. This active research has been extended to metallic photonic crystals, and more characteristics of photonic crystals are expected to be discovered compared with the conventional dielectric-dielectric photonic crystals [3]–[23]. It is well known that electromagnetic waves with frequencies lower than the plasma frequency of metals cannot propagate through a bulk metal. But it is possible for electromagnetic waves to be guided below the plasma frequency and attributed to the surface plasmon effect if an array of dielectric components is embedded in the bulk metals [24].

Kuzmiak et al. studied the dispersion relation of photonic crystals containing metallic components in two dimensions (2D) using the plane wave expansion method and the Drude model [10-12]. Low et al. continued their calculation by studying metallic photonic crystals using the modified plane wave expansion method with the Drude model with different dielectric rods in the E polarization mode [24]–[26]. Several characteristics were observed in the dispersion relation graphs, such as flat bands occurring at some of the frequencies, a group velocity anomaly in the band edges, and an effective plasma frequency in the E polarization mode. The H

polarization mode has also been extensively studied by several scientists [8], [10], [11]. Kuzmiak et al. [10], [11] calculated band structure graphs for frequency-dependent materials in a vacuum background using the plane wave expansion method. They also included the damping frequency of the metallic component in his calculation. But unfortunately their calculation was limited to only air or vacuum backgrounds. Their calculation was generalized by Low et al.[27]. Then, Low et al. [24], [26] continued the development of the band structure equation for photonic crystals in metals. The surface plasmon effect was detected in the band structure graphs in this investigation.

In this paper, a plane wave expansion method for metallic photonic crystals with different dielectric rods in H polarization mode is used. Although some results have been published [8], [11], [14], [28], [29], they have not included any extensive discussion of the surface plasmon effect when relative permittivity is changed. The surface plasmon effect is very obvious in the band structure graphs at first glance [24]. So, in this paper, we investigated the surface plasmon effect when the relative permittivity of rods is changed in the metallic photonic crystals. Because the band structure graph presents only the energy change in the metallic photonic crystals, we needed a commercial package to verify whether the surface plasmon effect exists in the metallic photonic crystals. The occurrence of magnetic field distributions at each flat band has been investigated by using COMSOL Multiphysics software.

2. Photonic Band Structure Graph of Metallic Photonic Crystals with Dielectric Rods

We sketch the cross section view of the photonic crystals in Figure 1.

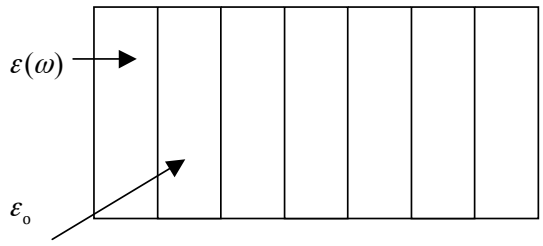

Figure 1 Illustration of the metallic photonic crystals arrangement (square lattice).

The band structure graph has been derived for H polarization for metallic photonic crystals with dielectric rods in Equation (1):

$$\varepsilon_0\mu^2 A(k\,|\,G) - \mu\left[\begin{array}{l}\left(\varepsilon_0 + \varepsilon_0\dfrac{c^2}{\omega_p^2}|k+G|^2\right)A(k\,|\,G) \\ +\left(1-\varepsilon_0\right)\dfrac{c^2}{\omega_p^2}\sum_{G'}(k+G)\mathrm{g}(k+G')2f\dfrac{J_1\left(|\,G-G'\,|\,R\right)}{|\,G-G'\,|\,R}A(k\,|\,G')\end{array}\right] \\ +\frac{c^2}{\omega_p^2}\sum_{G'}(k+G)\mathrm{g}(k+G')2f\frac{J_1\left(|\,G-G'\,|\,R\right)}{|\,G-G'\,|\,R}A(k\,|\,G') = 0 \tag{1}$$

where $\mu = \omega/c$, ε_0 is the relative permittivity, k is the wave vector, G is the reciprocal lattice, J_1 is the first Bessel function, R is the radius of the rods, ω_p is the plasma frequency of the metals, c is the speed of light, and ω is the eigenfrequency. Equation (1) represents a generalized eigenvalue problem. A linearization technique is used. An equation in the following form is obtained:

$$\mu^2\overset{\iota}{J} - \mu\overset{\iota}{K} + \overset{\iota}{L} = 0 \tag{2}$$

where the elements $\overset{\iota}{J}$, $\overset{\iota}{K}$, and $\overset{\iota}{L}$ of $NG \times NG$ matrices are given as

$$\overset{\iota}{J} = \varepsilon_{\mathrm{o}} \tag{3}$$

$$\overset{\mathrm{t}}{K} = \left[\begin{array}{l}\left(\varepsilon_{\mathrm{o}} + \varepsilon_{\mathrm{o}}\dfrac{c^2}{\omega_p^2}|k+G|^2\right)A(k\,|\,G) \\ +\left(1-\varepsilon_{\mathrm{o}}\right)\dfrac{c^2}{\omega_p^2}\sum_{G'}(k+G)\mathrm{g}(k+G')2f\dfrac{J_1\left(|\,G-G'\,|\,R\right)}{|\,G-G'\,|\,R}A(k\,|\,G')\end{array}\right] \tag{4}$$

$$\overset{\mathrm{t}}{L} = \frac{c^2}{\omega_p^2}\sum_{G'}(k+G)\mathrm{g}(k+G')2f\frac{J_1\left(|\,G-G'\,|\,R\right)}{|\,G-G'\,|\,R}A(k\,|\,G') \tag{5}$$

Equation (2) is a second-order eigenvalue problem, which can be represented by the following matrix form:

$$\overset{\text{t}}{M} = \begin{pmatrix} 0 & \overset{\text{ι}}{IJ} \\ \overset{\text{t}}{K} & \overset{\text{t}}{L} \end{pmatrix} \tag{6}$$

The complete solution of Equation (6) is obtained by solving the eigenvalues of $\overset{\text{ι}}{M}$ using the diagonalization of this non-Hermitian matrix.

3. Result and Discussion

In this article, four examples of different materials with the same filling fraction $f = 0.5$ are used as cylindrical rods in a copper medium. The plasma frequency of copper is $\omega_p = 1914 \times 10^{12}$ THz. The band structure graphs are plotted along $M(\pi/a, \pi/a)$ - $\Gamma(0,0)$ - $X(\pi/a, 0)$ in the first irreducible Brillouin zone. The magnetic field distribution graphs are plotted at k = 0 with their respective frequencies. The dimensions of photonic crystals are in micrometers.

From the theory, there should be no wave activities inside the metallic structure below the plasmonic frequency. But from the previous investigation [24], wave activities below the plasmonic frequency are detected. This is because the photonic crystals structure exhibits a very special characteristic, which is the surface plasmon effect. The band structure graph of copper photonic crystals with air rods is plotted in Figure 2(a). The band structure graph has a lot of flat bands. To confirm the effect of surface plasmons, COMSOL Multiphysics software was used to investigate the magnetic field distribution of the photonic crystals at k = 0 at each frequency. Figure 2(b) shows the magnetic field distribution when frequency at 1280 THz ($\omega a/2\pi c = 0.86$). Obviously, there is a surface plasmon effect at this frequency and we find that some of the wave is inside the air rods. Then, the frequency being used in the magnetic field distribution graph is lowered to 537 THz ($\omega a/2\pi c = 0.28$) and the result is shown in Figure 2(c). The wave is only on the surface of the air rods, which is the surface plasmon, and no wave is inside the rods. Then the frequency is further lowered to 185 THz ($\omega a/2\pi c = 0.098$) and the magnetic field distribution graph of this frequency is shown in Figure 2(d). There is a complete wave localized (peak to valley wave) across the air rods. The frequency range shows that the wave is near the surface of the rods. This agrees very well with the band structure graph. Flat bands in all the mentioned frequency points in the band structure graph are evidence of the surface plasmon effect [30]. But

the flat bands vanished when $\omega a/2\pi c \geq 1$. This corresponds to the fundamental metallic characteristic where the wave is able to propagate in a metal when the frequency is larger than the plasmon frequency. The magnetic field distribution graph of photonic crystals at $\omega a/2\pi c = 1.2$ (2255 THz) is plotted in Figure 2(e). The wave is propagating randomly across the air rods. So, it is obvious that the wave is distributed around the rods at frequencies below $\omega a/2\pi c = 1.2$. All the waves below this frequency are surface plasmon waves. This is described very well in the band structure graph.

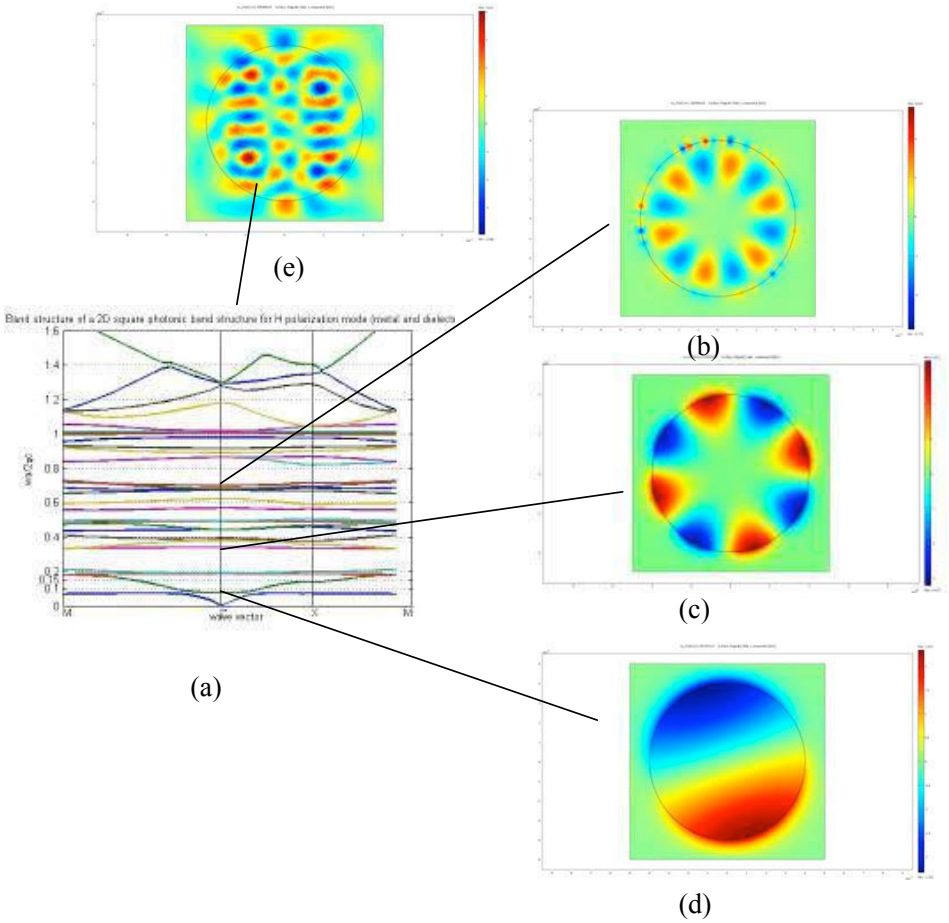

Figure 2 (a) Band structure graph of air rods with filling fraction $f = 0.5$ in copper medium in H polarization mode. Magnetic field distribution at frequency (b) 1280 THz (c) 537 THz (d) 185 THz (e) 2255 THz.

Equation (1) is utilized to plot the band structure graph of a Teflon ($\varepsilon_o = 2$) rod in the copper medium as shown in Figure 3(a). The band structure graph is very similar to the band structure graph of Figure 2(a). It has several flat bands below the normalized frequency, $\omega a/2\pi c = 0.8$ and the frequency is lower than the frequency of the previous structure. A band gap appearing in the frequency range $0.8 \le \omega a/2\pi c \le 1$ shows that this structure is a typical photonic crystal structure. Further, the magnetic field distribution at frequencies 1279 THz, 728 THz, and 138 THz are shown in Figures 3(b), 2(c), and 2(d) respectively. In Figure 3(b), the wave is localized in the Teflon rods and found on the surface of the rods. Figure 3(c) shows the same characteristic with longer wavelength. Then, Figure 3(d) shows that a complete wave is localized in the Teflon rods.

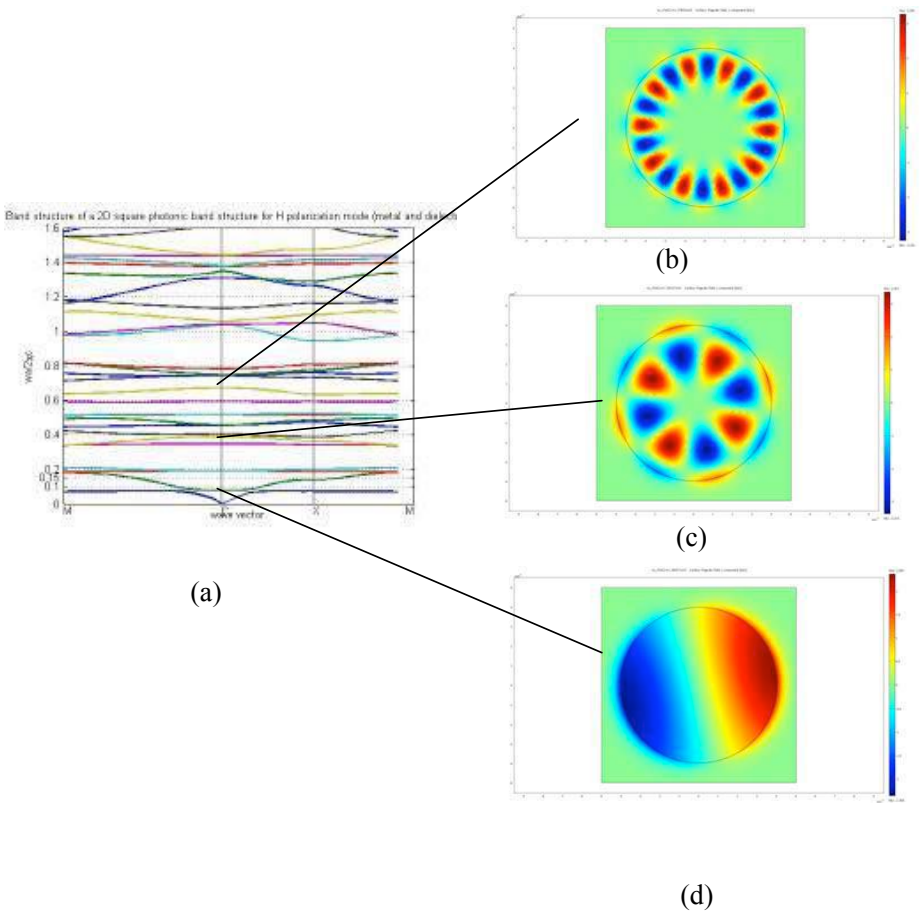

Figure 3 (a) Band structure graph of Teflon rods with filling fraction $f = 0.5$ in copper medium in H polarization mode. Magnetic field distribution at frequencies (b) 1279 THz, (c) 728 THz, and (d) 138 THz.

Then the dielectric constant of rods was increased to $\varepsilon_o = 4.9$ which is FR-4. FR-4 is insulator which is very common in electronic industry. The band structure graph is plotted in Figure 4(a). It is obvious that the flat bands are fewer; they are situated below the normalized frequency $\omega a/2\pi c = 0.6$. The magnetic field distributions of the flat bands at $\omega a/2\pi c = 0.34$(646 THz) and $\omega a/2\pi c = 0.075$ (142 THz) are plotted in Figures 4(c) and 3(d) respectively. In Figure 4(c), the wave is not only localized on the surface of the FR-4 rods but also inside the FR-4 rods. The

wave is in a regular waveform. In Figure 4(d), the waveform is different from the waveform of air and Teflon rods. In the air and Teflon rods, there is a complete wave propagating across the rods. But in the FR-4 rods, the waveform is separated into two complete waves, localized around the surface of the rods. The phenomenon appearing in Figure 2(e) is found in Figure 4(b). The wave is propagating irregularly. But the frequency of Figure 4(b) is lower than the frequency in Figure 2(e). This shows that the wave is propagating in the FR-4 rods at the lower frequency.

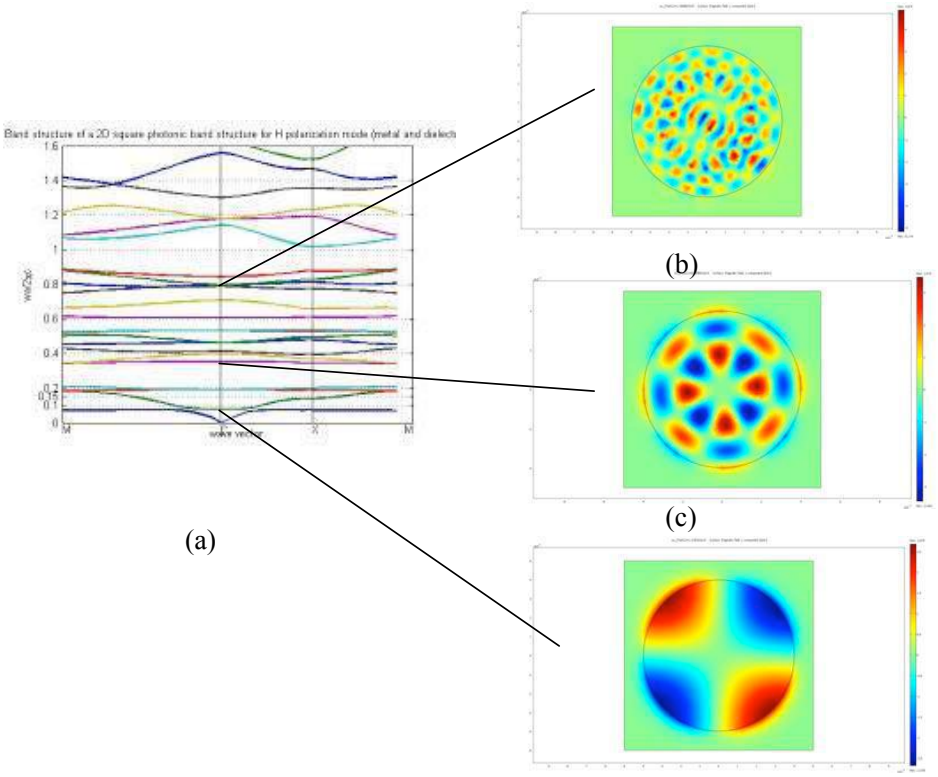

Figure 4 (a) Band structure graph of FR-4 rods with filling fraction $f = 0.5$ in copper medium in H polarization mode. Magnetic field distribution at frequencies (b) 1491 THz, (c) 646 THz, and (d) 142 THz.

The dielectric constant of the rods was further increased to 12.96 in the case of gallium arsenide (GaAs). The band structure graph is plotted in Figure 5(a). The flat bands are less frequent compared to the three materials investigated earlier. This means that the effect of surface

plasmons is reduced. The magnetic field distribution of $\omega a/2\pi c = 0.093$ (176 THz) is shown in Figure 5(d). The waves are localized near the surface of the GaAs rods. But when the frequency is increased to $\omega a/2\pi c = 0.39$ (743 THz), the waves are propagating out from the center of the GaAs rods. The magnetic field distribution graph is shown in Figure 5(c). It no longer shows a surface plasmon effect. Then, the frequency was further increased to $\omega a/2\pi c = 0.80$ (1499 THz); the waves are propagating randomly inside the GaAs rods.

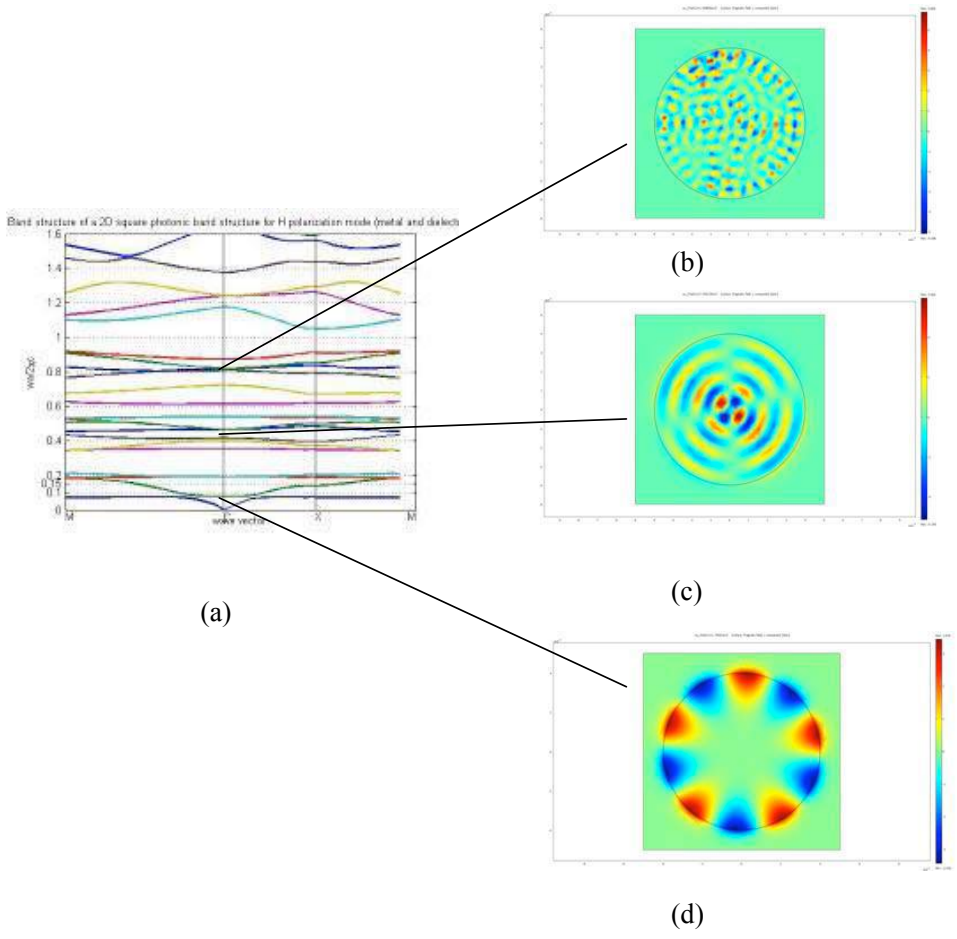

Figure 5 Band structure graph for GaAs rods with filling fraction $f = 0.5$ in copper medium in H polarization. Magnetic field distribution at frequencies (b) 1499 THz, (c) 743 THz, and (d) 176THz

3.1 Effect of Relative Permittivity on Photonic Cystals in Metals

The surface plasmon effect is reduced from vacuum to GaAs. The flat bands that represent the surface plasmon effect are less frequent when the relative permittivity of rods is increased. So, when a high relative permittivity material is coupled with the metals, the surface plasmon effect is not obvious. The structure will act as an ordinary photonic crystal, free of flat bands, while the relative permittivity of rods is increased. From the magnetic field distribution figure, the waves are localized inside the dielectric rods, especially for frequencies lower than the plasma frequency for all materials. The motion of the solid state plasma, whose characteristic is the plasma frequency in metals, is confined to the interior of the dielectric rods. So, the characteristic that an electromagnetic wave cannot penetrate metals can be overcome by insertion of an array of dielectric rods in metals.

4. Conclusion

We have plotted the band structure graphs of several materials rods in a copper medium in the H polarization mode using equations derived from the literature. When the relative permittivity of the rods is increased, the effect of the surface plasmons is reduced. The characteristics of wave propagation in the structure have been investigated using magnetic field distribution plots from COMSOL Multiphysics software. Both of the plots agree very well with each other. The surface plasmon effect is detected for all the materials investigated. The surface plasmon effect is reduced when the dielectric constant of the dielectric rods is increased. We also found that when the dielectric constant of the rods is high, the wave is prone to propagate inside the metallic medium. This phenomenon is found in different types of rods. Our method of calculation can be extended to find the band gap structure of defect modes and wave guide modes of photonic crystals made of metallic slabs.

5. Acknowledgments

This project was carried out using the Fundamental Research Grants Scheme (FRGS) with grant number 203/PFIZIK/6711146 and the Postgraduate Research Grant Scheme with grant number 1001/PFIZIK/841028. We would like to thank the technical staffs who participated in this project. Thanks are extended to USM for the support and encouragement given.

Abstract

The energy efficiency of optical interconnects can address the full performance of chip-scale photonic platforms. However, conventional optical compression designs had fundamentally limited such a device incompatible with the ultra-compact scale integration. Here, we designed a passive all-optical amplifier in a free-space waveguide by using the cavity-field interaction from a 2D photonic crystal (PhC) nanocavity pair. By introducing the controllable nanocavity parameters for a particular resonance frequency, an optical amplification was achieved by the strong oscillation within interfering field radiations from nanocavities. The obtained results had accomplished an occurrence of an amplified light intensity by 2.65% of 4.7 dB optical gain at the wavelength of 1550 nm. This embedded design may form the basis of self-pumping structures in an ultra-compact scale for the future photonic chip integration.

1. Introduction

The energy and cost efficiency of chip-scale light sources have drawn a strong attention to the optical network link devices on their sufficient power consumption which can be enhanced by the optical amplifier [1]. The functionalities of such a device can provide compensating attenuation, and coupling losses of optical interconnect for the multi-photonic chips integration [2]. Conventional approach is performed by the semiconductor optical amplifiers (SOAs) in order to conducts potential applications such as the spectrum narrowing for a single-frequency lasing [3], room-temperature slow light [4–5], high-bandwidth intra-band effects on pulse generation devices [6], controlling ultrafast quantum coherent Rabi oscillations [7] and self-induced transparency [8], and high energy femtosecond laser pulses generation [9]. However, these regimes require an electric current pumping for the optical amplification which faces the challenge to place onto all-optical chip-scale platforms.

The light-matter interaction on 2D photonic crystal (PhC) nanocavities have been attracted to on-chip designs due to their capabilities on the high-quality factor (Q) cavity mode volume, strongly field enhancement with free-space mode excitation in the nanostructure [10–11]. The photonic integration designs based on their structure can demonstrate the novelty theoretical ideas of nanolasers and lab-on-chip devices [12]. In particular, the 2D high-Q PhC nanocavity has been used to manipulate the strong waveguide-cavity coupling, in which produces the emitting photon from a nanocavity [13]. Leaked modes of a nanocavity coupled with the line defect on 2D PhC had been performed in both theoretical and experimental regimes [14] and gained the widely potentials for PhC-based devices and applications. However, one capability of their designs is to enabling the optical linewidth compression [15].

In this research, we have proposed the all-optical amplifier generation in a free space region of 2D photonic crystal waveguide (PCW) which can be embedded in on-chip photonic platforms. The system comprises of the two identical nanocavities formed by rod-type 2D PhC with side-shell layers of a lower dielectric rods material, locating across a three splitter 2D PCWs. Consequently, the radiated fields from high confined light in cavities would combine with the incoming light pulses. This phenomenon leads to the narrower spectral pulses with an amplification detection at the between of these two cavities. The simulation results had confirmed an occurrence of strong field intensity in free space for low-power light injection which depends on dielectric rods parameters of nanocavities.

2. Structure Design

The represented passive optical amplifier design is based on a rod-type 2D PhC nanocavity pair and embedded within a PCW. Because of their compact scale and self-amplification processes in free space, it can take advantage of needed no physical medium which serves as neutral amplifier between different compartments on photonics platforms for links with any on-chip optical interconnects. However, without an external, injection this structure had faced a challenge to changes the physical properties of an incident light in free space. The only existing nanocavities on PCWs had become an important character due to their abilities of the optically coupled with high-Q mode volume and the strong radiation fields from a cavity [16]. Thus, the light-cavity interaction had been considered for only a strong oscillation of localised frequency which matches to incident pulses, result to cavity linewidth narrowing generation [17].

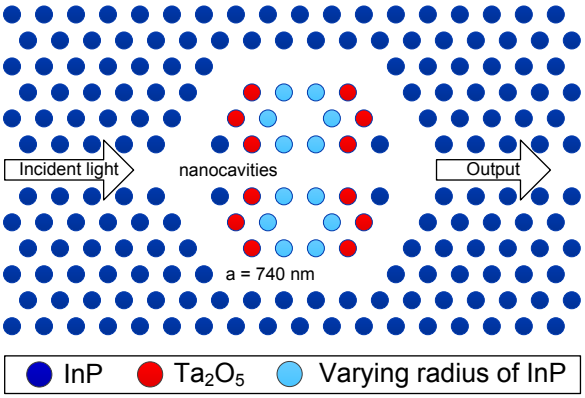

Figure 1: Schematic of an optical amplifier design (top view) which embedded in a three splitter 2D PCW onto a silicon substrate. The central free space area, positioning between nanocavities, represented as an amplification region.

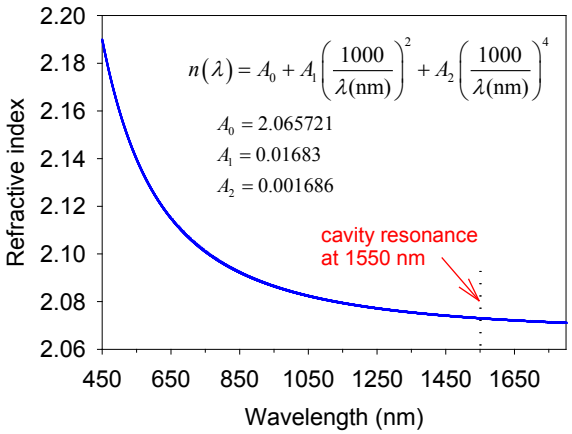

Figure 2: The wavelength dependent refractive index of Ta_2O_5 in a range from 450 nm to 1800 nm.

The design had been performed on a rod-type 2D PhC structure of indium phosphide (InP) on a silicon substrate as depicted in Fig.1. Its 220 nm of radius with the radius-lattice constant ratio (r/a) at 0.2973 was defined for light at a wavelength of 1550 nm for the perfect propagation within PCWs. Symmetrical nanocavities contain the larger InP rods which had been varied their radius from 241 nm to 246 nm, enabling them to realise the interaction between cavities mode and optical amplification. In order to enhance a strong confinement within nanocavities, the 230 nm of tantalum pentoxide (Ta_2O_5) rods have been served as a shell layer of nanocavities, improving the coupling and storage intensity. By performing a highly confined light in 2D PhC, the optical confinement inside nanocavities can be provided by the side-coupling of light in upper and lower waveguides of Y-branch. These branches would allow some fraction of light is conventionally coupling into both nanocavities, in which it generates the optical resonance of localised frequency. The narrow spectral pulse with amplification detection would be observed at a central position between two cavities due to the interference field formed by the cavity emission and directional light from an input port.

In addition to light amplification, the cavity-light field projection for this design has been considered based on three potential features of light-matter interaction. The embedded nanocavities structure can be adapted to the new approach of dynamics coherent controllable light with light for all-optical platforms which allow manipulation of intensity, propagation direction, and polarisation of light [18]. The cavity radiation propagates toward to the central position between two cavities due to an opposite direction of wave vectors as two identical high-Q nanocavities are precisely aligned to each other and support the symmetric leaked mode excitation [19]. Also, the symmetrically interfere with two cavity emission provides the stationary light field due to 2D PhC features [20], and light carries a nonzero transverse mode in the central area has corresponded to the two-wave interference framework [21]. Finally, the optical momentum exchange of the interfering pulse formed by an incident light and a stationary light field for the light-to-light interaction can be achieved due to unstructured paraxial beams intensify the momentum of light along an incidence propagation direction as they carry both angular and spin momentum [22]. Also, the length of middle PCW branch and interfering region formed by nanocavities radiation had unexpectedly been created in a proper position for pulses compression by phase matching of localised frequency between incidence light and field interference, offers the optical amplification phenomena [23] at the central position of PCW, considering energy and momentum conservation.

Importantly, the refractive index and radius of dielectric rods for shell layer have become a key factor in order to achieve the strong confinement in a free space nanocavity and emission decay fraction. The significant lower refractive index of cladding or shell layer than cavity rods would support the localised optical trapping enhancement and field emission into a central branch of PCW. However, the results of highly different in refractive index of dielectric rods between shell layer and cavity showed that the PCW-cavity coupling efficiency is decreased. The highly low refractive index value of dielectric rods in shell layer, compared to the cavity, causes the most fraction of an incoming light only passes through cavity shell without coupling into the cavity. Also, dielectric rods in shell layer act as the light blockage if the refractive index is equivalent or higher than its dielectric rods of nanocavities. As the results, Ta_2O_5 has been selected as the defect rods for shell layer based on high dielectric constant and low absorption material. However, self-amplification phenomenon in this work requires a broadband spectral linewidth of an incidence light, in which initiates the pulse compression. The refractive index wavelength dependence of Ta_2O_5 as illustrated in Fig.2 can be calculated in a function of Cauchy formula [24] as,

$$n(\lambda) = 2.065721 + \frac{0.01683\times10^{6}}{\lambda^{2}(\text{nm}^{2})} + \frac{0.001686\times10^{12}}{\lambda^{4}(\text{nm}^{4})} \qquad (1)$$

where λ is a broadband wavelength in the range from 450 nm to 1800 nm. Although Ta_2O_5 rods ($n \sim 2.0728$ at the wavelength of 1550 nm) shell can improve the capability of light confinement within PhC nanocavities, reaching only fundamental cavity mode resonance has been determined by the cavity size geometry, dielectric rods radius (r_{cavity}), and their material of InP ($n = 3.1$). The correspondence between light-matter interaction of single cavity mode and field radiation of homogeneous structure will experience with the effective cavity mode volume which is defined by [25],

$$V_{eff} = \frac{\int \varepsilon(\vec{r})\left|\vec{E}(\vec{r})\right|^2 d^3\vec{r}}{\varepsilon(\vec{r}_{\max})\max\left[\left|\vec{E}(\vec{r}_{\max})\right|^2\right]} \quad (2)$$

where λ is the wavelength of light in a free-space. r_{max} is defined as the position of the maximum electric field intensity E^2, the related dielectric constant ε and refractive index n. In fact, a nanocavity is based on dielectric rods surrounded by air which leads to the strong resonant at the centre of slot cavity. Therefore, the terms ε in eq.2 can be reduced to the dielectric constant of air, leaving an approximation value of maximum electric field position for modes resonance in a cavity.

3. Simulation Results

The optical amplification in a free-space waveguide based on a light-field interaction of leaked field interference from a nanocavity pair has been observed in the *x*-*y* plane. The finite difference time domain (FDTD) method provided by Freeware 32-bit OptiFDTD was used for light behaviour investigation in the proposed structure which their results were compared with Lumerical simulations software. Each of PhC cavity with identical rods dimension was defined as the emitter which light amplification efficiency satisfies the optical gain. According to the light-matter interaction in the previous context, the amplification wavelength in a central region between PhC cavities was controlled by its geometry breadth which results to the different manifestation of optical gain as illustrated in Fig. 3. Based on wavelength of 1550 nm operation, the 242 nm r_{cavity} of both nanocavities resulted to the maximum optical gain of 6.15 dB at 1548 nm (see green line in Fig. 3) with the Full-Width at Half-Maximum (FWHM) or bandwidth of 42 GHz. However, we also interested the downward amplification capability with r_{cavity} from 243 nm to 245 nm yielded two equivalent results of the negatively skewed curve of 4.63 dB at 1549.9 nm (red line) with bandwidth of 264 GHz, and the 4.70 dB optical gain at 1550 nm (blue line) with 249 GHz FWHM.

Reasonably, we had addressed that this proposed all-optical device has been designed as the neutral compartment for on-chip devices junction. Based on a linear system, the compared intensity of input and output was considered by single-wavelength of 1550 nm, also wavelength shifts were neglected from this investigation. Consequently, even through nanocavities with 242 nm radius of r_{cavity} gave rise to the light amplitude 4.12 times higher than incident power, it provided the blue shift of optical gain and resulted to dramatically drop the output intensity. As the results, the nanocavities formed by 243 nm rod radius had been selected in order to achieve the optical amplifier within a stable system. On the other hand, a blue line in Fig. 3 showed the gain of cavities system matched to incident pulses in both localised frequency and linewidth, offers the frequency and phase matching between the incoming power and light-field interference which gained the ability to amplified optical signals in a free-space 2D PCW.

Moreover, there are no mathematical approaches of electromagnetic field propagation description in the rod-type 2D PhC structure. However, the notion of light amplification occurred by the light-field interference phenomenon had been manipulated by the strong confinement of 2D PhC nanocavities. To evaluate the low power consumption capability of the device within a compact scale, the ratios of

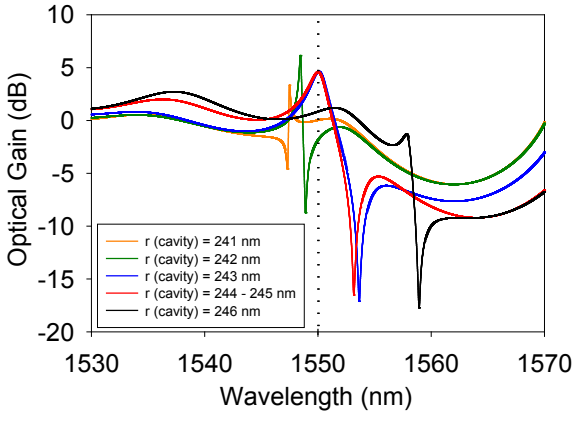

Figure 3: Optical gain of each dielectric rod radius of nanocavities, illustrating light amplification capabilities based on the field interference provided by symmetrically aligned two PhC cavities the difference radial dielectric rods.

It shows the total field direct toward to the output port. (c) Directional pulse along the propagation direction (*x*-axis) are combined, offers the enhanced optical power level due to the phase matching.

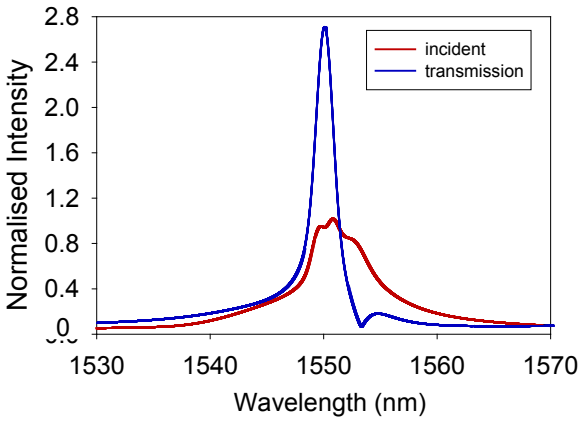

Figure 7: Simulation result of a normalised waveform with 243 nm cavities rod radii. The fluctuated curve at the peak of red line is affected by the interfering light between input and backscattered pulses from a three splitter region.

quality (Q) factor to mode volume (V) was determined as follows. While the coupling in a fundamental mode as dispatched in Fig. 5a, the confined light with Q~9,600 of each cavity offered the Q/V ratio exceeds 10^5, calculated by Lumerical 3D FDTD solutions. Accordingly, the optical effect formed by cavity leaked-field in Fig. 5b contributed Q~3,600, providing the downward Q/V ratio equivalent to 10^5, precisely. Consequently, the significantly dropped of Q factor by 6,000 of the spatially interacting light-field area allowed the incoming light was trapped and matched with the local field frequency. Based on energy and momentum conservation, the result of combined light-field emission increased in its intensity as displayed in Fig. 5c due to the vanished wavelength out of optical gain support its central wavelength energy increased

According to the simulation results, the transmission beam propagation direction direct toward to the output port of amplification region, see Fig. 6b. With the separated upper, lower, and light-field emission beams propagated independently, travelling waves had combined at the end of splitter PCW which results to the increased power level of output pulses due to phase matching as depicted in Fig. 6c. Eventually, the all-optical amplifier device in a free-space was achieved as a result of output intensity increased by 2.65% as illustrated in Fig. 7 wherein the operational light maintain a wavelength within the linear system.

4. Summary

The passive optical amplifier in a free-space waveguide based on 2D PhC nanocavity pair has theoretically been designed and analysed. In doing so, the system operation is performed by launching the beam propagation within 2D PCW to account for the cavity coupling. We focused on the leaked field from a strong confinement of both nanocavities, in which it forms to the spatial structure of dense light-field interference. The cavities with 243 nm rod radius show that optical gain achieves the amplification bandwidth relative to the incident light at 1550 nm. With the field is generated between cavities, the incoming pulses that pass through this region are trapped by the localised field-linewidth due to light-field interaction. This phenomenon diminishes the optical power of wavelengths beyond a local field in order to intensify the incident power, based on energy and momentum conservation. As the results, the calculated transmission power for the linear optical system was increased by approximately 2.65% of the input power. This proposed design may be taken advantage of the neutral system of optical self-amplifier, in which it can be applied for all-optical photonic chips integration platforms.

Abstract- We show, theoretically and experimentally, that photonic crystals with spatial filtering functionality, inside of a microchip laser cavity, can substantially improve spatial characteristics of the emission of microchip laser. The angular divergence of the emitted beam is reduced, and the radiation brightness is increased.

Microchip lasers (and generally most micro-size lasers, like diode lasers or VCELS) being extremely compact and efficient sources of coherent radiation, suffer from one drawback: the low spatial quality of the emitted beam. Only at low power emission regimes (close from the generation threshold) the microchip lasers can emit the beams and pulses of a reasonable spatial quality. Every attempt to increase the emission power, by increasing the pumping power, or by increasing the pumping area, leads to the deterioration of the spatial quality of the beams, equivalently to large angular divergence, and results to the lower brightness of the emitted radiation.

We proposed that the use of intracavity photonic crystals with spatial filtering functionality, can substantially improve the spatial quality of the emitted beam. Photonic crystals were recently shown to provide the spatial filtering [1]. Both the 1D spatial filtering, as well as axisymmetric 2D spatial filtering, see the left part of Fig.1, were experimentally demonstrated. Positioning of such photonic crystal spatial filters inside the cavity of microchip lasers enables to decrease the divergence of the radiation at high power regimes, and to increase the brightness of emitted radiation, see the right side of Fig.1. Presently we demonstrated an enhancement of brightness of emitted radiation approximately 3 times due to the intracavity photonic crystal spatial filtering, or, equivalently, we achieved a single-transverse-mode emission of approximately 3 times higher emission powers. The reported results [2] are presently limited by fabrication restrictions and imperfections of photonic crystal spatial filters, but potentially can be improved with advance of fabrication technologies.

The experimental measurements are justified by the numerical simulations of mean-field models of microchip lasers.

In summary, we demonstrate a new kind of micro-lasers, the Photonic Crystal Microchip Laser, with substantially improved radiation characteristics due to the intracavity photonic crystal spatial filtering.

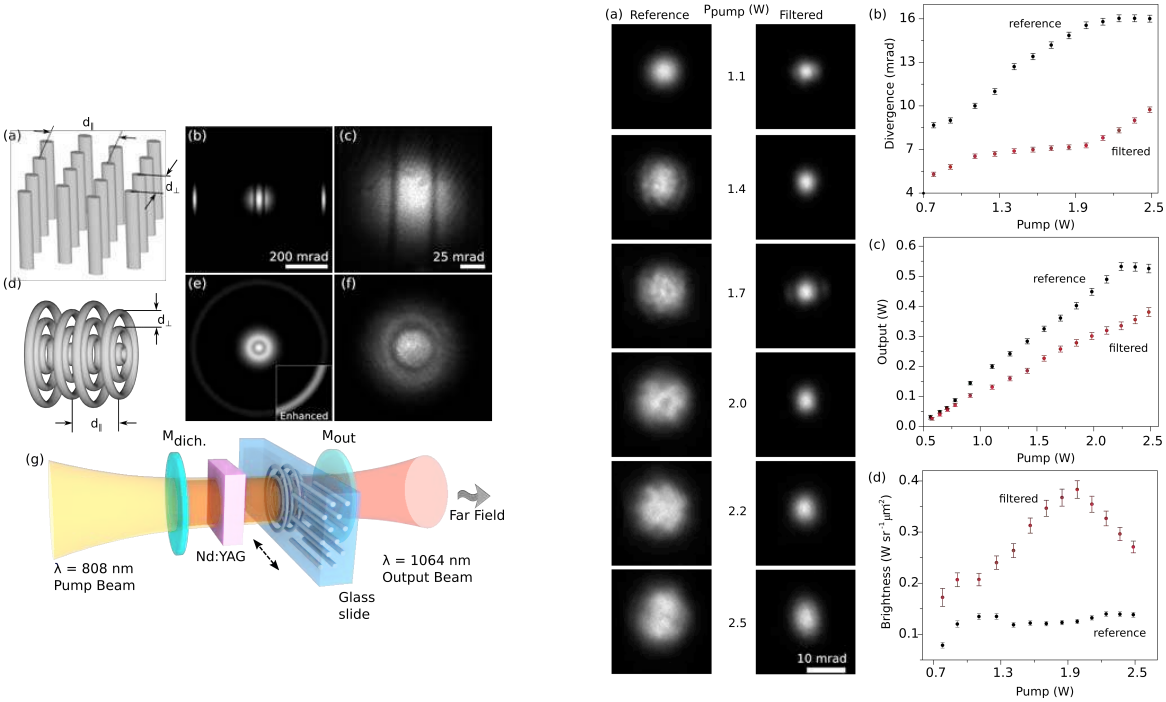

Fig.1 Left: single pass transmission characteristics of photonic prystal spatial filters, in 1D (a,b,c)- and of 2D axisymmetric (d,e,f) configuration. The spatial filters are positioned inside the resonator of microchip lasers (g). Right: whereas the beam divergence increases at increasing pumping power (first column from top to bottom, the far field distributions), the beam remains well collimated in the presence of intracavity Photonic Crystal (second column from top to bottom). Quantitative characteristics: (a) the beam divergence remains substantially lower (b), the generated power increases nearly so much as at the absence of the filtering (b), the brightness of emitted radiation substantially increases (c).

Acoustic metamaterials

Design of a double-negative flexural elastic metamaterial

Abstract-We present an elastic metamaterial for flexural waves with both negative density and elastic modulus. Nanoscale L-shaped holes are periodically drilled through a Au/Al/Au sandwich-structure plate of micrometer thickness. The structure is shown to have a double-negative frequency band at ~500 GHz for flexural waves by means of finite-element simulations. We calculate the dispersion relation, effective density and effective modulus of the structure, and demonstrating negative refraction of flexural waves in the double-negative band in a prism-shaped geometry.

Double-negative acoustic metamaterials that have negative density and modulus simultaneously over a particular frequency ranges have been recently proposed. In particular, two-dimensional elastic metamaterials for compressional plate waves (symmetrical 0th order Lamb waves) were recently demonstrated [1-2]. In addition, in the case of flexural plate waves (antisymmetrical 0th order Lamb waves) Gusev and Wright theoretically calculated that negative density can be achieved by introducing elements that involve normal-force interactions whereas negative modulus can be achieved by introducing resonant elements that involve lateral forces and rotational inertia [3]. Following on from this work, we designed a two-dimensional GHz flexural elastic metamaterial which can be fabricated by micro/nano machining techniques, and simulated its behavior.

We used the commercial finite-element software COMSOL Multiphysics to calculate the dispersion relation, effective density and effective modulus as the function of frequency and wavenumber. Our design is based on a composite slab in the form of a sandwich (see FIG. 1). In the design, softer parts (Al) are necessary to allow a resonant rotational vibration of harder parts (Au), as prescribed by the general approach of Ref. [3]. We introduce a chiral structure in the outside parts made of Au necessary to create a negative modulus. Making the

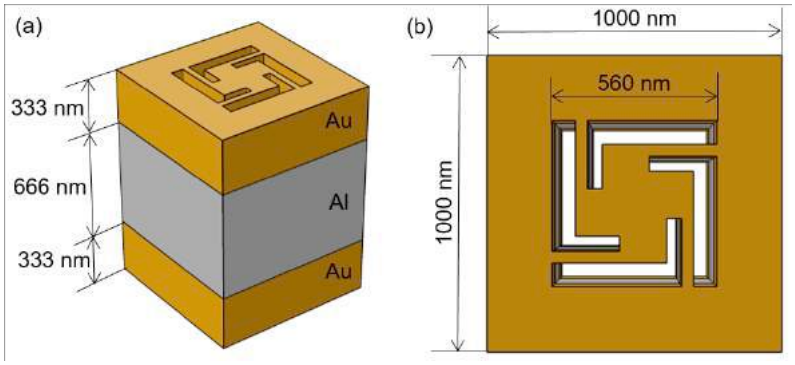

FIG. 1 Unit cell of the flexural elastic metamaterial: views (a) from diagonally above, and (b) from normal to the surface. Four L-shaped holes are drilled through this Au/Al/Au sandwich-plate structure.

inside Al portion of the slab light and the outside (Au) heavy is effective for this purpose, allowing a twisting rotational vibration of the outside portions. After many trials, we arrived the particular design shown in FIG. 1. The elastic metamaterial is designed in the form of a square lattice of unit cells, and is made from drilling a series of L-shaped holes through the Au/Al/Au three-layer plate. It has reflection symmetry in the depth direction and four-fold symmetry for rotation about an axis through the center of each unit-cell. This structure shows double-negative behavior in the frequency range from 510 MHz to 530 MHz, yielding a negative slope of the flexural wave branch in the ΓK direction in **k**-space.

We created a structure of this material in the form of a right-angle isosceles triangular prism to demonstrate negative refraction by simulation (FIG. 2). In the double-negative frequency range, negative refraction is observed. In conclusion, we have demonstrated the first concrete design of a flexural double-negative metamaterial. In future we plan to make samples of this GHz double-negative flexural metamaterial and to image the wave propagation at micron-spatial and picosecond-temporal resolutions by use of a real-time surface-wave imaging method based on an optical ultrafast pump-probe technique [4].

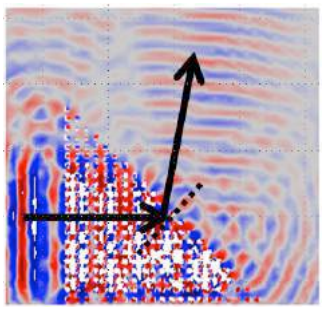

FIG. 2 Demonstration of negative refraction at the double-negative frequency 525 MHz. Flexural waves are incident from the left-hand side of the triangular prism. The colour scale represents the out-of-plane displacement. The arrows show the propagation directions, and dotted line shows normal vector to the interface.

Mimicking metamaterial functionalities in an immersive laboratory with exact boundary conditions

M. Molerón*, D.J. van Manen and J.O.A. Robertsson
Institute of Geophysics, Department of Earth Sciences, ETH Zurich, Switzerland

Abstract- This contribution presents an immersive wave propagation laboratory for the study of wave interactions with complex materials. The approach makes use of exact boundary conditions to link a physical experiment to a numerical environment in which a complex material is virtually implemented. This approach makes it possible to mimic exotic wave propagation properties without physically building complex materials.

Usual textbooks conceptions on wave propagation are being challenged by recent advances in metamaterials and parity-time (PT) symmetric media. Metamaterials exploit local resonances in their micro-structure to achieve extreme values of its constitutive parameters, ranging from positive, near-zero to negative. Such properties provide a considerable control on wave propagation, which includes focusing, filtering, negative refraction or cloaking. Complementary, PT-symmetric media, containing balanced loss and gain through the modulation of the imaginary part of the constitutive parameters, offer exciting new possibilities in wave propagation control, including loss-free negative refraction,[1] or unidirectional transparency and cloaking.[2] However, the practical implementation of these exceptional properties is still a major challenge due to, among other factors, inherent losses,[3] narrow bandwidth, or stability issues arising from the presence of active components.[4]

In this contribution, we present an immersive wave experimentation laboratory[5,7] that makes it possible to mimic exotic wave propagating phenomena without the need to physically build a complex material. The proposed approach makes use of exact boundary conditions[5] to link a physical experiment to a numerical environment in which a complex material is virtually implemented. The basic principle of this immersive laboratory is illustrated in Figure 1. The incoming waves from the physical environment are measured on the recording surface S_r and extrapolated to the emitting surface S_e. Then a source distribution on S_e cancels out the incoming waves and simultaneously inject a wave field that takes into account the interaction with the virtual material. This interaction takes place in real time using state of the art computing facilities. The quantities to be injected on the emitting surface are calculated based on a representation theorem between the physical and virtual environments (see References 5-7 for further details).

This approach has been successfully applied to implement broadband holography and cloaking of objects with arbitrary shape.[7] Currently, our research is focused on the experimental realization of PT-symmetric media for elastic and acoustic waves. Additional results from this ongoing research will be presented.

The proposed approach provides a new perspective for investigating wave interactions with complex materials, at the interface between numerical simulations and experimental research.

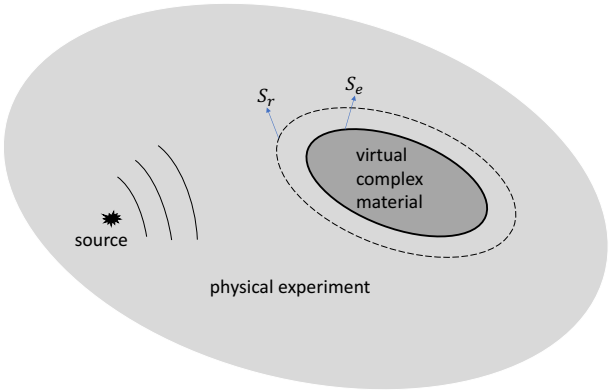

Figure 1. Schematic of the immersive wave experimentation laboratory. Waves emitted in the physical environment are measured on the recording surface S_r and extrapolated to the emitting surface S_e. Then, the emitting surface cancels out the incoming waves and simultaneously inject signals in the physical environment resulting from the interaction with the virtual complex material.

Abstract- Reported methods for retrieval of wave parameters for given metamaterial structures so far have been significantly different from classical theory of dielectrics. Here we demonstrate that the classical treatment, which is familiar with wide range of scientists and engineers, can be extended to the realm of electromagnetic metamaterials for exact accounting of the effective permittivity. Our scheme not only makes the calculations easier but also provides intuitive way of understanding the origins of negative parameters.

Abstract- We present the fabrication of an acoustic metasurface of thickness much smaller than the wavelength, which, placed in between water and air, matches impedances of water and air. This impedance matching metasurface is a two-dimensional array of unit cells, each of which consists of a thin cavity covered with five membranes. Experimentally we obtained about 40% power transmission through the interface using the metasurface, which corresponds to over 23.5 dB transmission enhancement.

Abstract-We have realized acoustic hologram via acoustic metamaterials with simultaneous controls of amplitude and phase. More importantly, the modulation of amplitude and phase is decoupled at specific points in the parameter space, leading to that all possible combinations of amplitude and phase can be accessed. Our method can stably generate hologram with high quality and high fidelity, which are unattainable with previous pure-phase approaches. Our findings will have far-reaching impacts on beam-steering, ultrasonic imaging and particle manipulation, etc.

In this paper, we numerically and experimentally demonstration high-quality acoustic holograms by acoustic metamaterials (AM). Holographic techniques are of fundamental significance to applications such as optical/acoustic tweezers, volumetric displays and medical ultrasound treatment but have high requirement on spatial control of complicated optical/acoustic field. It is known that optical holograms have significantly advanced with the cutting-edge nanotechnology. In ultrasound applications, the acoustic holograms are expected to offer new capabilities in beam-steering and improve medical imaging [1-4].

Figure 1 shows the design of acoustic metamaterials. Figure 1(a) shows the schematic, with the predesigned unit cells. Here we use absorbing boundaries at the back side to introduce controlled energy loss, which capable to modulate both amplitude and phase of reflection at the surface under the illumination of sound on the front side, as indicated by the red arrows in Fig. 1(a). By keeping the back of each unit cell open, as indicated in Fig. 1(e), each unit-cell comprises three components: upper channel, middle channel, and lower channel. The parameters are marked in Fig. 1(a). The operating frequency is 17150Hz. Due to the subwavelength nature, the amplitude and phase of reflection are independent of the incidence direction.

Figures 2(b) and 2(c) show the amplitude and phase responses of the unit cells. The amplitude (A) is modulated by w, and the phase (ϕ) is modulated by h_1. Figure 2(b) and 2(c) show that the tuning of amplitude and phase is decoupled. This decoupled point is achieved by choosing proper h value. As a result, all possible combinations of amplitude and phase can be accessed.

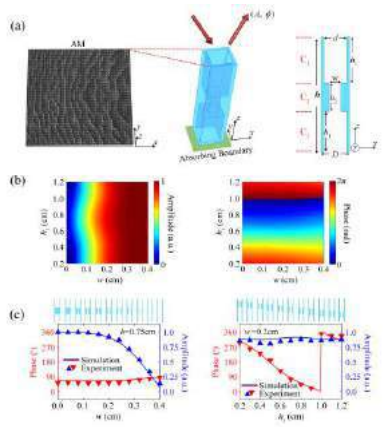

Fig. 1 (a) The design of AM and unit cells. (b) The amplitude and phase response. (c) The simulated and measured amplitude and phase versus w and h_1, respectively.

Figure 2(a) shows the calculated amplitude and phase for generating predesigned Penrose tiling pattern. We record the amplitude and phase information into AM. The photograph of the sample with 79×79 unit-cells is shown in Fig. 2(b). We plot the acoustic pressure amplitude distribution measured on the image plane in Figs. 2(c) and 2(d), showing a good agreement between numerical and experimental results of complicated spatial acoustic field. The hologram with both amplitude and phase modulation have high-quality and high high fidelity, which are unattainable with previous pure-phase approaches [1-4]. Our findings will have far-reaching impacts on beam-steering, ultrasonic imaging and particle manipulation, etc.

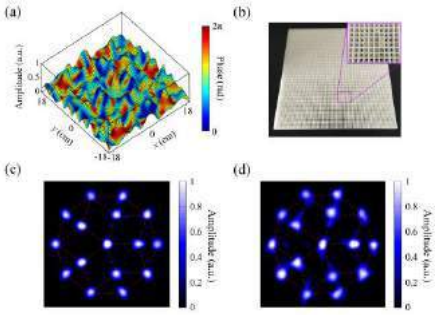

Fig. 2 (a) The calculated amplitude and phase for generating predesigned Penrose tiling pattern. (b) The photograph of sample. (c) The simulated acoustic field pattern. (d) The measured acoustic field pattern.

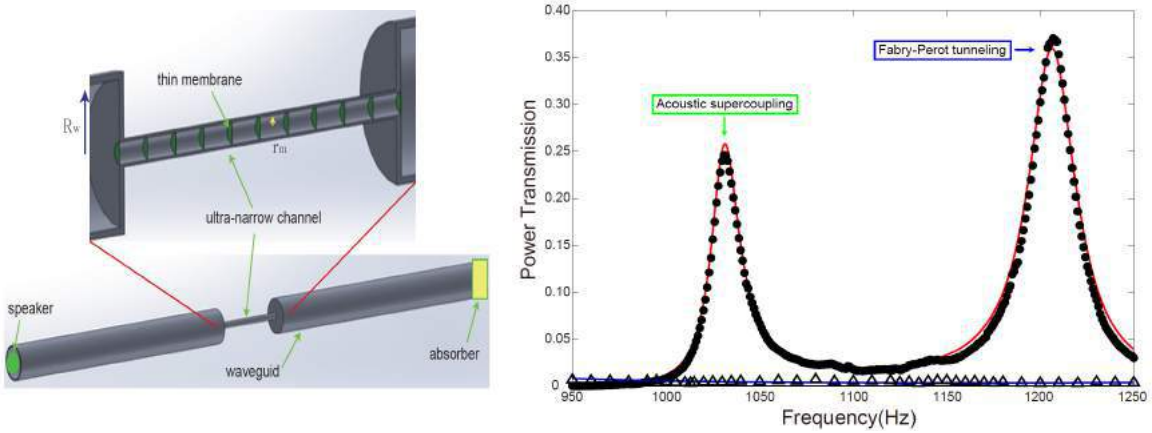
Experimental Verification of Extraordinary acoustic transmission through Density near zero extremely narrow tubes.

Jong Jin Park[1*], Jun-hyuk Kwak[1], Boyoung Kang[1], and Hakjoo Lee[1]
[1]Center for Advanced Meta-Materials, Korea.
[*]corresponding author: jjpark@kimm.re.kr

Abstract- We experimentally verify recently developed theory of ‘‘supercoupling’’ [Phys. Rev. Lett. 111, 055501 (2013)] by researching uniform acoustic energy squeezing through an extremely narrow acoustic tubes filled with near zero density metamaterials. So, we realized extraordinary acoustic transmission based on impedance matching by installing thin membranes with a subwavelength period along the tube. Potential applications in acoustic treatment, sensing and energy harvesting.

We introduce the concept of acoustic supercoupling associated with impedance matching and anomalous sound tunneling through ultra-narrow tubes. Alu and Engheta, pioneers of this work, have made metamaterials with near-zero permittivity theoretically and experimentally and matched transmission through very narrow channels filled with ENZ materials, also known as ‘‘supercoupling’’ [1]. This is a special phenomenon very different from the general Fabry-Perot (FP) tunneling resonance and is called "Supercoupling". Supercoupling, in theory, delivers the waves regardless of the length, bending and twisting of the tubes made of metamaterials. Alu proposed and theoretically explained acoustic supercoupling which applies the supercoupling phenomenon shown by electromagnetic wave to the sound wave [2]. This paper experimentally implements "acoustic supercoupling" which conveys acoustic energy by focusing acoustic wave to very narrow tube by overcoming acoustic impedance mismatch structure very extreme through acoustic metamaterial structure [3-5].



Figures 1. (a) An acoustic metamaterial design that achieves near zero effective density. An extremely narrow tube was connected between two large waveguides. A thin elastic membrane was installed at regular intervals inside the narrow tube. (b) Power transmission coefficient though ultra-narrow channel.

A tube with a narrow cross-section is connected between the same waveguides with the same cross-sectional area as shown in Fig.1 (a). The radius and length of both waveguides are 50 mm and 1 m. The diameter of the narrow tube is 7.5 mm. The length of the narrow tube is 200 mm and installed a thin elastic membrane having a thickness of 0.01 mm at intervals of 20 mm in the narrow tube. The material of the thin elastic membrane installed in the narrow pipe was made of polyethylene and attached with a tension of about 10 N/m. The cut-off frequency of the acoustic metamaterial connected to 10 unit cells is about 1030 Hz. The effective density of the acoustic metamaterial at the cutoff frequency is zero. Sound source was generated from the speaker in the left waveguide. On the other side, the sound absorbing structure was connected to remove the reflected wave.

As shown in Fig. 1(b), the red solid line is the theoretical calculation of the power transmission coefficient when using a narrow tube made of acoustic metamaterial, and the black dotted line is the experimental data. The blue solid line is the theoretical result of the power transmission coefficient when a typical narrow tube is used without the acoustic metamaterial, and the triangular point is the experimental data. As you can see in the result data, you can see two peaks, but the physical phenomena are quite different. The first peak (1032 Hz) is an "acoustic supercoupling" phenomenon where the acoustic impedance of a narrow tube is close to zero and satisfies the acoustic impedance matching conditions. The second peak (1207 Hz) is a characteristic that satisfies the FP resonance condition that is generally known, and is the value that is transmitted because the fundamental resonance mode occurs. The power transmission coefficient of the acoustic wave propagated through the acoustic supercoupling phenomenon is about 25%, and the power transmission coefficient of the general narrow tube with the acoustic metamaterial removed is about 0.3%. In other words, acoustic super coupling showed a power transmission coefficient of about 80 times higher than that of sound energy. By controlling the effective density of the narrow tube using the acoustic metamaterial, the ultra-transmission phenomenon with high transmission efficiency was experimentally realized.

This experimental implementation will play an important role in applications related to noise control, sensing, and sonic energy harvesting. In addition, the technique of concentrating and delivering sonic energy using a very narrow acoustic metamaterial tube can be extended to the ultrasound range and used for diagnosis and treatment by using the ultrasound endoscope.

Abstract— A methodology to calculate the deformation of crystal structure is presented in this paper. Al doped ZnO is used to form the acoustic cantilever in ideal wurtzite crystal structure. The expansion of the applied cantilever is calculated by the proposed methodology and presented accordingly.

1. INTRODUCTION

Recently, acoustic energy transfer (AET) technology has drawn significant industrial attention. Eventually, AET possesses wide range of applications, including, electronic vehicle and portable device charging, implantable devices powering and more [1]. Cantilever approach to propagate acoustic energy is particularly adventurous using multilayer formation. Several materials can be chosen for the cantilever formation. Among them, zinc oxide (ZnO) is one of the common material to use. To calculate the deformation of an acoustic cantilever, usually wave equation is preferable which is complex and difficult to understand. From that motivation, we proposed a set of approach to calculate the deformation of a cantilever in this paper. We have modeled the aluminum doped ZnO for the cantilever formation. The ideal wurtzite crystal structure is applied for the calculation [2, 3].

2. MODELING OF THE CANTILEVER

2.1. Unit cell Modeling

Number of unit cells can be found by applying the deposition length and thickness as follows,

$$\lceil N \rceil = \lceil \overrightarrow{N}^{x,z}_{cell} \rceil = \lceil \frac{\overrightarrow{L}^{x}}{L_{unit\ cell}} \rceil \times \lceil \frac{\overrightarrow{t}^{z}}{h_{unit\ cell}} \rceil \quad (1)$$

Where, $L_{unit\ cell}^{\rightarrow x} = 2\sqrt{ZnO_{slope}^2 + AlO_{slope}^2 - 2ZnO_{slope}AlO_{slope}cos\gamma}$ and $h_{unit\ cell}^{\rightarrow z} = dl_{ZnO} + l_{AlO} + dl_{AlO} = l_{ZnO} * sin(\alpha - 90) + l_{AlO}\{1 + sin(\beta - 90)\}$. Here, $ZnO_{slope} = \sqrt{l_{ZnO}^2 - \{l_{ZnO} * sin(\alpha - 90)\}}$ and $AlO_{slope} = \sqrt{l_{AlO}^2 - \{l_{AlO} * sin(\alpha - 90)\}}$, L and t are the deposition layer length and thickness. α, β and γ are the angles produced by Zn-O, Al-O and Zn-Al bond while l_{ZnO}, l_{AlO} are the bond length and ZnO_{slope}, AlO_{slope} are slopes by the bond.

2.2. Compression to the z-axis of Unit cell

The expansion of an Unit cell to the z axis can be calculated as,

$$|\overrightarrow{C}^{z}| = \sum_{k=1}^{\overrightarrow{N}^{z}} (\overrightarrow{C}^{z}_{ZnO} + \overrightarrow{C}^{z}_{AlO})_k \ where,\ \overrightarrow{C}^{z}_{ZnO} = \sqrt{l_{ZnO}^2 + l_{ZnO_{slope}}^2 - 2l_{ZnO}l_{ZnO_{slope}}cos(\alpha - 90)} \quad (2)$$

$$and\ \overrightarrow{C}^{z}_{AlO} = \sqrt{l_{AlO}^2 + l_{AlO_{slope}}^2 - 2l_{AlO}l_{AlO_{slope}}cos(\beta - 90)}$$

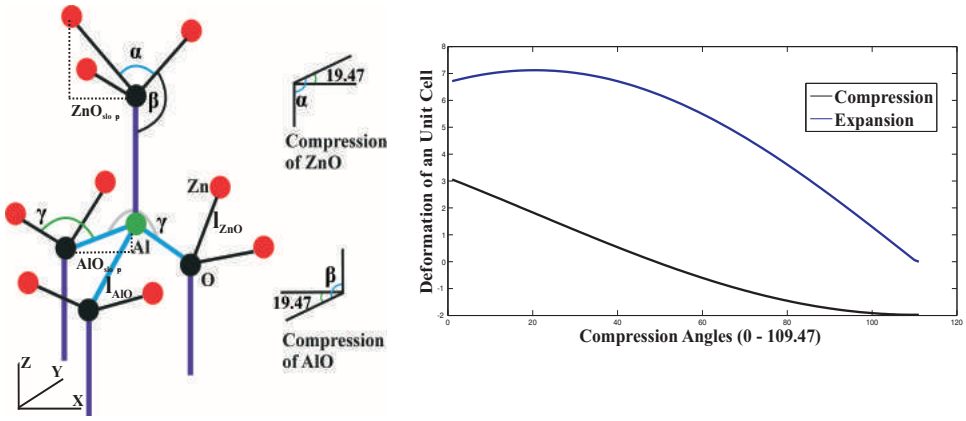

Figure 1: Al doped ZnO unit cell (left); here $\alpha = \beta = 109.47°; \gamma = 141.06°$; $l_{ZnO} = 1.9757$Å, $l_{AlO} = 1.8$Å is considered. Unit cell deformation towards cantilever length.

2.3. Expansion to the x axis of Unit cell

The expansion of an Unit cell to the x axis can be described as,

$$\overrightarrow{E}^{x,y} = \sum_{l=1}^{\overrightarrow{N}^{x}} 2(|\overrightarrow{E}^{x,y}_{ZnO}| + |\overrightarrow{E}^{x,y}_{AlO}|)_l; \; where, \; \overrightarrow{E}^{x,y}_{ZnO} = \overrightarrow{E}^{x,y}_{AlO} = \overrightarrow{E}^{x,y}_{ZnAl} = \sqrt{l^2_{ZnO} + l^2_{AlO} - 2l_{ZnO}l_{AlO}cos\gamma} \quad (3)$$

Which requires the following condition to be satisfied for the maximum deformation,

$$\exists! \; \overrightarrow{E}^{x,y}_{max} = \prod_{k=1}^{n=110} \alpha_k \wedge \beta_k; (0 < \alpha_k < 109.47; \; 0 < \beta_k < 109.47)$$

Table 1: Cantilever dimension and deformation descriptions

Cantilever size	Deposited layer thickness	Unit cell deformation	Total deformation
Length 60 mm Width 10 mm	0.02 mm	0.4072Å (x-axis) 1.2585Å (z-axis)	3.6391e+6 Å (x-axis) 8.22e+5Å (z-axis)

3. CONCLUSION

A geometric approach is proposed in this paper to calculate the deformation from a doped crystal structure. Al doped ZnO is applied for the crystal configuration. By applying the proposed structure, we have calculated the deformation of the Al doped ZnO cantilever. It is found that, the cantilever can be expanded up to 3.6391e+06 Å in length to x-axis with the unit cell expansion 0.4072Å. Results are presented in table 1 and in figure 1.

Abstract- Sonic metamaterials have important applications in both military and commercial fields such as noise control, and acoustic communication. To broaden the resonant band gap and sound-absorbing spectrum, Woodpile structure was introduced into sonic metamaterials. Calculations suggest that Woodpile LRSMs have wider band gaps, which are adaptable to all types of vibration polarizations. Using vibration modes and a mass-spring model, strong coupling effect is confirmed between the orthogonal resonances at the upper edge of the band gap. Moreover, considering viscoelasticity of materials, woodpile LRSMs can implement strong sound-absorbing effect in a wide range.

Locally resonant sonic metamaterials (LRSMs) have attracted much attention for their ability to break through the mass density law and exhibit novel physical properties, such as band gaps [1]. A key issue for the industrial application of an LRSM is the narrow bandwidth produced by the formation mechanism of the resonant band gap. It has been found that relatively wide band gaps can be obtained by changing the LRSM structure [2–3] or by varying the elastic characteristics of the component materials [4]. However, these methods are usually based on changing intrinsic local resonance properties and thus usually limited and ineffective.

The present paper proposes a novel wider bandgap LRSMs with complex lattices: a structure that is Woodpile structure and having orthogonal resonations. The structure of a Woodpile LRSM is shown in Figure 1b and its two-dimensional LRSM variant in Figure 1a. The Woodpile structure can be obtained when the coated square column of the two-dimensional LRSM in the interval position is rotated 90 degrees.

The band structures of the two-dimensional LRSM and Woodpile-structure LRSM are shown in Figures 2 a and b, respectively. The width of the square rods is 0.3 cm. The thickness of the coating materials is 0.1 cm, and the lattice constant is 1 cm. For the Woodpile structure, there is a band gap between 1758.9 and 2411.5 Hz. The bandwidth of the Woodpile-structure LRSM is approximately 652.6 Hz, which is approximately 128 Hz broader than that of the two-dimensional LRSM in the x, y plane. It is thus easier to realize a wider band gap that can be adapted to different polarization states with the Woodpile-structure LRSM. The calculations suggest that two resonances exist in one unit cell at the upper-edge band gap: compression resonance (subject to the tensile modulus) and shear resonance (subject to the shear modulus). The analysis reveals that there is strong coupling between cross resonances at the upper-edge band gap of the Woodpile-structure LRSM originating from the interaction between compression resonance and shear resonance.

In LRSMs, locally resonant absorption coincides with viscoelastic deformation [5]. Considering viscoelasticity of materials, woodpile LRSMs can implement strong sound-absorbing effect in a wide range (as shown in Fig. 3), which provides a new idea for the design and preparation of light weight and low frequency underwater sound-absorbing materials.

Abstract- We present the fabrication of an acoustic metasurface of thickness much smaller than the wavelength, which, when placed in between water and air, enhances the transmission by more than two orders of magnitude. This metasurface is a two-dimensional array of unit cells, each of which consists of a thin cavity covered with five membranes. Experimentally we obtained about 40% power transmission through the interface using the metasurface, which corresponds to an over 23.5 dB transmission enhancement.

Abstract— Concentrating acoustic wave energy in tiny sub-wavelength regions is a subject of much recent interest. One method for achieving this is the principle of extraordinary transmission, in which a resonant structure is combined with an aperture to achieve greatly enhanced transmission. Here, we make use of acoustic Fabry-Perot resonances combined with surface-wave resonances in a solid-solid structure to demonstrate bulk-wave acoustic extraordinary transmission. We show by simulation an enhancement in the acoustic amplitude transmission efficiency up to ∼20 times at GHz frequencies. Possible applications are in acoustic imaging or particle sensing.

Acoustic metamaterials are artificial structures designed to manipulate the propagation of sound in ways not possible in naturally occurring materials. One example is their use in extraordinary acoustic transmission, the passage of more acoustic energy than expected through a small sub-wavelength aperture. This has been studied in liquid-solid and air-solid systems [1, 2], but not for waves purely confined to solids. Here, by means of simulations, we investigate extraordinary acoustic transmission (EAT) in a solid-solid structure at GHz frequencies.

Our structure is shown in Fig. 1(a), consisting of a two half-spaces made of tungsten joined by a cylindrical pillar surrounded by a vacuum region. Tungsten is chosen because of its effectively isotropic acoustic behaviour. To enhance the EAT for incident plane longitudinal waves, we also make use of a concentric structure of circular grooves, as shown in Fig. 1(a), by analogy with similar geometries in optics. We consider three cases, one in which there are no grooves, one in which there are grooves only on the input side, and one in which there are grooves only on the output side, termed respectively the no groove case, the input-groove case and the output-groove case. The output-groove case is only analysed qualitatively. The diameter of the pillar is 5 nm, and the groove width and depth are both 5 nm. We adjust the pitch of the groove structure (p) and length of pillar (L) to vary the resonant frequency of the surface-wave and pillar longitudinal resonances. The central groove width is chosen to be 40 nm, measured from the outer diameter of the pillar. Plane longitudinal bulk waves are impulsively excited on the input side, and travel towards the output side. In order to evaluate the extraordinary transmission of longitudinal acoustic waves, we make use of analysis regions for amplitude sampling that are disc-shaped (diameter 700 nm, thickness 5 nm, and 200 nm before the pillar) on the input side and dome-shaped (inner and outer radii 477 nm and 500 nm, and centred on the output end of the pillar) on the output side. The volumes of these two regions are chosen to be the same. We obtain values of the amplitude transmittance $T(f)$ by making use of the average values of the amplitudes A_{in} and A_{out} in these regions at specific frequencies f. We then find, by analogy with the optical case, the EAT efficiency $\eta(f)$ using the following equation:

$$\eta(f) = T(f)^2 \frac{D^2}{W^2}, \tag{1}$$

where D is the diameter of the disc analysis region and W is the pillar diameter. In our case $D^2/W^2 = 196$.

In the the case of no grooves, the EAT is expected to depend on the Fabry-Perot resonance of the pillar at frequency f_n,

$$f_n = \frac{nv_p}{2L}. \tag{2}$$

Here v_p is the wave velocity in the pillar, i.e. the longitudinal velocity of longitudinal acoustic waves in a cylindrical rod, expected from literature values of density and elastic constants to be 4320 m/s for tungsten, and n is the mode number. In our simulations we choose L=50 nm. We

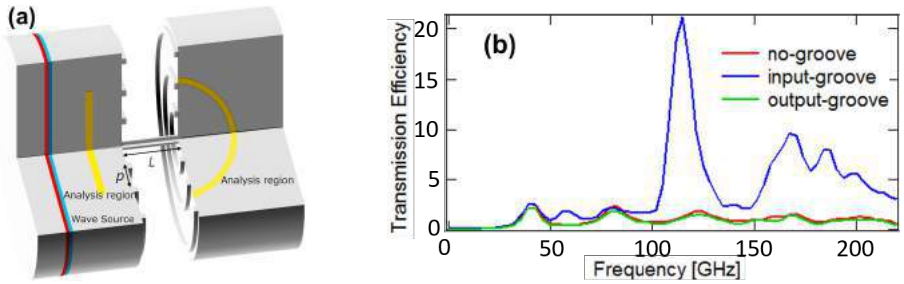

Figure 1: **(a)** Simulation geometry (all grooves shown). **(b)** Transmission efficiency spectra for the no groove case (red line), input-groove case (blue line) and output-groove case (green line).

find $f_1 = 43.2$ GHz from the simulations, indicating that $v_p = 4320$ m/s as expected [3]. In the case of grooves of pitch p being present on the input side, it has been observed that resonances are introduced that depend on surface acoustic waves, for example at a frequency close to [1]

$$f_{gm} = \frac{m v_{\mathrm{SAW}}}{p}, \tag{3}$$

where v_{SAW} is the surface wave velocity, similar to the Rayleigh velocity 2468 m/s for tungsten [4] and m is the mode number. We choose $p = 40$ nm corresponding to $f_{g1} = 61.7$ GHz for both the input and output-groove cases. For the no-groove case (red line in Fig. 1(b)) peaks at integral multiples of about 40 GHz are observed, similar to that expected from the estimated value of $f_1 = 43.2$ GHz. For the input-groove case (blue line), a smaller series of peaks is again observed, this time at integral multiples of about 60 GHz, the first peak similar to that expected from the estimated value of $f_{g1} = 61.7$ GHz. A particularly strong peak appears in the input-groove case at $f = 120$ GHz. This frequency corresponds to $n = 3$ for the longitudinal resonance and also to a surface-wave resonance, and the result is to enhance η by a factor > 10 to a value $\eta = 21$. For the output-groove case (green line), we obtain a spectrum very similar to the no-groove case. Peaks at integral multiples of about 40 GHz are observed, and they are not enhanced. We find that the spectrum does not depend on the pitch of grooves. However, a comparison of the acoustic field for the output-groove case and the input-groove case reveals that the wave patterns in the far-field are modified by the output grooves. In the output-groove case, surface waves decay by radiation of longitudinal waves, giving a strong amplitude perpendicular to the vacuum-solid surface.

In conclusion we have considered the case of extraordinary acoustic transmission in a solid-to-solid system. We chose the generic case of a cylindrical pillar connecting two solid half spaces. We show that concentric grooves installed on the input surface can dramatically improve the transmission efficiency η. Considerably enhanced values of $\eta \sim 20$ can be obtained by tuning the surface-wave resonance to a Fabry-Perot longitudinal resonance of the pillar. In addition, we find that the use of concentric grooves on the output side modifies the the transmitted acoustic waves in the far field but not the transmission efficiency. This work should find future applications in high-resolution acoustic imaging and nano-particle sensing.

Abstract-We propose efficient generation of tunable optical band gaps through acousto-optic (AO) interaction. The optical system proposed in this study consists of a thin dielectric slab coupled to a metal surface with a nanoscale air gap in between and provides hybridization of highly guided photonic–plasmonic gap modes squeezed in the air gap. Enhanced AO interaction occurs through the disturbance of acoustic Lamb waves in the slab, strongly boosting the AO interface effect and scattering the optical fields. As a result, wide optical band gaps are opened.

Acousto-optic (AO) interaction has been widely applied to processing light signal. High-frequency acoustic waves modulate dielectric constants of media so that light can be manipulated [1]. AO interaction can also be an effective contributor to scatter light to influence photon transport. In the past two decades, on the other hand, formation of photonic band gaps (PBGs) in man-made periodic structures has received great interest. However, most PBG materials were immutable while tunable PBGs by external fields were rarely demonstrated.

Photonic-plasmonic hybrid system can lead to tighter spatial confinement of optical energy. Intriguingly, the squeezing features can provide enhanced effects for strong modulation of light by AO interaction. The coupling mechanisms contributing to AO interaction include photoelastic (PE) coupling as a volume interaction effect and the coupling of acoustic field induced mechanical displacement of geometrical boundaries, which are referred to as bulk and interface effects, respectively [2]. To the best of our knowledge, PBG in deep-subwavelength regime opened by AO interaction is still lacking. In this study, we present dynamic modulation of hybrid optical modes in a metal-air-dielectric system using Lamb waves. In the system, a nano air gap is inserted in between an Ag substrate and a GaAs slab, and deep-subwavelength gap modes (TM modes) that hybridize plasmon and photon energy yield to propagate. We show that the system excited with high-frequency Lamb wave eigenmodes in the slab significantly enhance the AO interaction to open tunable PBGs for the squeezed hybrid gap modes.

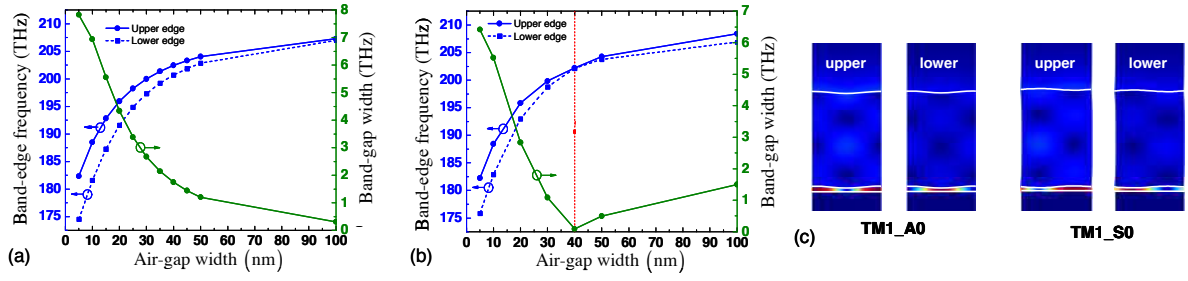

Figure 1. The upper and lower photonic band-edge frequencies of TM1 mode at first BZ boundary separated by the acoustic (a) A0 and (b) S0 modes at acoustic phase $\Omega t = 0$ as a function of air-gap width. (c) Intensity distribution of electric field of TM1 mode at lower and upper edges disturbed by A0 and S0 modes.

We employ a finite-element algorithm in our computational work to deal with elasto-electrodynamics and the AO coupling behavior. The computational procedure follows that the acoustic fields generate a time-varying refractive indices and boundaries, and then effects of AO interaction on the optical fields are calculated in the disturbed system. The interface and bulk effects are introduced by acoustic displacement and strain-optic relation, respectively. The PE coupling and moving mesh technique are used to address the disturbed refractive indices (bulk effect) and geometrical boundaries (interface effect).

We consider the TM1 mode at 193.4 THz and the lowest-order symmetric and antisymmetric eigenmodes A0 and S0. On the basis of co-localization of the optical and acoustic fields, we then calculate the optical bands in an acoustically disturbed system. Figure 1 shows the upper and lower photonic band-edge frequencies of TM1 mode at the first Brillouin zone (BZ) boundary opened by the acoustic A0 and S0 modes as a function of air-gap width. The excited acoustic amplitude is 5 nm. It is observed that a narrower air gap produces a wider PBG by the given acoustic fields because, in the narrow-air-gap regime, the interface variation significantly perturbs the air-gap width, and the effect dominates the PBG opening. Reducing the air-gap width increases the PBG width induced by the Lamb modes. Figure 1(c) shows the TM1 mode at lower and upper edges under the disturbance of A0 and S0 modes. Figure 2 shows the calculated transmission spectrum and propagation decay of TM1 waves passing through A0 waves. Obviously drop off in the PBG range appears at the first BZ boundaries (1.53–1.56 μm). High AO interaction efficiency prohibits the TM1 wave propagation within a 35 μm propagation length.

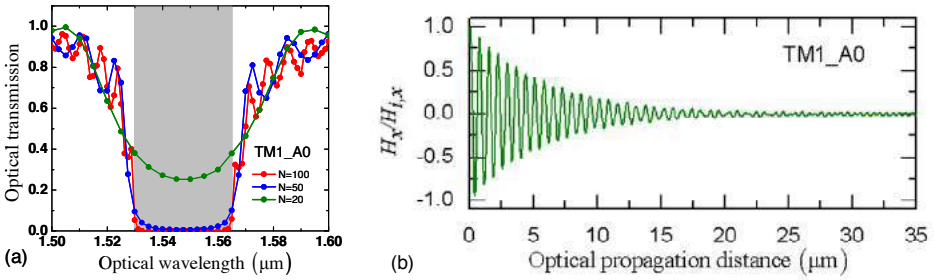

Figure 2. (a) Transmission spectra of TM1 waves passing through A0 acoustic-wave trains composed of N = 20, 50, and 100 waves propagating in the GaAs slab. (c) Transverse magnetic field H_x decay of TM1 waves, divided by the incident intensity $H_{i,x}$, along the z-direction induced by the A0 Lamb waves (N = 100).

In conclusion, we studied the PBG opening in the deep-subwavelength regime through AO interaction. The interface effect can be significantly boosted through an increased ratio of acoustic amplitude to air-gap width and opens wide PBGs. Present study introduces the mechanisms for achieving strong AO and SPP/photon–phonon interaction in deep-subwavelength structures and applications to tunable AO devices in nanometer scales.

Abstract— This paper presents a multilayer harvester for acoustic energy transfer. A four layer cantilever configuration is used to design the harvester with Aluminum, Silicon and Zinc Oxide. The displacements of the cantilever is obtained through mathematical and simulated analysis and found 5.5e-27 mm and -7e34 mm scale from simulation and mathematical modeling. However, 1.1-4.0 mV output voltage is obtained by the cantilever from minimum finger pressing on tip in open load mode.

1. INTRODUCTION

We propose a cantilever based harvester for acoustic energy transfer in this paper based on the related research works [1, 2, 3]. The cantilever model is designed by following a four layer configuration using Aluminum, Zinc Oxide and Silicon. Zinc Oxide is used for the piezoelectric layer. Top and bottom electrode layers are developed by Aluminum. The base layer is confirmed by Silicon and the thickness is settled to 0.42 mm whereas all other 3 layers has 0.03 mm thickness each. The length and width of the cantilever is 20 mm and 4 mm respectively. Hence, the total device size is $20 \times 4 \times 0.51$ mm^3. Air is used as the medium to analyze the displacement pattern in simulated environment. The proposed and fabricated cantilever is presented in Fig 1. The scope is limited to the study of the receiver end only. Section 2 and 3 presents the governing equations and performances.

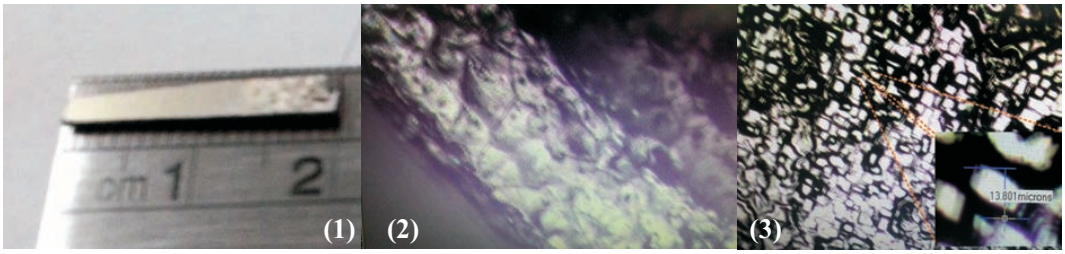

Figure 1: (1)Fabricated Cantilever $20 \times 4 \times 0.51$ mm^3; (2) Deposited Cantilever Layers: Side View; (3) Deposited Aluminum Surface: Top Layer (13.801 microns)

2. GOVERNING EQUATIONS

The bending modulus per unit length for a piezoelectricnonpiezoelectric unimorph is given by [4],

$$D = \frac{E_p^2 t_p^4 + E_{np}^2 t_{np}^4 + 2E_p E_{np} t_p t_{np}(2t_p^2 + 2t_{np}^2 + 3t_p t_{np})}{12(E_p t_p + E_{np} t_{np})} \quad (1)$$

Where, E_p and t_p are the piezoelectric Young's modulus and layer thickness; E_{np} and t_{np} for the non-piezoelectric layers. Bending moments per unit length in the x and y directions resulting from

piezoelectic and non-piezoelectic layers for a four layer cantilever,

$$M_{x,y,p} = \frac{E_{np}^2 t_{np}^2}{(E_{np}t_{np}+E_p t_p)^2} M_E^2 \; and \; M_{x,y,np} = \frac{E_p^2 t_p^2}{(E_{np}t_{np}+E_p t_p)^2} M_E^2; \; here, \; M_E = \frac{E_p E_{np} t_p t_{np}(t_p+t_{np})}{2(E_p t_p + E_{np} t_{np})} d_{31} E$$

$$Hence, \; M_{x,y,p,np} = \frac{3}{2} \frac{E_p^3 E_{np}^3 t_p^3 t_{np}^3 (t_p+t_{np})}{(E_{np}t_{np}+E_p t_p)^5} d_{31} E \tag{2}$$

Here, d_{31} is the piezoelectric coefficient of the piezoelectric layer and E is the applied electric field. Therefore, for a rectangular cantilever with L_x and L_y edges on x and y plane, the displacements can be described as,

$$h = \frac{1}{4}\frac{M'}{D}[x(L_x - x) + y(L_y - y)]; \; where, \; M' \; = M_{x,y,p}(1 - v_p) + M_{x,y,np}(1 + v_{np}) \tag{3}$$

Here v_p and v_{np} is the Poisson ratio of the piezoelectric and nonpiezoelectric layers.

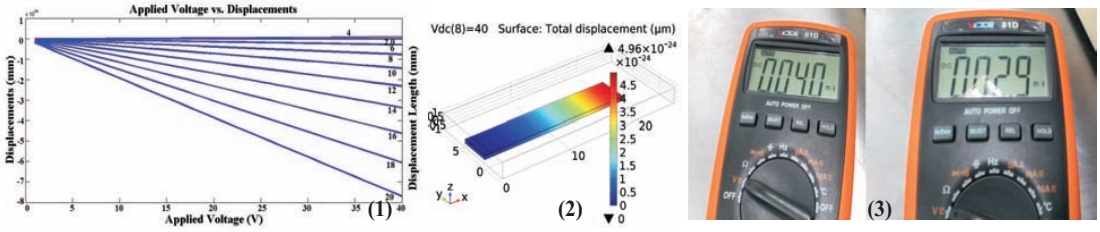

Figure 2: (1)Displacements in Mathematical Analysis; (2) Displacements in Simulated Environment; (3) Finger Pressure Generated Voltage

3. PERFORMANCE ANALYSIS OF THE CANTILEVER

Cantilever displacements is presented in Fig 2. Displacements in Fig 2(1) is calculated by applying equation 3. Fig 2(1) shows, the displacements can be as high as -7e34 mm on the tip of the cantilever and decreases with the occurrence length of the cantilever. Similar effects are found from the simulation as well with 5.5e-27 mm maximum deformation at the tip of the device, as depicted in 2(2). This type of cantilever possesses less displacements and much force by nature, hence, the displacements lie within the nanometer range. Additionally, the finger pressure generated output voltages are found in 1.1-4.0 mV range. The findings are presented in Fig 2(3).

4. CONCLUSION

A multilayer energy harvester based on piezoelectric cantilever is presented in this paper. Cantilever displacements are presented and discussed along with the experimental validation. From the findings, it is obvious that, the proposed harvester can produce voltage as high as 4.0 mV with minimum finger pressure. The obtained displacements from the cantilever is low compared to the conventional ones which lies within nanometer range due to the multilayer configuration. However, it possesses significant energy density due to high stress and can be beneficial in acoustic energy transfer and ambient vibration energy harvesting.

Abstract

A novel concept of A0 Lamb wave mode focusing by piezoelectric array transducers is investigated. Instead of phased array approach and beamforming at certain angle, focusing is performed at desired point. Due to dispersive nature of A0 mode of Lamb wave direct implementation of such approach would be ineffective. This problem is overcome by pre-compensation of dispersion in excitation signals. It means that broad band signal at excitation point will change the shape during propagation so that it forms two cycle Hanning windowed signal at certain distance. The designed excitation waveform for each piezoelectric transducer in the array is different and has embedded appropriate time delay so that interference of waves occurs at desired focal point. Developed technique could be useful for damage detection purposes.

1. Introduction

Anomalies of propagating Lamb wave modes are used for damage detection purposes. Lamb wave modes are excited and registered by array of piezoelectric transducers. Some concepts of damage detection and localization algorithms are similar to radar. Thus, there have been attempt to steer the array of actuators so that the wave will propagate at certain angle. This principle is known as beamforming and it is realized mostly as signal processing of appropriate time delay of propagating wave packets [1, 2]. Moreover, the beamforming algorithm is realized mostly only for receiving signal (sensing at different angles) and actuation-sensing is sequential for the whole phased array. This is because devices for multiple piezoelectric transducers actuation is expensive and complex in development. The other idea of steering the waves at certain angle have been proposed by Salas and Cesnik [3]. They manufactured special micro-device called CLoVER which is able to amplify amplitudes of Lamb waves at certain angles (the resolution of the CLoVER is limited). Both mentioned methods relay on extraction of wave packets related to reflections from damage. These wave packets are often dispersive and of low time–space resolution so that it is difficult to obtain precise damage location. The proposed method uses dispersion compensation to improve resolution. Moreover, completely new approach of piezoelectric array steering is used in which waves energy is not sent to certain angle but to certain focal point.

2. The method for Lamb wave focusing

The proposed method is based on ideas given in [4, 5, 6]. It is desired that at selected distance L short time duration signal $f(t)$ will be obtained such as two cycle Hanning windowed toneburst centered at 100 kHz. This can be achieved by applying at piezoelectric transducer specially designed signals according to formula in frequency domain [6]:

$$G(\omega) = F(\omega) \cdot e^{-ik(\omega)\cdot L}, \tag{1}$$

where $F(\omega)$ is the Fourier transform of $f(t)$, $k(\omega)$ is dispersion relation between wavenumber k and angular frequency ω of compensated Lamb wave mode and L is the compensation distance. The dispersion curve $k(\omega)$ can be obtained experimentally. The time domain designed waveform can be obtained by the inverse Fourier transform of (1):

$$g(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} F(\omega)\cdot e^{i(-k(\omega)\cdot L+\omega t)}\mathrm{d}\omega. \tag{2}$$

For the given array of piezoelectric transducers and selected focal point (see Fig. 1), distances between actuators and focal point are calculated (L_i). For each actuator excitation is calculated according to formula (2). Since distance L_i can be different for each actuator also excitation signals $g_i(t)$ have different form and have embedded time delay so that they interfere at focal point after the same time. The pre-compensation concept is depicted in Fig. 2. It can be seen that designed waveform in Fig. 2(a) applied to piezoelectric transducer causes that the shape of wave packet is changing with the time so that at 0.5 ms (see Fig. 2(d)) has a form of 2 cycle toneburst. Beyond that time the shape of wavepacket changes again due to dispersive nature of Lamb waves.

The results of A0 Lamb wave mode focusing in the form of full wavefield at the top surface of the plate are presented in Fig 3. The excited wave is dispersed at the beginning then it starts to form more compact waveforms. Finally, at the desired location at the time 0.5 ms particular waveforms interfere giving strong amplification of wave amplitude at focal point. The idea is that if at the focal point is a damage it creates strong reflection. Since reflected

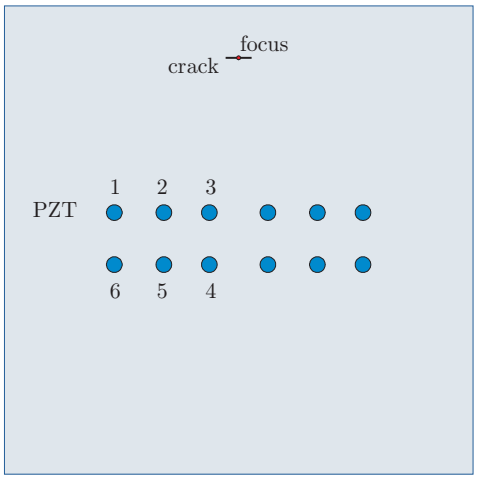

Figure 1: Schematic diagram of piezoelectric transducers array and 20 mm long crack placement on 1 m by 1 m plate.

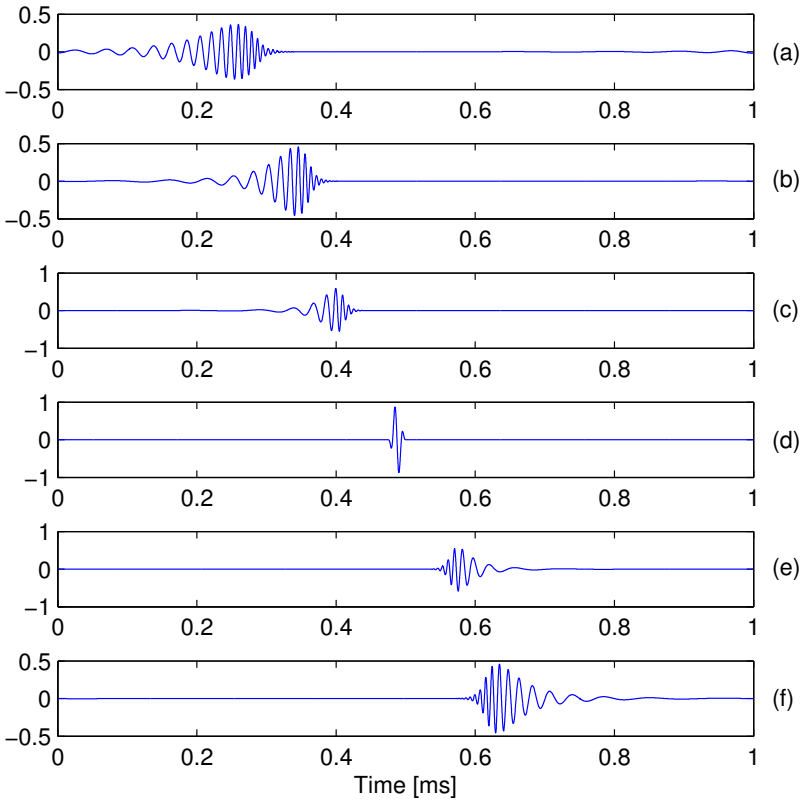

Figure 2: Pre-compensation: (a) response at excitation point (the designed waveform), (b, c) responses between focus and excitation point, (d) response at focus and (e,f) responses beyond focus.

waves are dispersive the signals registered at sensor array have to be post-compensated. Post-compensation of signals registered by sensors is done by using again eqs. (1)–(2) but with positive sign in the exponent. Finally, post-compensated signals from each sensor are summed. The energy value of resulting signal around the designed time (0.5 ms in this case) is a damage indicator. The procedure is repeated for different focal points in order to obtain damage map for the whole surface of the plate.

3. Numerical results

The proof of the concept was conducted by numerical simulation using the time domain spectral element method. 12 piezoelectric transducers were modelled on the 1 mm thick aluminium alloy plate of the size 1 m by 1 m. Transducers were arranged in the form of two rows at the central part of the plate. The distance between the transducers was set to 6 cm. Focal point was selected at coordinates (0, 0.25) m in respect to the origin at the center of the plate (see Fig. 1).

Two cases were considered: undamaged plate and plate with the damage located at the focal point. The signals registered at sensor array for the latter case are shown in Fig. 4. Nothing particular can be said about these signals and it is difficult to indicate a part of signal which corresponds to damage reflection.

However, signal processing described in the previous section connected with post-compensation and summation of signal's contribution from each sensor leads to clear damage indication. The results for the damaged case and undamaged case are presented in Fig. 5 and Fig. 6, respectively. The additional spike in signal caused by the crack has comparable amplitude to the first incoming wave packet. Additionally, it is much stronger than the following part of the signal. It means that it is above certain noise level and can be utilized as damage indicator.

The method can be a little bit modified by utilization of weights assigned to sensors depending on the angle and distance in respect to focal point. Such approach can slightly increase the amplitude of additional spike in signal caused by a damage. The weighted approach is indicated in Fig. 5 by blue color.

The beauty of the proposed method is that it is very easy to extract damage feature from the signal. It can be noticed that the additional spike in the signal caused by the crack is at around the time 0.5 ms which is exactly at the same time as in case of designed pre-compensated signal forming 2 cycle toneburst (vide Fig. 2). It means that the time of interest is known *a priori* and we can calculate signal's energy or maximum value from the interval around this particular moment of time as the damage indicator.

4. Conclusions

New method for Lamb wave focusing was presented. The principle of the method was tested exclusively by numerical methods. It has been found that the proposed method has great potential for damage detection and localization in structures. Further studies will be performed experimentally in order to confirm the effectiveness of the method.

Abstract-It has been observed researchers use triangular bump which is generally called as baseline shape to hide objects under it using Helmholtz resonator[1] or membrane[2] or such kind of metamaterial for manipulating the reflected phase to cloak it. Our approach is to find the surface impedance for a shape analytically and then using it for manipulating the phase to cloak the obstacle. We have confirmed it by 2D numerical simulation.

For getting surface impedance we have mainly focused on the following three relationship:

$$\varphi = -2kh \quad \text{.....(i)}$$

$$R = e^{j\varphi} \quad \text{.....(ii)}$$

$$Z_n = Z_0 \frac{1+R}{1-R} \quad \text{.....(iii)}$$

Using the equations (i)-(iii), we have deduced the required surface impedance and using them, we have got promising result for cloaking the triangular and dome type bump. The figures are given below:

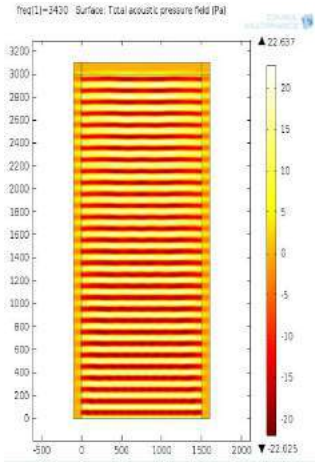

Fig1.a: with wall only

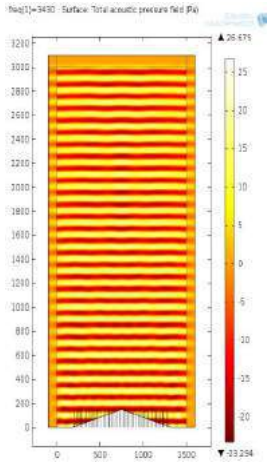

Fig1.b: With the surface impedance on the bump

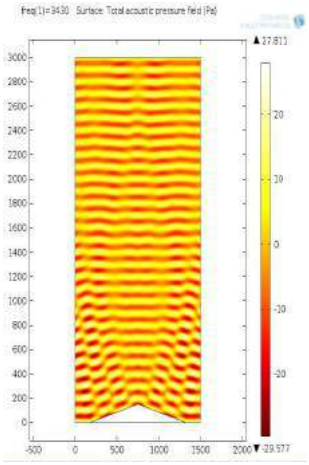

Fig1.c: with bump only

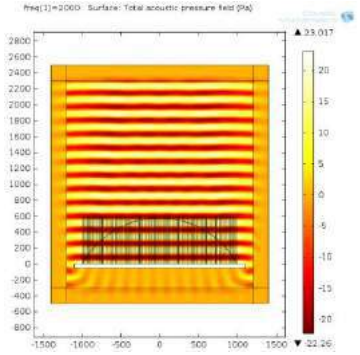

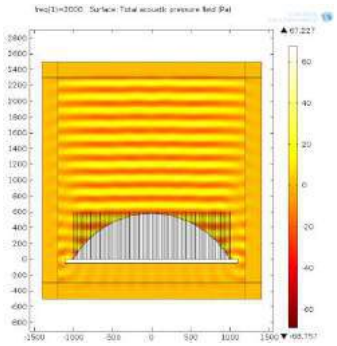

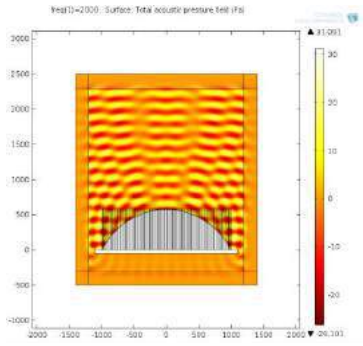

Fig2.a: with wall only Fig2.b: with the surface impedance on the dome Fig2.c: with dome only

If we see fig.1(a) and fig. 1(b), it can be seen that the wave pattern of both figure is similar though at fig1.(b), there is an triangular bump. It seems from fig.1(b) as if the sound is being reflected from a plane wall. From fig1.c, we can see the original scattering behavior of the sound as we didn't use the surface impedance for this case. So, from those figure, we can realize that the bump has been cloaked. Similarly from fig2-(a), (b) and (c), we can realized the dome shaped structure has also been cloaked by the same manner. The main feature of our study is that as we can deduce the required surface impedance at first, have a choice to select a method to design it such as Helmholtz Resonator or Membrane based structure and thus opportunity to cloak a variety types of shapes. This study was done by COMSOL 2D numerical simulation. At next, we have a plan to do it experimentally.

Materials for photonics (Graphene, MoS2, WS2, etc)

The Synthesis of the Novel Fe_3O_4@Void@Ag Yolk-shell Nanostructures from the Fe_3O_4@Carbon@Ag Core-shell Nanoparticles

Di Liu[1], **Jaebeom Lee**[1*]

[1] Department of Cogno-Mechatronics Engineering, Pusan National University, Busan, 609-735, Republic of Korea

Abstract- Compared with the core-shell and hollow nanoparticles, the yolk-shell nanoparticles (YSNs) with the void space between the core and shell have attracted more attention because of their appealing structures, tunable physical and chemical properties. Here, we tried to synthesis the Fe_3O_4@void@Ag YSNs with removing the carbon shell of Fe_3O_4@carbon@Ag core-shell nanoparticles (CSNs) by the calcination. The area of void space could be adjusted by the thickness of the carbon shell of the Fe_3O_4@carbon@Ag CSNs.

The interspaces provide the place not only for the cores to be freely movable, but also for the storage of the chemicals. Combined with the functional shells, they can endow the YSNs some new properties, and thus render them appealing for more applications, such as nanoreactors, biomedicine, lithium-ion batteries, and photocatalysis[1-6].In the past decade, most researchers focus on the synthesis of YSNs with the template-assisted selective etching approach, however, this approach showed some defects, such as environmentally unfriendly features, low efficiency and complicated processing steps.

Currently, magnetoplasmonic (MagPlas) nanoparticles have attracted more and more attention because of their remarkable combination of the functional natures of magnetic and plasmonic optical property. Fe_3O_4@Ag CSNs, which is one of the representative MagPlas NPs, have been applied in many fields.

In this study, we challenged to fabricate the Fe_3O_4@void@Ag YSNs with a feasible method, which will display better properties than the CSNs. Firstly, the Fe_3O_4@carbon@Ag CSNs were synthesized by the menas of step by step. Secondly, the obtained Fe_3O_4@carbon@Ag CSNs were calcinated by the tube furnace in the pure air atmosphere, which could remove the carbon shell. Finally, we could get the Fe_3O_4@void@Ag YSNs. This approach to the synthesis of Fe_3O_4@void@Ag YSNs exhibited some distinguished advantages. It avoided using the environmentally hazardous alkali, and the synthetic process was simple and feasible. By the control of the synthesis of carbon shell, we could easily acquire the Fe3O4@carbon@Ag YSNs with different void spaces. Hence, the novel Fe_3O_4@void@Ag YSNs would obtain more application in many fields.

Abstract- The expansion of the graphene family by adding silicene, germanene, and stanene opens a promising platform to probe the complex interplay between topology, photonics, and 2D Dirac materials. In this work we investigate the behavior of the photonic local density of states close to buckled materials and show that it can undergo various phase transitions and present topological behavior, all enabled by the rich electronic phase diagram of the graphene family.

In the last few years, notions of topology have been applied to both electronic and photonic systems, opening the field of topological quantum materials [1, 2] and uncovering a myriad of novel effects in classical optics [3, 4]. Even more recently, the expansion of the graphene family by adding silicene, germanene and stanene (2D allotropes of Si, Ge, and Sn) [5], has led to the discovery of various Hall transitions involving the complex interplay between topology, electronic phase transitions, and spin-orbit coupling in such systems. These new 2D van der Waals materials have a layered honeycomb structure similar to graphene, but the two inequivalent atoms in the unit cell are arranged in staggered layers (Fig. 1a) due to strong sp^3 bonding. Owing to their heavier constituent atoms such materials have an intrinsic spin orbit coupling that opens a small gap in the electronic band structure. Under the presence of a static electric field E_z and a circularly polarized laser of coupling strength Λ, the mass gaps of each Dirac cone can be controlled individually and the material can be driven through several topological phase transitions, as shown in the phase diagram in Fig. 1b [6]. Recently we discovered that graphene family materials give origin to Casimir force phase transitions [6].

In this work, we exploit the rich and unique optical properties of the graphene family to examine topological phase transtions in the photonic local density of states (ph-LDOS). The ph-LDOS is a key quantity in the description of the electromagnetic field at the nanoscale, which encodes spatial, spectral, coherence and polarization properties of light. Besides, the ph-LDOS is known drive basic processes in quantum electrodynamics, such as fluorescence, thermal absorption and emission. We show that, in addition to doping, the external static electric field and circularly polarized laser provide extra degrees of freedom to efficiently manipulate the ph-LDOS at the nanoscale. It is shown that the behavior of the ph-LDOS as a function of E_z and Λ resembles the electronic phase diagram of the graphene family materials, with the ph-LDOS being largely enhanced close to phase transition boundaries (Fig. 1c,d). While topology effects are subdominant in the near-field electric ph-LDOS, we discover that the magnetic ph-LDOS presents signatures of the Chern number of each phase of the material.

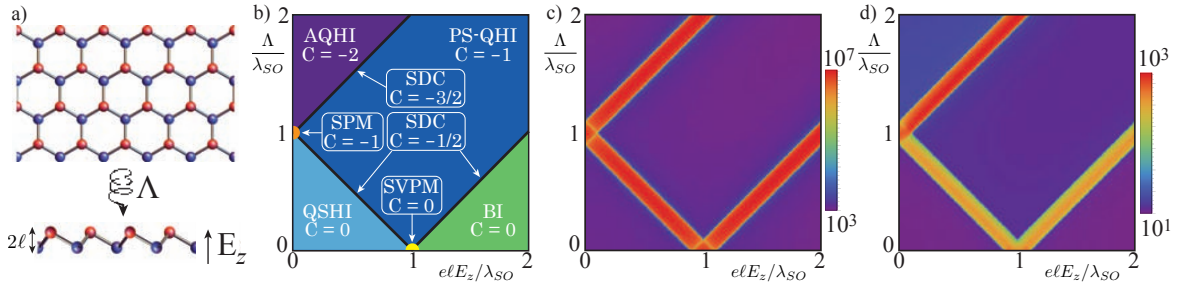

Fig. 1: Topological phase transition in the photonic local density of states. (a) Top view of the hexagonal lattice structure of the graphene family. The red and blue colors represent the two inequivalent atoms in the structure. While graphene has a planar atomic configuration, silicene, germanene, and stanene have a finite staggering 2*l*. (b) Phase diagram of the graphene family materials under the influence of a static electric field E_z and a circularly polarized laser of coupling stregth Λ. The Chern number *C* is shown for each phase and λ_{SO} is the spin-orbit coupling energy. Panels (c) and (d) depict the phase diagram of the electric and magnetic components of the photonic local density of states (normalized by the free space ph-LDOS) near a neutral layer from the graphene family. The distance to the layer is $d = \hbar c/50\lambda_{SO}$, and the frequency $\omega = \lambda_{SO}/10\hbar$.

Tip-enhanced exciton-plasmon coupled imaging and control in monolayer WSe_2

Kyoung-Duck Park[1], Vasily Kravtsov[1], Tao Jiang[1], Genevieve Clark[2], Xiaodong Xu[2], and Markus B. Raschke[1*]

Abstract Combining tip-enhanced Raman and photoluminescence with active atomic force tip interaction, we nano-image the exciton behavior associated with defects, grain boundaries, and local strain. Based on exciton-plasmon coupling we achieve a ~10^5-fold enhancement of photoluminescence yield. This hybrid tip-enhanced nano-spectroscopy and -imaging method also enables to probe and control neutral-, multi-, localized-, and dark-excitons at room temperature.

Since the electronic properties of monolayer (ML) transition metal dichalcogenides (TMDs) are strongly influenced by defects and strain, we present a new hybrid nano-optomechanical tip-enhanced spectroscopy and imaging approach combining nano-Raman (tip-enhanced Raman scattering, TERS), nano-PL (tip-enhanced photoluminescence, TEPL), and atomic force local strain control to investigate the excitonic properties through exciton-plasmon coupling [1]. Fig. 1a shows a TEPL image of the as-grown ML WSe_2 resolving exciton-quenching (47%) at twin boundary (TB) due to nonradiative recombination from midgap states of defects. Given the only atomic-scale dimensions of the TB, the spatial scale of PL quenching (~25 nm) could be associated with the exciton diffusion length. From controlled tip–sample nano-mechanical force interaction we can tune the bandgap reversibly (up to 24 meV) and irreversibly (up to 48 meV) through local nanoscale strain

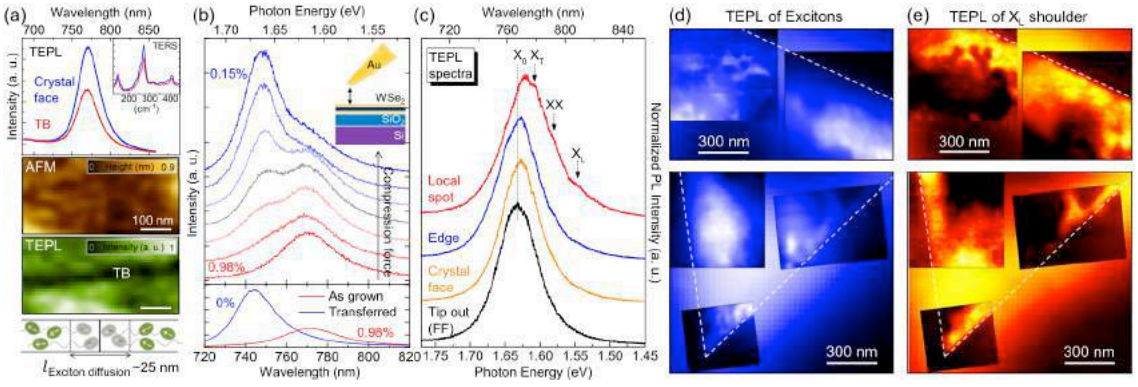

Fig. 1. (a) TEPL spectra and image of the as-grown ML WSe_2 at crystal face and twin boundary regions. (b) Evolution of TEPL spectra with increasing compressive force by the tip, giving rise to a release of the tensile strain of the crystal. Bottom: far-field reference PL spectra for the as-grown (red) and transferred (blue) ML WSe_2. TEPL spectra for various spots (c), and TEPL composite images for the integrated intensity of X_0 (725-760 nm, (d)) and X_L (810-850 nm, (e)).

engineering (0–1%) as shown in Fig. 1b. This allows to actively control the PL energy and quantum yield of nanoscale defects. Further, we achieve a ~10^5-fold enhancement of PL for a ML WSe_2 on the SiO_2/Si substrate as a result of resonant excitation by *in-plane* local plasmon field, the enhanced radiative decay rate in quantum emission through the Purcell effect, and optimization of the exciton-plasmon coupling strength to suppress exciton-quenching. TEPL also enables to observe trions (X_T), bi-excitons (XX), and localized excitons (X_L) signatures even at room temperature (Fig. 1c). These assignments are confirmed by the peak energy difference with neutral exciton peak, and power dependence of PL peak intensities. These plasmon coupled new excitonic properties allow us to investigate spatial local heterogeneity of X_L modes with ~10 nm spatial resolution. As can be seen in Fig. 1d-e, X_L modes concentrate in the vicinity of the crystal edges in contrast to X_0 modes associated with the density of structural defects.

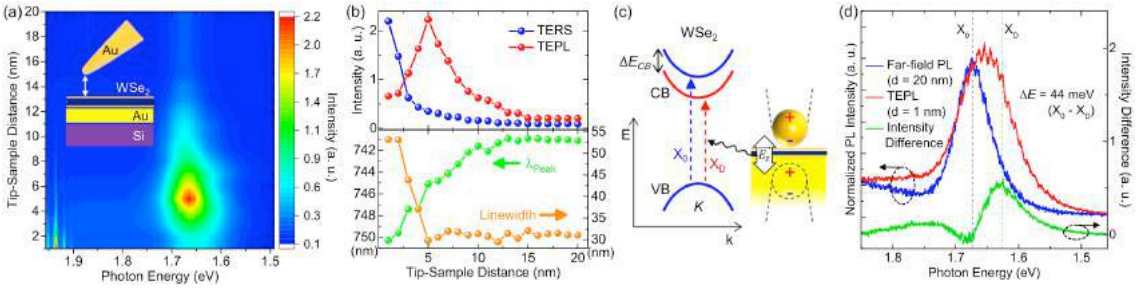

Fig. 2. (a) Tip-sample distance dependence of TERS and TEPL of a ML WSe_2 on the Au substrate. (b) Peak intensity dependence of TERS (273 cm^{-1}) and TEPL (X_0), and peak position and linewidth dependence of TEPL response with respect to the tip-sample distance, derived from (a). (c) Schematic illustration of an optical transition of dark excitons at the *K* point of WSe_2. (d) Normalized PL spectra for the tip-sample distances of 20 nm (blue) and 1 nm (red), and their intensity difference (green) exhibiting peak energy of dark excitons.

We then transferred the sample onto a Au substrate to induce a strongly confined *out-of-plane* optical field to a ML WSe_2 from the plasmonic nano-gap. As shown in distance-dependent spectra (Fig. 2a), the TERS response is significantly enhanced at <5 nm, while the exciton-quenching sets in, as expected. An associated linewidth increase is observed in this regime with significant spectral redshift (Fig. 2b), in contrast to the sample on the SiO_2/Si substrate. We believe the plasmonic tip-sample coupling facilitates transition to intra-valley excitons degenerated in a lower-lying conduction band, i.e., nominally spin-forbidden dark excitons (X_D), as illustrated in Fig. 2c. To estimate an energy gap of dark excitons, far-field PL (d = 20 nm) and TEPL (d = 1 nm) spectra are normalized and their spectral difference is plotted as shown in Fig. 2d. The energy splitting of bright/dark excitons is estimated to ~44 meV, which is comparable to results from recent report at low temperature [2].

In summary, we demonstrate the tip-induced manipulation of excitonic properties of ML WSe_2 from active control of the exciton-plasmon coupling. We expect that this new approach broadens the opportunities for applications of TMDs in novel photonic and optoelectronic devices.

Abstract-Graphene has many exceptional properties such as electrical and optical properties. Therefore, it has attracted attention for applications in electronics, optics and THz technology. The purpose of this work is to study the sensitivity of a composite material made of graphene sandwiched between two layers of dielectric materials. The top layer is linear dielectric and the substrate is nonlinear dielectric. The results will be presented.

Graphene is a two-dimensional crystalline material in which the carbon atoms are arranged in a hexagonal lattice. For this reason, Graphene has particular electronic properties since every carbon atom attached to other atoms by tough sp^2 hybridization. This material has a little overlap between valence and conductance bands; furthermore, high density of electrons or holes can be stimulated by gate voltage applications. In graphene, electrons interact with the hexagonal network; consequently, the electrons act as massless particles. They are named Dirac fermions since they are described by the Dirac equation. The Dirac fermions in graphene can be controlled by electromagnetic fields because they transmit one part of electric charge.

A substantial amount of research are conducted on graphene, which has versatile applications. Papasimakis et al. (2010) proposed a structure comprised a monolayer graphene placed on a metamaterial. They showed that the graphene improved the metamaterial sensitivity indicating that the structure is viable for optical sensing.

El-Khozondar et al. (2017) studied the sensitivity of a composite material made of single graphene layer cladded by dielectric and metamaterial. The concluded that the sensitivity depends on the metamaterial parameters.

We propose to study a graphene layer coated by two dielectric media. The crowned dielectric has a linear permittivity ε_2 and the underlying nonlinear material has permittivity $\varepsilon_{NL}= \varepsilon_1 +\chi^3 |E|^2$. The incident TE waves are considered constant in the y direction.

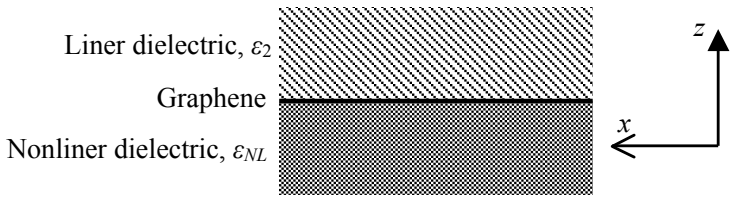

Figure 1. Graphic of a graphene sheet surrounded by linear and nonlinear dielectric media.

The dispersion equation of nonlinear surface polaritons is given by,

$$s\left[p_1^2-\left(\frac{\omega}{c}\right)^2\left|\varepsilon_y\left(0\right)\right|\right]^{1/2}+p_2=i\omega\mu_o\sigma\left(\omega\right), \tag{1}$$

where s=±1 refers to the sign of z_o (the point at which the wave is localized), $p_j^2=k_x^2-\left(\frac{\omega}{c}\right)^2\varepsilon_j; j=1,2$, $\sigma(\omega)$ is the graphene conductivity, which is given by

$$\sigma\left(\omega\right)=\sigma_1+i\sigma_2+\sigma_D \tag{2}$$

$$\sigma_1=\sigma_o\left(1+\frac{1}{\pi}\arctan\frac{\hbar\omega-2E_F}{\hbar\gamma}-\frac{1}{\pi}\arctan\frac{\hbar\omega+2E_F}{\hbar\gamma}\right) \tag{3}$$

$$\sigma_2=-\sigma_o\frac{1}{2\pi}ln\frac{\left(2E_F+\hbar\omega\right)^2+\hbar^2\gamma^2}{\left(2E_F-\hbar\omega\right)^2+\hbar^2\gamma^2} \tag{4}$$

$$\sigma_D=\sigma_o\frac{4E_F}{\pi}\frac{1}{\hbar\gamma-i\hbar\omega} \tag{5}$$

where $\sigma_o=\pi e^2/(2h)$, e is the electron charge, γ is the relaxation rate and E_F indicates for the Fermi level. The sensitivity is defined as the variation of the propagation constant k_x with respect to linear permittivity ε_2. Therefore, differentiating Equation (1) with respect to linear permittivity ε_2, we get the following expression for sensitivity,

$$\frac{dk_x}{d\varepsilon_2}=\frac{k_o^2}{2k_x}\frac{\sqrt{p_1^2-k_o^2\left|E_y\left(0\right)\right|^2}}{sp_2+\sqrt{p_1^2-k_o^2\left|E_y\left(0\right)\right|^2}} \tag{6}$$

Sensitivity in equation (6) depends on the nonlinearity, which make it possible to tune it by changing the field strength. It also depends on ε_2. Therefore, our proposed sensor is capable to detect environmental changes at the cladding area.

Ultralow-loss copper films for plasmonics: structural morphology is the key to the improvement of optical properties

D. I. Yakubovsky and D. Yu. Fedyanin*
Laboratory of Nanooptics and Plasmonics, Moscow Institute of Physics and Technology, Russian Federation
*corresponding author: dmitry.fedyanin@phystech.edu

Abstract – Plasmonics is widely considered to be a promising candidate for the next generation of chip-scale platforms. However, it is based on noble metals, which are incompatible with the industry-standard manufacturing processes. Here, we demonstrate both experimentally and theoretically that copper can efficiently substitute gold in plasmonic devices and open the prospects for commercialization of plasmonic technologies.

Metal is the essential part of plasmonic and metamaterial devices and components. It gives the possibility to confine light to a space much smaller than the light wavelength and enhance light-matter interaction. However, the performance of metal-based plasmonic devices is severely limited by ohmic losses in the metal, which are determined by electron scattering. For this reason, the most widely used metals in plasmonics are gold and silver due to their exceptional electron conductivity. However, it has been recently reported that thick copper films can exhibit optical constants better than that of gold [1,2], which casts doubt on the previous studies.

In this work, we explain these unexpected experimental results. Furthermore, we have developed a deposition process which gives the possibility to fabricate ultralow-loss thin copper films whose optical properties are superior to gold even at very low film thicknesses (Figure 1a). We have found both theoretically and experimentally that optical properties of copper films are mostly governed by their structural morphology. In turn, the structural morphology is determined by the fabrication process and by the film thickness (see Figure 1). Our findings demonstrate that by controlling the structural morphology in the deposition process, it is possible to greatly decrease ohmic losses in copper and design 'gold quality' plasmonic devices for diverse practical applications.

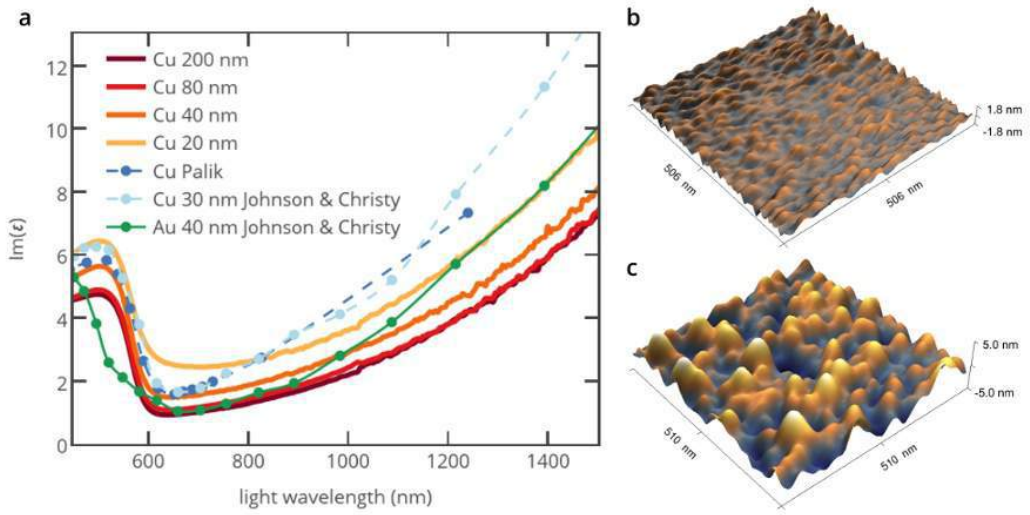

Figure 1. **(a)** Spectral dependence of the imaginary part of the dielectric function, which is responsible for ohmic losses, for the as-deposited copper films and the data from Johnson and Christy [3] and Palik [4]. Despite that the fabrication process was absolutely the same for all samples, the structural morphology of the obtained films is different, which results in different optical properties. **(b,c)** Surface morphology for two copper films of different thicknesses fabricated in same technological process. The grain size for the 200-nm-thick film (panel c) is much larger than for the 20-nm-thick film (panel b), so is the surface roughness.

Enhanced Optical Absorption in MoS_2 Layers Grown on Si Nanocone Arrays

Eunah Kim, Yunae Cho, Soyeong Kwon, and Dong-Wook Kim*
Ewha Womans University, Korea
*corresponding author: dwkim@ewha.ac.kr

Abstract-We prepared MoS_2 layers on SiO_2/Si nanocone (NC) arrays and investigated their characteristics. The NCs strongly concentrated incoming light at the surface and increased optical absorption of the MoS_2 layers in broad wavelength range. Finite-difference time-domain simulations were performed to explain the experimental optical properties of the MoS_2-NC integrated structures. The influences of the enhanced absorption on the reflection, photoluminescence, and Raman spectra were investigated.

There has been growing research interest in 2D atomically thin semiconductor, MoS_2, of which physical properties are very distinct from those of conventional 3D semiconductors. MoS_2 has a sizable band gap (1.2 ~ 1.8 eV), which has stimulated active research efforts to realize 2D optoelectronic devices. Extremely small thickness of a few atomic layers, however, limits the optical absorption in MoS_2 despite its very high absorption coefficient. Many researchers have attempted to improve the optical absorption in MoS_2 based on plasmonic effects and interference. In this work, we fabricated integrated structures consisting of 2D MoS_2 layers and 3D SiO_2/Si nanocone (NC) arrays, where the MoS_2 layers were synthesized by chemical vapor deposition method. The periodic arrays of NCs concentrated incoming light near the surface with the help of Mie resonance, multiple reflection, diffraction, and interference. Consequent enhanced optical absorption raised photoresponsivity (R) of MoS_2-NC structures in broad wavelength range: R of the MoS_2-NC structure at wavelength of 532 nm was almost an order of magnitude larger than that of the planar counterpart [1]. Further optical characterizations, such as photoluminescence and Raman measurements, were performed to investigate the influence of the surface concentrated light on the optical properties of the MoS_2 layers on the NC structures. This work demonstrates that the 2D MoS_2 and 3D NC integrated structures could provide a useful means to achieve high-performance optoelectronic devices.

Strong Coupling between the WS_2 Excitons and Metallic Plasmonic Nanoholes

Xuexian Chen[1], **Huanjun Chen**[1*]

[1]State Key Laboratory of Optoelectronic Materials and Technologies, Guangdong Province Key Lab of Display Material and Technology, School of Electronics and Information Technology, Sun Yat-sen University, Guangzhou 510275, China

Abstract-We demonstrated that the strong coupling between WS_2 excitons and plasmonic gold nanoholes. By transferring monolayer WS_2 onto the Au nanoholes fabricated by focused ion beam technique (FIB), a hybrid two dimensional optical system has been achieved. Rabi splitting was observed by measuring scattering spectra from the hybrid system. A Rabi splitting of 162 meV is observed at room temperature for this system. Furthermore, the coupling strengths can be tailored by changing the diameter of the hole.

Among the various two-dimensional atomic crystal materials, transition metal dichalcogenides (TMDs), which changes from an indirect to a direct band-gap material when passing from multilayers to a single−layer, have raised much attention in the past five years. On the other hand, tailoring the light−matter interactions from weak to strong coupling regime can endue with a variety of novel physical phenomena, which forms the basis for realization of high performance optoelectronic devices. Metal nanostructures exhibit exceptional electromagnetic field localization due to their surface plasmonic characteristics, which make them excellent platform for achieving strong coupling at room temperature.[1] In the strong coupling regime, upon light irradiation, the electromagnetic coupling between exciton−plasmon yields a hybrid state consisting of two spectrally separated energy bands. The energy separation between these two bands i.e., Rabi splitting energy, was used to measure the coupling strength between the exciton and plasmon.[2] Although such a strong coupling behavior has been reported in the MoS_2 coupled with metal nanostructure arrays,[3] studies using WS_2 which exhibit larger exciton binding energy remained unexplored.[4]

In our study, a hybrid system composed of a monolayer WS_2 and plasmonic gold nanoholes was explored to demonstrate the strong coupling effect. We showed from both of the experiments and numerical simulations that the Rabi splitting can be obtained between the WS_2 excitons and plasmons supported by the gold nanoholes. By changing the diameter of the nanohole, we were able to tailor the coupling strengths facilely. The charge density distributions of a single nanohole coupling with exciton were also studied by a finite-difference time-domain (FDTD) method.

In summary, we have proposed a strong coupling system by integrating the monolayer WS_2 with plasmonic gold nanohole arrays. The coupling strengths can be tailored by tuning the diameter of the nanohole. At lager diameters, charge density distributions were observed to form more circular interference fringes due to the strong coupling process. We strongly believe that such a system can open new avenues to manipulate the light−matter interactions at the nanoscale.

Highly confined phonon polaritons in thin van der Waals crystal of orthogonal molybdenum trioxide

Zebo Zheng, Huanjun Chen*

State Key Laboratory of Optoelectronic Materials and Technologies, Guangdong Province Key Lab of Display Material and Technology, School of Electronics and Information Technology, Sun Yat-sen University, Guangzhou 510275, China

*corresponding author: chenhj8@mail.sysu.edu.cn

Abstract- Here we report the study on the surface phonon polaritons (SPhPs) in a representative layered oxide crystal, orthogonal molybdenum trioxide (α-MoO_3). The ultra-confined SPhPs waves resulted from the coupling of IR light and optical phonons of α-MoO_3 were launched, detected, and imaged in real space. Our results suggest α-MoO_3 as a new platform for studying on novel regimes of light−matter interactions and the future nanophotonic devices.

Polaritons, the hybrid electromagnetic modes, can offer efficient approach towards subwavelength light trapping and manipulating, which therefore open up new avenues for enhancing light−matter interactions at the nanoscale. In recent years, van der Waals (vdW) layered materials are demonstrated to support a variety of polaritons, which have attracted enormous interests from the nanophotonics community due to their high degree of confinement compared to other materials systems [1][2]. To date, vdW materials such as graphene, hexagonal boron nitride (h-BN), tungsten diselenide (WSe_2) supporting different types of polaritons have been theoretically and experimentally demonstrated by different groups [3-6].

Polar dielectrics can on one hand sustain polaritons (for example, phonon polaritons in h-BN) with confinement comparable to other counterparts (such as plasmon in graphene), and on the other hand offer lower optical loss and higher quality factor. As an expected member of vdW 2D materials, 2D oxides such as α-MoO_3 with rich infrared active optical phonons may lead to the polaritonic functionalities similar to that in h-BN. On one hand, α-MoO_3 is thermally stable and less susceptible to air, making it a potential polaritonic materials with high stability. On the other hand, it tend to react with minority chemicals such as hydrogen and some metal ions, this may benefit the active tuning of polaritons that are limited in the present platform such as h-BN. However, the study on polaritons in 2D oxides have not yet been explored.

In this study, By using scattering-type scanning near-field optical microscopy (s-SNOM), the low-loss ultra-confined SPhPs waves resulted from the coupling of IR light and optical phonons of the α-MoO_3 were launched, detected, and imaged in real space. Our results demonstrated that the α-MoO_3 exhibit natural hyperbolicity results from the strong dielectric anisotropy, where the in- and out-of-plane permittivities have opposite signs. The highest electromagnetic confinement on one hand can reach ~ 10^{-2} λ_0 which is comparable to those in other materials such as grapheme and hexagonal boron nitride, and on the other hand, can be tuned by altering the thickness of the α-MoO_3. Due to the orthogonal lattice structure, the SPhPs in our specimen also showed in-plane anisotropic propagation along different crystalline directions. We further experimentally demonstrated the active controlling of the propagation of SPhPs by applying the facile chemical doping manner. In this manner, metal atoms are intercalated into the gap between adjacent α-MoO_3 layers, resulting in a

reversible lattice disorder, and therefore the annihilation of surface wave.

In summary, We studied the surface phonon polaritons in the layered α-MoO_3 crystal using near-field optical microscopy. Our results suggest the natural optical hyperbolicity of the α-MoO_3 crystal resulted from the in- and out-of-plane dielectric anisotropy. We also demonstrated the tailorable spatial confinement and active controlling of the SPhPs in the α-MoO_3. We believe that our results can offer new avenue for research on 2D oxides and offer guidelines for exploring new 2D polaritonic materials.

Anisotropic high field terahertz response of free standing multi walled carbon nanotubes

Byounghwak Lee[1], Ali Mousavian[2], Michael Paul[2], Eunhee Jeang[3], Dai-Sik Kim[4], and Yun-Shik Lee[2*]

Abstract-We demonstrate that multi-walled carbon nanotubes (MCNTs) highly aligned on a U-shaped polyethylene reel exhibit distinctly anisotropic terahertz (THz) responses. For THz polarization parallel to the MCNTs axis, strong THz pulses induce nonlinear absorption in the quasi-one-dimensional conducting media, while only linear effect is observed in the perpendicular polarization configuration. A theoretical analysis of transmitted THz pulses measured in THz time-domain spectroscopy (THz-TDS) reveal that intense THz fields enhance permittivity in carbon nanotubes by generating charge carriers.

The high responsivity of CNTs to THz electromagnetic wave which has the spectral regime where photonics and electronics encounter creates great potential for a wide range of applications, including ultrafast nano-photonics[1] and electronics[2]. Recently, high-field electron dynamics become important when CNT devices shrink to nanometer dimensions, where operating frequencies are in the THz range and internal electric fields exceed 100 kV/m. It is, however, rarely studied how electrons in CNTs behave in the presence of strong THz fields.

In this summary, we present an experimental study[3] based on a nonlinear THz transmission spectroscopy performed to investigate THz responses of free-standing MWNTs sheets drawn from the CNT forest[4] synthesized by catalytic chemical vapor deposition (CVD). We generate strong THz pulses ($E_{THz} \geq 1.0$MV/cm) via optical rectification of femtosecond laser pulses with titled pulse front for phase matching between optical and THz pulses in $LiNbO_3$ crystal[5] and detect THz pluses transmitted through the four samples of which areal density is proportion to the deposition number N_w (=2, 5, 10 and 20) on the PE reel, using a liquid-He cooled Si:Bolometer and electro-optic (EO) sampling with a 1-mm ZnTe crystal. When the THz polarization is aligned parallel to the MCNTs axis, THz response of the samples is significantly stronger than that of the perpendicular configuration (Fig1. a-i & ii): The parallel absorption coefficient is 0.47 per deposition and the normalized di□erential transmission (ΔT/T) exhibits a larger change for higher nanotube density, while the perpendicular absorption coe□cient is 0.024 per deposition and ΔT/T is almost zero. To better understand the THz induced nonlinear e□ect for the parallel polarization configuration, we extract the complex refractive indices, $\tilde{n}(\omega) = n_{Re} + in_{Im}$, of the MCNTs samples from the transmitted THz waveforms measured in THz-TDS using the Fresnel transmission coefficient of a layer[3], $t(\omega)$, and an optimization protocol (Taylor approximation and Hessian matrix, and the deviation of the theory),[3,6] . We fit the results to the relative permittivity of a conducting medium based on Drude model:

$$\varepsilon_r(\omega) = \varepsilon_b - \frac{\sigma_0 \tau}{\varepsilon_0} + i\frac{\sigma_0}{\varepsilon_0 \omega} = \tilde{n}(\omega)^2 \qquad (1)$$

where ε_b is the contribution from bound electrons, τ is the scattering time ($\tau \ll \omega^{-1}$), and σ_0 is the DC conductivity of MCNTs. As shown in Fig1.d-iii, the conductivity of the low density sample (N_w =2) increases as the field strength increases, where the e□ect of the carrier generation dominates that of the scattering time reduction. In the high density samples of N_w =5 and 10, the reduction of the conductivity at the high field strength suggests that the scattering rate becomes much higher than the carrier generation rate.

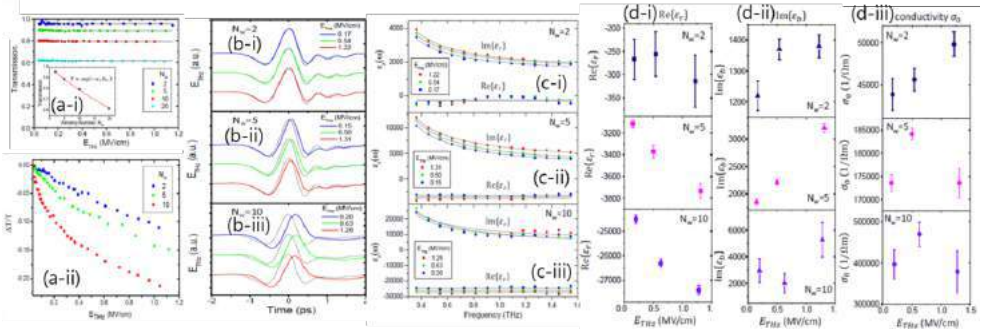

Figure1. THz transmission for THz polarization (a-i) perpendicular / (a-ii) parallel to MWCNT axis measured by a Si:Bolometer. (b-i, ii, & iii) transmitted THz waveforms measured in THz TDS, (c-i, ii, & iii) relative permittivity of MCNTs, and (d-i, ii, & iii) dielectric constant and conductivity depended on N_w =2, 5, 10 and 20 (Transmission through the N_w = 20 sample is too low to acquire meaningful data)

In conclusion, strong THz pulses give rise to highly anisotropic linear and nonlinear responses in freestanding MCNTs. In particular, intense THz fields induce large nonlinear absorption for the polarization parallel to the CNT axis, while no nonlinear response is observed in the perpendicular case. A theoretical analysis based on the Drude model suggests that strong THz fields enhance the permittivity of the MWNTs (Fig1 c-i, ii, & iii) inducing strong nonlinear electron dynamics.

Abstract

A unique two-stepped combination of chemical and microwave reduced method successfully synthesizing the high performance of graphene antenna. The antenna recorded ultra-wide band radiation frequency of 2.5 GHz until 12.2 GHz with high energy produced of 5.5dB to 14.5dB. Small dimension of 90 mm × 45 mm made the antenna suitable enough to be applied and integrated in microwave related system. Most importantly, the measured and simulated results are within in acceptable similarity.

1. Introduction

Graphene is the promising radiating material for the sensor for cancer detection purpose [1]. Since graphene is very expensive to buy, having reduced graphene oxide originated from cheap graphite which has almost the same performance with pure graphene is the ultimate solution for that particular matter. Graphene oxide, a derivative of pure graphene loses most of its electrical conductivity properties during oxidation process. In order to restore back its electrical conductivity, special reduction procedures need to be done [2].

2. Antenna Design and Structure

Two unique methods using a two stepped chemical and microwave method to reduce the graphene are done for that purpose. Figure 1 shows reduced graphene oxide (RGO) in liquid form. It has conductivity of 3.38 × 107 s/m, resistivity of 2.01 × 10-3 Ω.m, voltage of 0.2 V and current of 9.48 × 10-1 I. Test have been done using Four Point Probe device. Meanwhile figure 1 (c) and (d) show antenna views from front and back respectively.

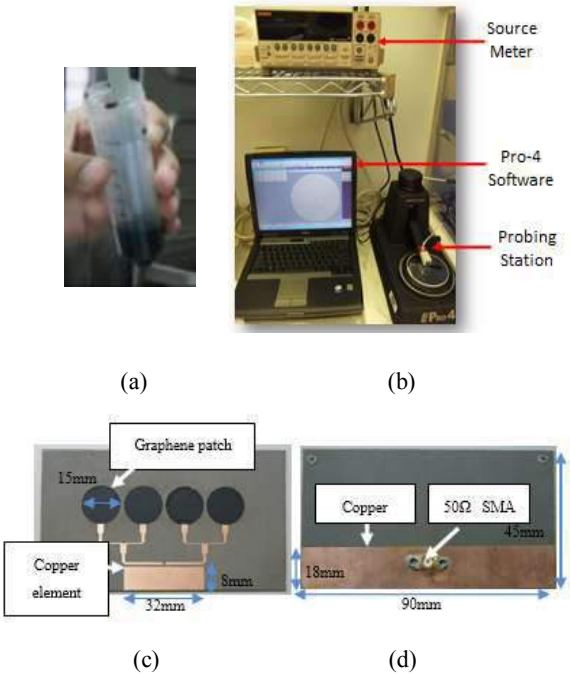

Figure 1: (a) Graphene in liquid form, (b) Four Point Probe, (c) Graphene antenna front view, (d) back view.

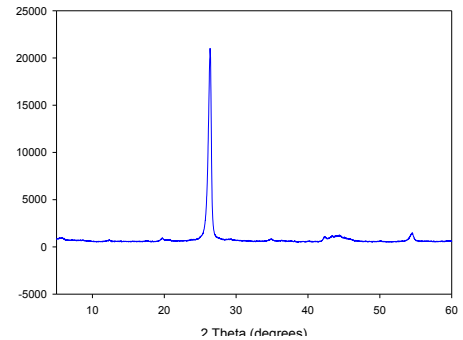
3. Discussion

The most intensive peak at 26.60 is recorded by pure graphite [3] as shown in figure 2(a) for XRD pattern. Due to oxidation reaction, the characteristic peak for graphite becomes broader and shifts toward 12.70. However, XRD pattern for RGO display an increasing broader peak which reveals the disappearance of multilayer structures and the formation of graphene single sheets [4] where the broad hump at 2θ = 20-300 indicated the smaller sheet size and an amorphous structure as shown in figure 2(b). The two-stepped processed product for RGO exhibit adequate reduction as seen in other reduction methods [5]. Figure 3 (a) and (b) show the overall performance of the graphene antenna.



(a)

(d)

Figure 3: (a) Antenna measured and simulated S11 and gain, (b) antenna radiation pattern at 2GHz (Azimuth plane)

4. Conclusions

As conclusion, high performance grapheme antenna has been successfully realized. A unique combination of two-stepped utilized in synthesizing RGO as the radiating element of the antenna. Low cost RGO synthesized recorded similar characteristic of pure expensive grapheme.

Abstract

Fabricated Polydimethylsiloxane Magnetite graphene detector successfully detecting brain cancer using SAR measurement. Combination of fabricated PDMS Ferrite as the substrate and graphene sheet as the radiating element realize the ultra-wide band radiation (2.5 GHz-11.2 GHz) with high energy (2.5dB-11.7dB) in microwave frequency ranges. Amount of energy absorbed by the human brain indicated the present of tumor. Human brain with cancer absorbed more energy and recorded higher SAR value (3.98 W/kg) compared with brain without tumor (2.28 W/kg).

1. Introduction

Since beginning, cancer is one of the most complicated disease ever exist in the world. In 2030, according to statistics done before, around 13.2 million people will suffer and die due to cancer [1]. Microwave cancer detection offers several significant advantages compared to others imaging technique including low costs, noninvasive, involves nonionizing radiation and have high accuracy in detecting tumor existence [2]. In Specific Absorption Rate (SAR), microwave cancer detection is realized by the interesting characteristic of the normal tissue and malignant tissue which demonstrated huge difference in term of dielectric property at the microwave frequency. Malignant tissues will record higher dielectric property due to more absorption of electric field compared to normal tissues which help the researcher to identify the tumor presence [3]. The rate could be calculated from following scientific formula (1):

$$SAR = (\sigma|E|2)/\rho \quad (1)$$

where σ is the tissue conductivity (S/m), E is the internal electric field (V/m) and ρ is tissue mass density (Kg/m3).

PDMS is used due to its unique characteristics especially low permittivity, mixable with other inclusions, flexible, transparent, thermally stable and water resistant [4]. In addition, until now there is yet an investigation in exploring the application of magneto-dielectric substrate for UWB antennas in term of its performance such as mutual coupling, correlation coefficient and diversity gain. Recently, graphene as the radiating material has gained much interested among the communication device community. Eventhough Copper patch antennas demonstrated good results yet it is slightly less good as compared to Graphene due to Graphene has slightly higher conductivity compared with Copper (10^8).

2. Substrate Design and Structure

Figure 1(a) shows the geometry of fabricated new Polydimethylsiloxane Magnetite graphene detector for front view and 1(b) for its gain and reflection coefficient (S11).

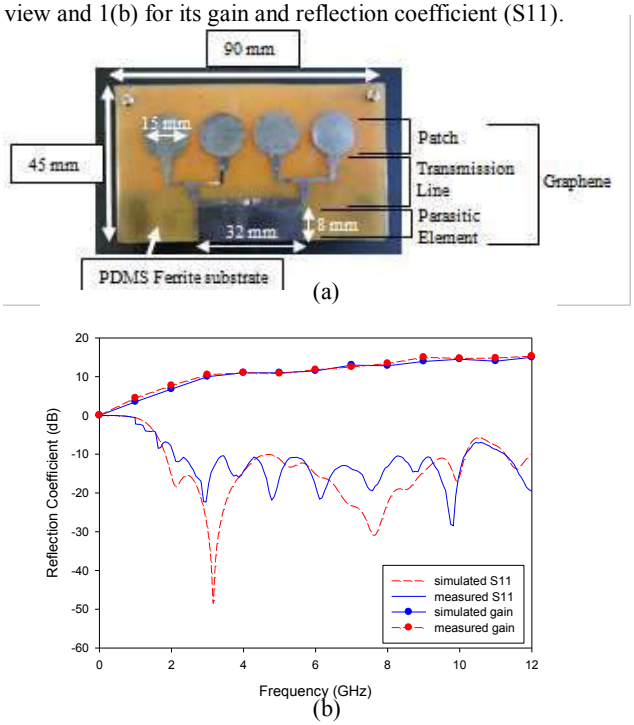

Figure 1: (a) Fabricated PDMS Graphene detector structure, (b) Detector performance in term of gain and S11

3. Discussion

The detector is placed 10 mm away from the multilayer human head phantom as the ideal distance to have maximum energy absorption. The detector radiated the energy towards two different kind of human head phantoms which are the one with tumor present meanwhile another one is without the tumor present to obtain the different SAR value. On the other hand, in order to predict the exact location of the tumor, the detector radiated the energy towards nine different areas to cover the whole one sided area of those two phantoms. The highest different in SAR value among the nine scanned areas between phantom with tumor and without tumor among indicate the tumor position at that particular area. The results are tabulated in table 1 which proposed the tumor position at the area 4 that recorded the highest SAR difference of 1.702 w/kg.

Table 1: SAR measurement result

Scanned Area	Without Tumor (W/Kg)	With Tumor (W/Kg)	Difference
1	0.984	1.563	0.579
2	1.218	1.889	0.671
3	1.439	2.511	1.072
4	**2.284**	**3.984**	**1.702**
5	1.767	1.893	0.126
6	1.102	1.748	0.646
7	1.167	1.951	0.784
8	1.201	1.605	0.404
9	1.323	1.700	0.377

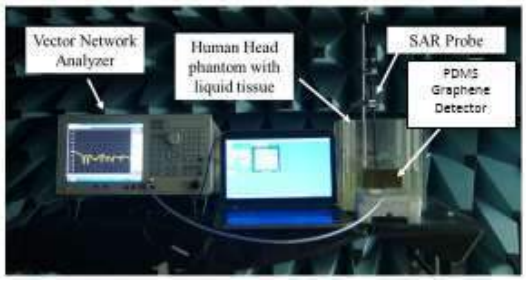

Figure 2: Measurement setup for SAR measurement

4. Conclusions

As conclusion, the detector is successfully detecting human brain tumor based on SAR technique. It is realized by the high performance of the UWB Array antenna which recorded high energy (2.5dB-11.7dB) with wider operated frequency (2.5 GHz-11.2 GHz) due to the presence of grapheme as the radiating material and PDMS-Ferrite as the substrate for the detector. Amount of energy absorbed by the human brain indicated the present of tumor. Human brain with tumor absorbed more energy and recorded higher SAR value (3.98 W/kg) compared with human brain without tumor (2.28 W/kg).

Abstract

In the next generation of mobile communication, fifth generation (5G) will come up with higher frequency band. However, this situation affected reducing antenna size which is more difficult to manufacture especially when using conventional copper as radiating or receiving element. Hence, conductive graphene ink is introduced for smaller antenna and screen printing fabrication. From this conductive ink and approach used, 1 GHz impedance bandwidth is obtained at 15 GHz. The simulated gain achieved is 2 dBi and antenna efficiency is about 80%.

1. Introduction

In every 10 years, communication technology changes from one generation to next generation. Each generation has its own features, improvements and beneficial for mankind. Now, 5G is expected to be a phenomenon in year 2020 at once to overcome the lack of the previous features. In addition, by considering the statements in [1], the spectrum of 5G is above 6 GHz by the time we still do not rule out the statement as reported in [2].

In the latest 4G technology, multi input multi output (MIMO) system is exploited because it has the potential of large capacity gain [3] by enlarging the array of antenna. But in 5G case, enlarge the array of antenna contributes to the increasing of antenna size and then consume extra circuitry area for a particular application. In contrast to small antenna, when it comes in complex design and small element, it cannot be fabricated by copper on Flame Retardant-4 (FR-4) and Rogers easily. Even though the copper possess outstanding conductivities but it is easily oxidized [4]. While silver nanoparticle are popular but it is expensive [5]. Besides, [6] added the increasing printed circuit board (PCB) thickness exceeding 1 mm will directly related to the rising production cost and bulkier design.

Regarding to this situation, the alternative way to manufacture smaller antenna size is by proposing conductive ink as radiating or receiving element and screen printing as the suitable fabrication process. Graphene has ideal properties to be an excellent component of radio frequency integrated circuit (RFIC) [7]. Besides, conductive graphene ink provides chemical stability and flexibility [5], the dimension can be up to centimeter [8], which it is a promising candidate to decrease the antenna size [9] and it is labor-intensive sample preparation compared to the conventional copper [10]. It has lower resistance and inductance caused by its thickness effect [10] where the thickness of graphene in the range of several nanometer. High speed also can be achieved due to special energy band structure and ultrahigh electron mobility in graphene [9]. Hence, several study has been done on graphene ink antenna in order to observe the antenna performance at X-band [5] is, and at lower frequency [11]-[13], respectively. However, very low gain is the main drawback of proposed antenna.

Recently, graphene based antenna employing graphene conductive ink can be achieved through doctor-blading [14], inkjet printing [15], rolling compression method [5] and others. The screen printing technique is proposed because of its simplicity, scalability, environment-friendly process, cost effective and good accuracy [16] on the printed design pattern. It also one of the most versatile and fast [17]. Screen printing is a mass-printing method realized by pressing an ink through a patterned stencil with a squeegee [18]. It has been widely employed for electronics and compatible with a wide variety of functional inks and substrates [18]. Furthermore, it can be used in fine patterning with less than 60 µm of multilayer interconnection in integrated circuit but not suitable for thin film which less than 100µm thickness.

Further details, part 2 will explain the antenna design and its specifications. The screen printing process also was presented to produce the antenna made by conductive graphene ink. Then in part 3, the simulation and measurement result of reflection coefficient magnitude, bandwidth, radiation pattern, gain and antenna efficiency are presented and discussed.

2. Antenna design

The single antenna size consists of its length and width is 11.8 mm and 12.2 mm, respectively. It consists of radiator or receiver element with rectangular shaped of 6.8 mm width and 7.2 mm length, respectively. Then the antenna is

fed by a 50 Ω coplanar waveguide (CPW) with full ground which has chamfer on both side of 1 mm. The gap between ground and transmission line is about 0.08 mm. Figure 1 shows the dimension of graphene antenna. CPW feed is chosen because of its simplicity and ease of fabrication during screen printing process as the radiator or receiver element and the ground plane are printed on the same surface of substrate [19]. The antenna is designed at frequency of 15 GHz. The conductive graphene ink purchase from Sigma Aldrich and characterize with conductivity, σ of 33333.33 S/m with thickness of 0.1 µm, respectively. The substrate used in this work is Kapton polyimide film with dielectric constant, ε_r of 3.5, loss tangent, δ = 0.002, and 0.075 mm thick, respectively.

Screen printing is used to print conductive graphene ink onto a Kapton substrate with simulated design pattern and then the sample is cured for 20 minutes at 250°C. During curing condition, the high temperature does not destroy the Kapton substrate since its maximum operating temperature can be as high as 400°C. Figure 2 shows the fabricated graphene antenna.

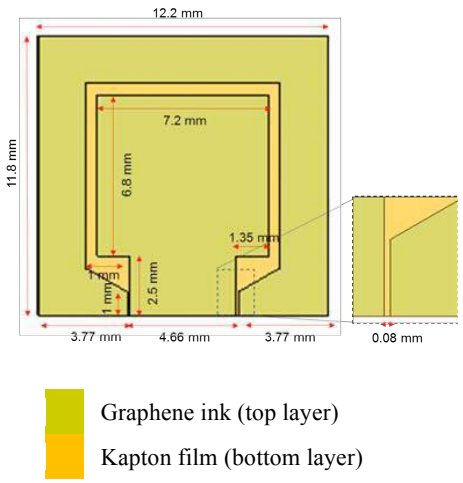

Figure 1: The optimization of antenna parameter length. Green colour is graphene represent as antenna radiator or receiver element on the top layer while yellow colour is Kapton film represent as antenna substrate at bottom layer.

Figure 2: Fabricated antenna after being cured and connected to the 50 ohm SMA connector.

2.1. Screen printing

The advantages of screen printing mentioned in [16] are cost effective since the mesh used in stencil is made by fabric or stainless steel and another one is the alignment between stencil and substrate can be performed easily since the stencil is semi-transparent and both stencil and substrate are planar. In this study, the equipment of screen printing are showed in Figure 3. The wooden frame is stencil contained antenna pattern with mesh resolution of 120 µm. The squeegee rubber is used for spreading the graphene ink on stencil to print the antenna pattern on substrate. Then, to remove the graphene ink is by using solvent 151. The others equipment for safety are disposable mask, disposable glove, disposable dropper and industrial wiper.

Figure 3: Screen printing equipment's'.

The substrate (Kapton film) is placed at the bottom of stencil with spacer between stencil and substrate. The spacer thickness can be in range of 2 mm to 3 mm to avoid the substrate stick to the stencil while printing. Firstly, graphene ink is placed on top of the stencil near to the antenna pattern by using disposable dropper as showed in Figure 4. Then, the ink were spread through antenna pattern by forcing the squeegee rubber and pressing the stencil simultaneously as shown in Figure 5.

Figure 4: The graphene ink is ready to be printed on Kapton film.

Figure 5: The squeegee rubber must be in the incline position, the angle of 45°.

Figure 6 shows the graphene ink antenna after screen printing process. The conductive graphene ink used containing binder of polymer ethyl cellulose (EC) for scalable, efficient production of graphene [20] and providing high conductivity [12]. Since binder are insulator and to increase the conductivity, so high-temperature thermal annealing is required to decompose the binder [5] and made Kapton film being the suitable substrate compared to paper, plastics, textiles, polyethylene terephthalate (PET) and the others sensitive substrate. The graphene ink antenna was cured for 0 minutes at 250°C. The graphene ink antenna after cured was showed in Figure 7.

Figure 6: The antenna pattern made by graphene ink are printed on Kapton film substrate.

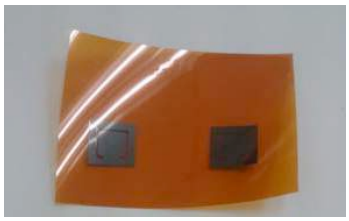

Figure 7: Grey colour appeared after the graphene ink antenna being cured.

3. Discussion

The reflection coefficient magnitude (S11) of this printed graphene antenna was measured using the vector network analyzer (VNA). The simulated and measured results of S_{11} are shown in Figure 8. Simulated S_{11} covering the range between 14.25 GHz to 15.72 GHz, while measured S_{11} ranging between 10.3 GHz to 16.8 GHz at -10 dB level, respectively. The resonance frequency has slightly shifted in S_{11} measurement due to the effect of curing condition on conductive graphene ink. The EC binder contained in the graphene ink may not fully decompose. Hence the bandwidth range of S_{11} measurement is larger than S11 simulation. Moreover, the dielectric constant of Kapton polymide film used as substrate must also changed due to the curing condition in high temperature. Table 1 summarize the comparison between simulation and measurement result obtained.

Figure 9 shows the simulated of normalize radiation pattern of printed graphene antenna where bidirectional at E-plane and nearly omnidirectional at H-plane, respectively. The simulated gain obtained is 2.392 dBi which is higher compared to the graphene antenna produced in [5], [11]-[13]. Then the calculated antenna efficiency is 80.74%, hence it shows that the printed antenna is good.

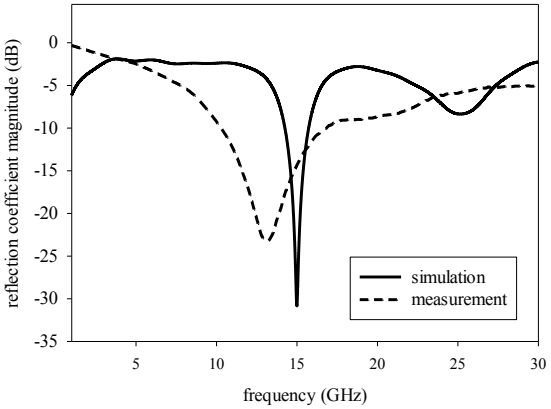

Figure 8: The reflection coefficient magnitude of printed graphene antenna shows straight line for simulation while dash line for measurement.

Table 1: The simulation and measurement of frequency resonance, reflection coefficient magnitude and bandwidth for simulation and measurement.

Characteristics	Simulation	Measurement
Frequency (GHz)	15	13.09
S11 (dB)	-30.82	-23.21
Bandwidth (GHz)	1.47	6.5

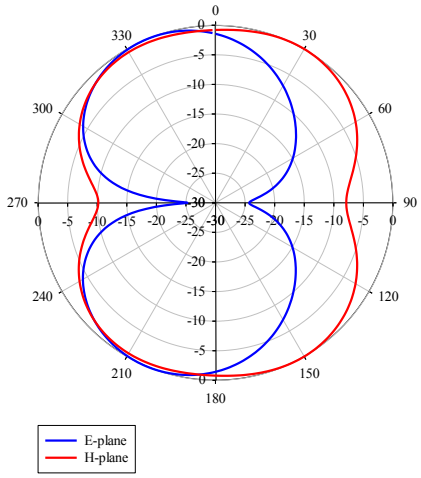

Figure 9: The normalize radiation pattern at E-plane and H-plane at frequency of 15 GHz.

4. Conclusions

High gain of printed graphene antenna has been successfully design for 5G applications and the screen printing technique is used for providing printed graphene antenna. The printed antenna has been through the high temperature process. Therefore the measurement result of printed antenna on Kapton substrate shows that the resonance frequency is slightly shifted and bandwidth is larger. Besides, the dielectric constant of substrate used will change while cure even the physical is not affected. However, the antenna which has smaller size with shaped design still gives high resolution, very light, thin and has a very low cost and fast to produce it. With the proposed antenna and technique used, it will provide one of the alternative ways to produce 5G antenna which needs a very small design and low-cost antenna production.

Abstract

Due to the difficulties that facing the transfer of graphene onto dielectric substrate of antenna, where sometime the samples produced have tears and cracks due to the process of transfer. A new technique proposed in this study based on adhesion technology. This technique suggest the adhesion of chemical vapor deposition (CVD) graphene to the antenna substrate without removing of the transition metal substrate from the CVD sample. Modeling of antenna based on this technique show promising results, specifically with doped graphene.

1. Introduction

Thanks to its remarkable properties, graphene has been intensively researched, it considers a promising material for devices of next generation wireless communication systems [1], which require high mobility, low power and broadband operation [2]. Graphene can be potentially applied in wireless nanosensors and devices of the THz band [3]. Originally, exfoliating is the commonly standout method for the graphene production of graphene via peeling strips form a graphite. The other method of production is chemical vapor deposition (CVD). The CVD-grow is efficient approach for the production of high-quality monolayer graphene (HQMG) [4]. However, the graphene sheet must be detached from tape or foil, then it transfers to the application substrate [5].

The transfer procedure, of CVD-grow graphene, requires removing the metal substrate beneath the graphene layer to produce HQMG. Supporting layer of polymer (PMMA) has been employed [6]. A simple technique for the graphene transfer from the substrate of copper presented in [7]. However, the process of graphene transfer could be not entirely acceptable, where the samples produced sometime have tears and cracks due to transfer process [4], the solvent cannot completely wash PMMA away [8], PMMA residue tend to behave like scattering centers of charge carriers, which are leading to a degradation in the graphene electrical properties [9].

The bonding between two wafers or substrates represents an important issue in the fabrication, which enables the fabrication of new substrates and also permits for fabricating and packaging of microcomponents[10]. The wafer bonding has used increasingly in the integration of materials [11].

Adhesion technology are used widely in various applications [12]. In adhesive wafer bonding (AWB) an adhesive intermediate layer is employed for bonding between surfaces. The main features of AWB involve, insusceptible to the surface contour, lower bonding temperatures, compatible with processing of integrated circuit wafer, and able to join various wafers. AWB does not need specific treatments to the wafer surface. Textures and particles at wafer surfaces can be overcome via an adhesive material[12]. A review of the recent studies on adhesion with a specific concentration on its mechanisms presented in [14]. According to the above review, the adhesion plays a significant role in the above technologies, while there are no significant studies employ this technique in antennas fabrication. So the employment of adhesion in the fabrication graphene-based antennas is a promised consideration.

In this study a new technique for graphene utilization, adhesion of CVD monolayer graphene without the process of transfer graphene on the target substrate, in the millimeter wave (MMW) microstrip patch antenna design, modeling and characterization. The calculated performance parameters of antenna based on the proposed technique show promising value at the designed resonance frequency, which are shown in Table:1 that elaborate comparison between copper based antenna and adhesive CVD graphene based antenna performance parameters.

Table1: Antenna parameters for non-doped (NDG) and doped graphene (DG) referenced to Copper.

The materials of antenna conductive layers for both Patch and Ground	Patch Width in μm	f_r in THz	S_{11} at f_r in –dB		Gain in dB		η_{rad} at f_r (%)		Prad in watt	
			NDG	*DG*	*NDG*	*DG*	*NDG*	*DG*	*NDG*	*DG*
Adhesive CVD graphene	**1500**	**0.0695**	**21.49**	**24.35**	**6.46**	**6.9**	**80.36**	**89.43**	**0.398**	**0.441**
Copper based	**1500**	**0.0745**	**19.22**		**6.74**		**80.37**		**0.396**	

2. Conclusions

The results that has been gotten in this study considers promising for the researchers of antenna, who are interesting to employ graphene in high frequencies of microwave band and the lower frequencies of millimeter wave band. Where many of antenna engineers and antenna laboratory lack to the facilities and technical knowledge of the graphene production. The new technique based on the modeling design and fabrication of graphene depending on the products of CVD graphene (available in the required dimensions) fabricated from specific factories for graphene production.

In millimeter-wave (MMW applications, the conducting parts of most communication devices can easily degrade when using conventional metals such as copper. Moreover, oxidation could also take place when such devices are operated in harsh environmental conditions. Conventional conductors such as copper in most of these devices are coated with other materials to overcome this problem. In this study, doped and non-doped monolayer graphene are employed as coating layers of conductors for MMW antennas. Results indicated that coating such antennas using monolayer graphene improves the antenna performance at MMW frequencies.

Graphene, is a single-atom layer of graphite, has an exceptional combined properties that are perfect for corrosion protection coating in different applications, for example, microelectronic parts (interconnects, implantable devices and aircraft components) [1]. Coating is considered an essential technique in enhancing surface quality and giving protection to a substrate or conductor. Attempts have been made to create excellent device properties via coating using graphene [2]. The evaluation, future perspective, and brief description of the production and functionalization of graphene as coating material were studied and proposed in [3]. Many recent pioneering studies have elaborated the ability of graphene to efficiently decouple their underlying surface with the environment Specifically, the inert chemical property of graphene leads to its employment as a defensive metal layer against oxidation and corrosion in electrochemical applications [4]. Besides that, both monolayer and multilayered graphene films have exhibited acceptable transparency [5], indicating that graphene coating does not alter the optical features of the metal placed beneath it [6].. Moreover, the monolayer graphene films are impermeable to the gas molecules [7]. , with a good capability in protecting the underlying metal (copper) against oxidation [8] [1]. The utilization of chemical vapor deposition (CVD) graphene films demonstrates anti-oxidation ability of the metallic surfaces grown on Cu and Cu/Ni alloys [8]. Graphene coating of copper increases their resistance to the electrochemical degradation [9], while low-alloy steels coated with graphene nanocomposite enhanced anticorrosive efficacy by more than three orders in comparison to bare steel [10].

From the antenna design point of view, low loss coating materials are crucial in protecting its existing conductors besides being satisfactory in terms of conductivity, which significantly contributes to antenna performance [11]. In this work, a monolayer graphene is used to coat the metallic surfaces of patch antennas. Coating the patch significantly improved gain, radiated power and radiation efficiency, besides featuring lower losses. .The proposed antennas were coated using two types of coatings: doped and non-doped monolayer graphene. These conductive layers are then utilized as either the patch only or patch and ground of the milimeterwave antenna. The resulting antenna performance is doubled when monolayer graphene is used to coat both conducting layers (the patch and ground) of the proposed microstrip antenna[12]. Moreover, monolayer graphene coating indicated very good results, and this is further enhanced when doped graphene is used at these frequencies. Table 1 summarizes the performance for an elliptical patch antenna when its conducting (copper) layers were coated with gold, non-doped graphene, and doped graphene. The results

indicated that coating copper with doped graphene improved the performance of the antenna most efficiently.

Table 1 Performance of the copper based elliptical patch antenna when the antenna conducting (copper) layers coated with gold, non-doped graphene, and doped graphene.

Abstract

We have solved the full 6×6 Kane Hamiltonian within the envelop function formalism to calculate the band structure $E(d_1)$, $E(k_z)$ and $E(k_p)$, respectively, as a function of InAs well width d_1, in the growth direction and in-plan of the long-period InAs(d_1= 160 Å)/GaSb(d_2= 105 Å) type II superlattice (T2SL), with the valence bands offset Λ= 510 meV. The carrier's effective masse $m^*(k_z, k_p)$ is successfully described over the first Brillouin zone. Moreover, for a fixed ratio d_1/d_2= 1.52, the dependencies of SL band gap on d_1 and/or d_2 as well as on Λ and temperature are investigated. The photodetector absorption wavelength, $|\lambda_c|$ is found to be further optimized by the proper choice of d_1 and/or d_2. The semiconductor to semimetal transition is also analyzed in the range of 4.2-300 K. The Fermi energy is relatively insensitive to the temperature and increase from 504.5 to 514.5 meV. At 141 K, using the Boltzmann magnetic-field-dependent Hall coefficient, we have the transport parameters n_e= $3.1.10^{12}cm^{-2}$, n_h= $4.6.10^{12}cm^{-2}$, μ_e= 137343.7 $cm^2/V.s$, μ_h= 442.2 $cm^2/V.s$ and the Hall mobility μ_H= $1.37.10^6 cm^2/V.s$. The conductivity shows the transition from p-type to n-type. In the studied temperature range, the absorption wavelength situates this sample as a terahertz photodetector.

1. Introduction

The broken-gap InAs/GaSb type-II superlattice (T2SL) have proved to be an attractive system for both military and civilian applications [1]. The fabrication of InAs/GaSb SL has stimulated a growing number of experimental and theoretical studies, including the first proposed in 1977 by Sai-Halasz et al.[2] and GaInSb/InAs strained-layer SL infrared detectors proposed by Smith and Mailhiot in 1987 [3]. The intriguing aspect of InAs/GaSb lies in its extreme type-II "broken gap" band alignment, wherein the conduction band (CB) minimum of InAs lies below the valence band (VB) maximum in GaSb. In contrast to conventional SLs such as GaAs/AlAs in which the conducting electrons and holes are located mainly within the same layer. In T2SL the conduction states are found to be confined primarily on the InAs side, whereas the valence states are confined on the GaSb side. Thus, the ground state of this system is separated spatially in different well layers. Therefore, the positions of the SL CB and VB edges can be, to first order, tuned independently. As a result, when it is irradiated by an infrared light, the photon absorption condition can be easily satisfied since the SL band-gap can be tailored to a desired value anywhere from zero to a few hundred meV by choosing the appropriate well and barrier widths. Another distinctive feature of this SL is associated with the relatively light electron mass in InAs layer. Then, the corresponding de Broglie wavelength is so long that, even for thicker GaSb layer thickness, there is considerable tunnelling probability between electrons in successive InAs layers.

From technological perspective, T2SLs have proven to be an excellent material for third-generation infrared (IR) photodetectors [4], tunnel field-effect transistors [5] and high-power light emitting diodes [6]. Recently a good photodetector performance has been demonstrated for focal plane arrays (FPAs) [7]. In the other hand, many fundamental studies on T2SLs material, such as the in-plan and vertical effective masses [8], mobilities [9], and carrier concentration [10], have been conducted for a better understanding of the electronic transport. Despite these impressive progresses, because of their low detection efficiency, such a SLs with long periodicity has been less concerned for photodetection. A good practical applications of T2SLs require a good understanding of their bands structure. In this work, we will prove that with the band structure engineering; this kind of SLs can be used for high-efficiency terahertz (THz) photodetectors.

2. Model and calculation method

Many theories have been conducted for calculating the electronic properties of semiconductor heterostructures. However, different sophisticated theories based on k.p theory, like the envelope-function formalism [11], have been very popular. In this work we show that it is possible to predict the complete photodetector response using only small number of band parameters, together with the widths of the layers in the detector structure.

We have solved the full 6×6 Kane Hamiltonian within the envelop function formalism in the first Brillouin zone. The general dispersion relation of the particles (electrons, light and heavy holes) subbands are given by [11]:

$$\cos[k_z(d_1+d_2)] = \cos(k_1 d_1)\cos(k_2 d_2) - \frac{1}{2}[(\xi+\frac{1}{\xi}) + \frac{k_p}{4k_1k_2}(r+\frac{1}{r} \quad 2)] \times \sin(k_1 d_1)\sin(k_2 d_2) \qquad (1)$$

Here we employ the following notations to describe such a SL. The subscripts 1 and 2 stand to InAs and GaSb layers, respectively. d_1 refers to the InAs layer width, and d_2 to the GaSb layer width. The 2D wave vector $k_p(k_x, k_y)$ describes the motion of particles perpendicularly to k_z. The SL states are labeled by an index i, which identifies the subbands E_i, h_i and HH_i, for electron, light and heavy holes subbands, respectively. The procedure of our band structure computation has been discussed in our previous work [12]. The zero energy is taken at the top of the InAs VB edge.

The temperature dependence of the SL band gap energy is introduced in our calculation by taking into account the temperature dependence of the two bulks band gap energies.

3. Results and discussion

We have calculated, over the first Brillouin zone, the dispersion relations for InAs(d_1= 160 Å)/GaSb(d_2= 105 Å) T2SL at 141 K. Figure.1(a) shows the dispersion results along the in-plan (k_p) (in the left hand panel) and the growth (k_z) (in the right hand panel) directions. Two lowest CBs and three highest VBs are shown. It was necessary to include a second electron subband E_2 for this sample due to the wider InAs layer. The layers are thicker enough that HH_i(i= 1, 2) lie higher in energy than both E_1 and h_1, thus the SL is semimetallic with a small and negative energy gap of $E_g = E_1\text{-}HH_1$= –65.4 meV. The corresponding cut-off wavelength is 24 µm and the cut-off frequency is f_c= 12.5 THz. The latter justify the choice of this sample for THz detection. We have calculated the energy of Fermi level by:

$$E_F(2D) = \frac{h^2 k_F^2(2D)}{2m^*_{HH1}(\Gamma)} \text{ with } k_F(2D) = \sqrt{2\pi|n_h - n_e|} \qquad (2)$$

where $m^*_{HH1}(\Gamma)$ = -0.45 m_0 is our calculated heavy hole effective masse and the measured net hole concentration is $|n_h\text{-}n_e| = 1.51.10^{12}$ cm^{-2} [13]. E_F(2D)= 511.7 meV, indicates that this SL had a p-type conductivity at 141 K.

As seen in Figure.1 (b), when the temperature decreases, the variation of SL band gap E_g is dominated by the contribution of E_1. Note that the HH_i(i=1,2) states remain almost constant in energy. In the studied temperature range, the position of the Fermi energy has been evaluated by (2). When the temperature increases from 4.2 K to 300 K, the SL band gap and the Fermi level increase, respectively, by 50 meV and 11 meV. The latter small variation of E_F indicates that the energy of the Fermi level is constant with a two-dimensional (2D). carrier's gas is

The result plotted in Figure.2 gives the evolutions of the subbands energies and bandwidths as a function of InAs layer width for light particles and heavy-holes at 141 K. All states have **k** vectors at the centre Γ and at the limit of the

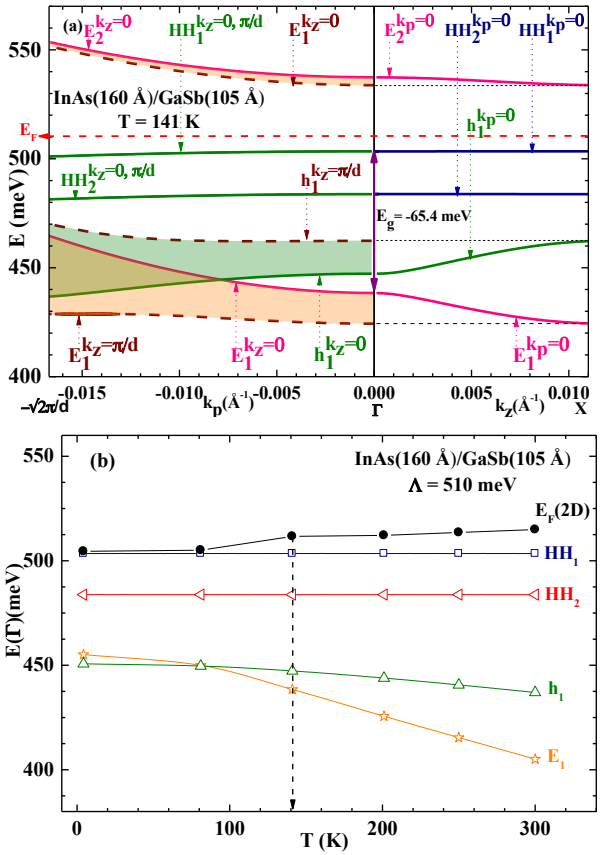

Figure. 1: **(a)** Energy bands structure of InAs(160 Å)/GaSb (105 Å) SL. The growth direction dispersion E(k_z, k_p= 0), the in-plan dispersion E(k_p, k_z=0) and E(k_p, k_z=π/d). HH_i stands to heavy-hole bands, h_1 is the first light hole band, and E_i(i=1,2) refers to the conduction bands. The energy gaps are adjusted according to the given temperature (T= 141 K). E_F stands to the Fermi energy.**(b)** Evolution of the calculated Γ-point energy of light particles, heavy-holes bands and the two-dimensional (2D) Fermi level, plotted as a function of temperature for the investigated InAs/GaSb T2SL.

first Brillouin zone. When d_1 increases, E_1 decreases in the InAs quantum wells. While h_1 and HH_1, located in GaSb quantum wells, increase. It follows that $E_g = E_1\text{-}HH_1$ decreases with increasing d_1. With a further increase in d_1, E_1 and HH_1 invert and the SL becomes semimetallic with overlapping bands. The semiconductor to semimetal conductivity transition occurs at the transition point T_c(d_{1c}= 94.2 Å, E_c= 493.2 meV).

In order to show the effect of InAs (or GaSb) layer thickness on the gap E_g, we have plotted in Figure.3 (a) the variation of E_g, at different temperatures, as a function of d_1. At a fixed InAs layer thickness, $E_g(\Gamma, d_1)$ decreases with increasing temperature.

For each temperature, $E_g(\Gamma, d_1)$ decreases significantly with increasing d_1 and/or d_2, goes to zero at the transition point

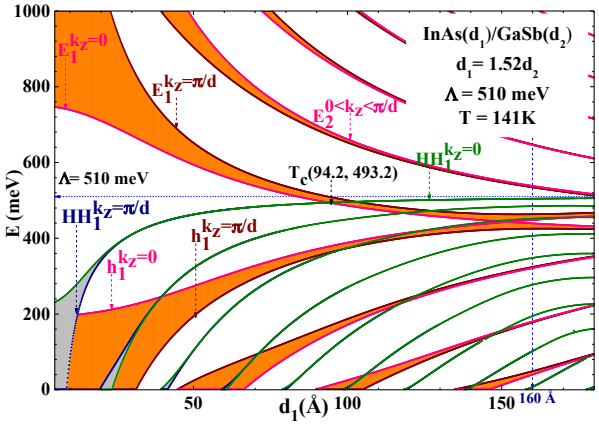

Figure 2. Calculated subband energies and bandwidths at 141K for E_i, HH_i and h_1), at the Γ-point (k_z= 0) and at the limit (k_z= π /d) of the first Brillouin zone, as a function of d_1, with d_1= 1.52d_2 for the investigated SL. The allowed energy bands are hatched. Notice the E_1-HH_1 crossing at T_c(d_{1c}= 94.2 Å, E_c= 493.2 meV) transition point.

T_c(d_{1c}, E_c), with d_{1c}= 104.4, 101, 94.2 and 78.4 Å, respectively, at T= 4.2, 81 , 141 and 300 K. At 141 K for example, when changing InAs well width from 5 to 180 Å, the band gap decreases from 516.6 to -74.2 meV or a 442.5 meV reduction. Using the Tight-binding theory which can describe a system by the location of each constituent atom, Pour et al. [14] calculated the effect of temperature on the energy gap of III–V semiconductors as well as of InAs/GaSb structure. The model suggests that the shifts of our calculated band gap reflect the expansion of the crystal lattice constant which alters the interatomic bonds. Weaker bonds means less energy is needed to break a bond and get an electron in the CB.

Beyond the transition point the band gap becomes negative with a semimetal conductivity. The situation is particularly striking in that a semimetallic SL can be created with two host semiconductors. Accordingly, as shown in the inset of Figure.4, the transition goes to a higher d_1 when the temperature decreases. For this sample, the band gap energy is negative for all studied temperatures, indicating that the SL is in the semimetallic regime, but changes very little with increasing temperature. This variation of E_g is smaller than that observed in our previous study [12] for the shorter period InAs (25Å)/GaSb(25Å) SL. We note that the large band gap observed in figure 3 (a) for small d_1, can be qualitatively understood in terms of the enhancement of the 2D confinement of the wave functions as the layers thicknesses get smaller.

It is interesting to make some remarks about the results reported in Figure.3 (a). For example at 141 K: i) when d_1 approaches zero, the SL band gap tend towards the value of ~ 527 meV. ii) when d_1 get larger, the band gap is obtained to extrapolate to $-\Lambda(1+\varepsilon_2/\varepsilon_1)^{-1}$which is roughly equal to -167 meV in agreement with γ/γ'= -160. The InAs layer width dependence of E_g is described quite well by our deduced expression as shown in Table. 1, where d_1 is expressed in angstroms and E_g in meV.

It is therefore very useful to examine the dependence on d_1 and/or d_2 of the detector absorption wavelength, λ_c(μm). The evolution of $|\lambda_c|$ as a function of d_1 is shown in Figure.3(b). These results were calculated by using the expression:

$$\lambda_c(\mu m)=\frac{1240}{E_g(meV)} \qquad (3)$$

A prominent feature of Figure.3(b) is that $|\lambda_c|$ diverge at T_c. The Figure shows also that the interesting absorption wavelength for infrared detectors around 8-12 μm should correspond at 141K, for example, to the InAs layer width in the range of 45.5 to 56.7 Å which are quite reasonable values from the point of view of the MBE growth. Therefore, in a comparable $In_{1-x}Ga_xAs/GaSb_{1-y}As_y$ alloy, to adequately control λ_c, one must control the compositions x and y with a higher precision.

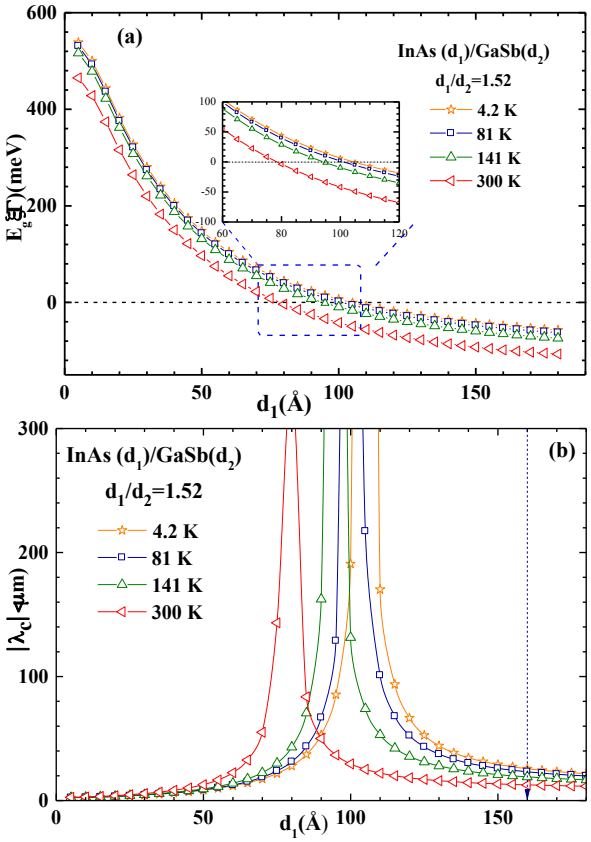

Figure. 3**:** Evolution of **(a)** the band-gap energy between the bottom of the electron miniband in the InAs layer and the top of the heavy-hole miniband in the GaSb layer and **(b)** the corresponding cut-off wavelength, plotted as a function of InAs well width, d_1, with d_1=1.52d_2.

Table. 1: The summary of the parameters that appear in our deduced relation expressing the variation of band gap as a function of InAs layer width for all studied temperatures.

		$E_g(d_1) = (\alpha+\beta d_1+\gamma d_1^2)/(1+\beta' d_1+\gamma' d_1^2)$			
T(K)	α	β	γ	β'	γ'
4.2	550	15.4	-0.195	0.0233	0.0014
81	542	15.5	-0.204	0.024	0.00141
141	527	16.4	-0.232	0.0257	0.00145
300	473	18.8	-0.317	0.0319	0.00159

Based on our calculations, it has been argued that the SL system allows better control over the detector absorption wavelength. For the present sample, the agreement between our results of $|\lambda_c|$(μm)= 25.7, 22.9, 19 and 12.6 and the experimental ones [13] $|\lambda_c|$(μm)= 24.3, 24.8, 24 and 27, respectively for 4.2, 81, 141 and 300 K, is satisfied at low temperature regime. At high temperature regime, the difference is due to the typical measured layer width uncertainty as well as to the fact that InAs and GaSb layers share no-common atoms across the interface. In fact, there are two different types of interfaces in such SLs, namely InSb and GaAs. Many experimental and theoretical studies suggest that the band overlap for an InSb interface is 40 meV larger than that of GaAs. As a consequence the smaller band gap energy can be achieved for InSb interface [15].

Among the most important physical parameter for a given SL is the valence band offset (VBO), at least because it governs the SL band structure and thus many properties of such a SL. Indeed, the quality and even the feasibility of device concepts depend crucially on the value of this VBO. Over the last years there have been a considerable controversy on VBO of InAs/GaSb SL; Srivastava et al. produced Λ= 670 meV [16]. However, M. S. Daly has obtained an average offset of 520 meV [17].

The effect of the VBO on the band structure was investigated by varying the VBO in our script, while holding the other parameters constant for each temperature. In Figure.4 we show the SL band gap, for various temperatures, as a function of Λ. The Figure divides itself into two regimes:

i) For $-200 < \Lambda < \Lambda_c$ meV, the SL is semiconductor with a positive band gap energy. When the offset Λ increases, E_g (Γ, Λ) go to a maximum of 445.7, 439.8, 427.1, and 388.2 meV, respectively, for 4.2, 81, 141 and 300 K at Λ= -60.7 meV. As Λ continues to increase, $E_g(\Gamma)$ shifts strongly to zero yielding a semiconductor to semimetal transition at Λ_c= 463, 457.2, 447.7 and 421.9 meV, respectively, for 4.2 , 81, 141 and 300 K. This can be understood intuitively using this simple model: an increase in the VBO brings the GaSb-VB and the InAs-CB closer to each other, reducing the SL band gap.

ii) For $\Lambda > \Lambda_c$ the system is in the semimetallic regime. Thus, as plotted in the inset of Figure.4, the transition goes to higher Λ_c when the temperature decreases.

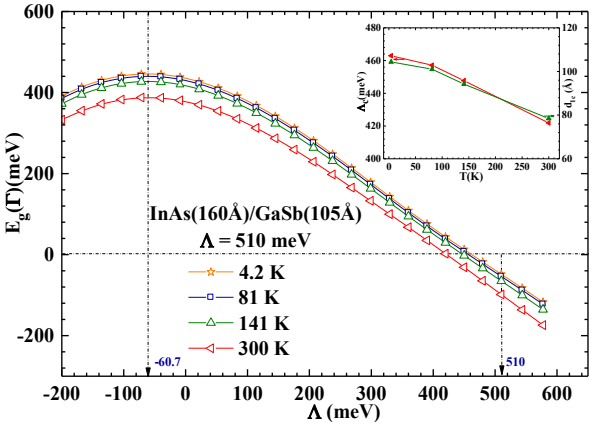

Figure 4: Evolution of the band gap energy of a representative SL with the valence band offset. The calculation includes effects due to temperature. The inset figure shows temperature dependence of the coordinates of the semiconductor-to-semimetal transition point in the investigated InAs/GaSb asymmetric SL.

The most dramatic feature of these results is the rapid variation of the band gap beyond Λ = -60.7 meV.

The effective mass is a necessary parameter for analyzing the carrier transport in materials. A theoretical effective mass in general turns out to be a tensor with nine components m_{ij} defined as [18]:

$$\frac{1}{m^*_{ij}} = \frac{1}{h^2}\frac{\partial^2 E(k)}{\partial k_i \partial k_j} \qquad (4)$$

Where E is the carrier energy and k_{ij} are the components of the wave vector k in a periodic potential of a semiconductor. In Figure.5 (a) we have plotted the carrier's effective mass of two lowest CBs and the first VB, along k_z and k_p, directions, in the reciprocal space. The second derivative of E is obtained directly from the dispersion relations plotted in Figure.1(a). Along k_z direction $m^*_{E1}(k_z, k_p=0)$ varies strongly from the center of the first Brillouin zone, diverges at k_z=3.4.10^{-3}Å^{-1}, and decreases thereafter to 2.510^{-2} m_0 at the limit of the first Brillouin zone. In the two panels, the vertical solid lines correspond to the inflections point of $E(k_p,k_z)$. Since there is no inflection point along k_p, $m^*_{HH1}(k_p, k_z=0)$keep a negative constant value of about -0.45 m_0.

Figure. 5 (b) shows the in-plan carrier's effective masses near k_p= 0, plotted versus temperature. The studied SL , with a relatively small band gaps energies, is seen to have a very small longitudinal light-hole and electron effective masses. This latter decreases slightly from only 3.9.10^{-2} m_0 to 3.7.10^{-2} m_0 when the temperature increases from 4.2 to 300 K. Whereas the heavy-holes effective mass, in the GaSb layer, is constant at about -0.45 m_0 (electron-like). The electron and heavy-hole masses differ from each other and the predicted hole to electron mass ratio $m^*_{HH1}(\Gamma)/m^*_{E1}(\Gamma)$, which increases slightly with temperature, is less than a

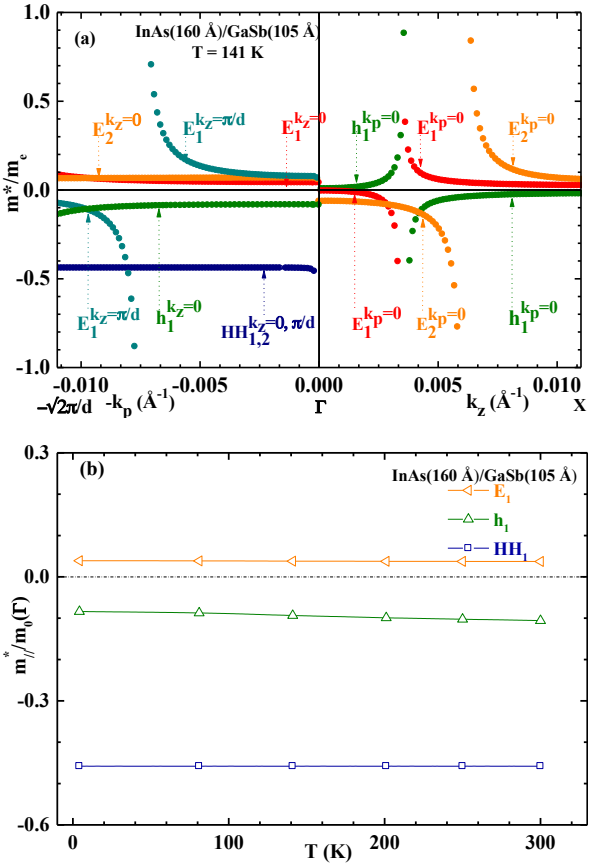

Figure. 5: **(a)** Calculated carriers' effective mass along the growth direction, k_z, and in-plan of the investigated SL at 141K .**(b)** carriers' effective mass as a function of temperature for the representative SL.

factor of 13 over the entire temperature range. This has a significant effect on the in-plan transport properties for free carriers.

4. Hall coefficient and magnetotransport properties

Figure.6 shows the calculated Hall coefficient versus the applied magnetic field at 141 K. Also shown for comparison are the available experimental data. According to the classical expression for the Hall coefficient of two-band model derived from the Boltzmann equation [19]:

$$R_H=[(\mu_h^2 n_h-\mu_e^2 n_e)+(\mu_h\mu_e)^2B^2(n_h-n_e)]/ [e(\mu_e n_e+\mu_h n_h)^2+(\mu_h\mu_e)^2B^2(n_h-n_e)^2] \quad (5)$$

This equation can be simplified as:

$$R_H=(\alpha^2\beta-1)+(\beta-1)\mu_h^2B^2/n_e e(1+\alpha\beta)^2(\beta-1)^2\mu_h^2B^2 \quad (6)$$

Where: $\alpha=\mu_h/\mu_e$ and $\beta=n_h/n_e$

At a weak magnetic fields, the Hall resistance is inversely proportional to n_e and is described by the following formula:

$$R_H^w=e^{-1}(\alpha^2\beta-1)/n_e(1+\alpha\beta)^2 \quad (7)$$

While at high magnetic fields for $\mu B >>1$, Equation (3) is well approximated by:

$$R_H^h=1/e(n_h-n_e) \quad (8)$$

These results show that R_H keep almost magnetic field independent below 10T. However, when the magnetic field increases above 10T, R_H go to zero and changes sign to negative value at:

$$B_0=[(1+\alpha^2\beta)/(\beta-1)\mu_h^2]^{0.5}=32.4\ T \quad (9)$$

A reproducible change of sign of R_H is a clear signature of the coexistence of at least two types of carriers, which suggests a semimetallic character of the conduction mechanism, and also the dominance of holes transport for B ≤ 32.4 T. This was confirmed by the observation of the oxford group regarding the field dependence of Hall resistance [13]. They found that the dependence of the Hall resistance on magnetic field curves go down at high temperature (especially at 141 K), indicating that the hole concentration is slightly larger than that of the electrons ($\beta \backsim 2$). The Hall mobility is given by:

$$\mu_H=\mu_e/(1+\alpha\beta) \quad (10)$$

The difference in carrier concentration, n_h-n_e=1.5.10^{12} cm^{-2} was extracted from the slope ($\backsim R_H^h$) of the Hall resistance at high magnetic fields [13]. This value constitutes strong signature for the existence of interface and donor states. By a simple combination between (7) and (9), we have found: n_e= 3.1.$10^{12}cm^{-2}$, n_h= 4.6.$10^{12}cm^{-2}$, μ_e= 137343.7 cm^2/V.s, μ_h= 442.2 cm^2/V.s and the Hall mobility μ_H= 1.37 10^6 cm^2/V.s. Such a low value of hole mobility carrier's is consistent with high value of the effective masse of heavy holes $m^*_{HH1}(\Gamma)$ = -0.45 m_0.

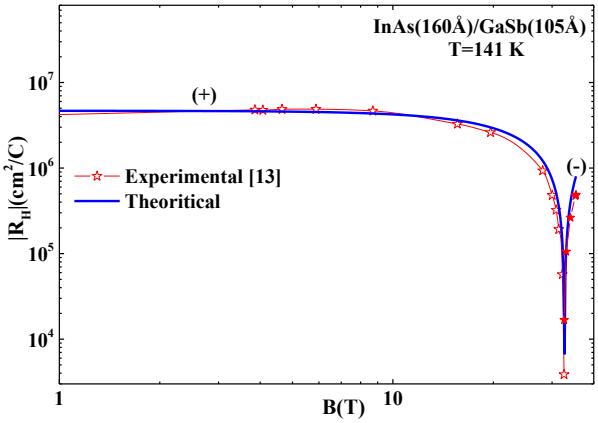

Figure. 6: Hall coefficient versus the magnetic field at 141K for the investigated SL. The open stars are positive values while the solid stars are negative.

5. Conclusion

We have used the envelop function formalism (EFF) for the proper engineering of electronic bands structure of a long-period InAs (d_1= 160 Å)/GaSb (d_2= 105 Å) T2SL for THz photodetection. We have investigated in detail the dispersion relations in the reciprocal space at 141 K. The photodetector parameters like fundamental band gap, absorption wavelength, and the carrier's effective masse were treated as a function of d_1/and or d_2, and temperature for a constant ratio of d_1/d_2=1.52. The band gap E_g decreases when d_1 increases. The evolutions of $E_g(\Gamma)$ as a function of d_1 and Λ, shows that the semiconductor to semimetal transition goes to higher d_{1c} and Λ_c when the temperature decreases.

For T≤ 141 K, our results are in agreement with the experimental data. Further, on the basis of the Boltzmann Hall coefficient magnetic field-dependent, we have interpreted the magnetoresistance results of D. M. Symons et al. We have observed the p-type to n-type conductivity transition. The transport parameters of this SL are: n_e= $3.1.10^{12}cm^{-2}$, n_h= $4.6.10^{12}cm^{-2}$, μ_e= 137343.7 cm^2/V.s, μ_h= 442.2 cm^2/V.s and the Hall mobility μ_H= $1.37.10^6cm^2$/V.s. The Fermi energy is relatively insensitive to the temperature and found to increase from 504.5 to 514.5 meV. The range of absorption wavelength $25.7 \leq |\lambda_c|(\mu m) \leq 12.6$, corresponding to the cut-off frequency $11.6 \leq |f_c|(THz) \leq 23.8$ indicates that this sample can be used as a terahertz (THz) detector.

Patch antenna enhanced graphene infrared photodetectors

J. Zhou[1*], C. L. Liu[1], D. H. Zhang[1,2], L. Wang[1], X. S. Chen[1], W. Lu[1]

Abstract-By integrating a graphene photodetector with an optical patch antenna, the responsivity is enhanced in both optical and electrical way. At resonance, the absorption of the single layer graphene is increased by ~29 times. Besides, the top patches connected with an electrode extend the graphene/contact borderline and hence enlarges the optical sensitive area. The asymmetrical distribution of the top patches over the two contacts allows a net signal under uniform flood illumination.

Graphene has attracted significant attention as a promising candidate for infrared photodetection because of its broadband absorption, ultrafast carrier dynamics, and good controllability through electrostatic doping [1,2]. However, the efficiency of those graphene based photodetectors (PD) is limited by the poor absorption as a consequence of the atomic thickness. Micro photonic structures, such as waveguides and photonic crystal micro cavities, could largely enhance the absorption of graphene, but suffer from the bulky pixel sizes [3,4]. Nano photonic structures, such as plasmonic resonantors and nano antennas, offer a more compact solution [5-7]. However, in order to enhance the practical responsivity of graphene PDs and preserve their unique advantages, designing of the nano photonic structures requires more study with consideration on the optical as well as electrical properties of the devices. For example, the incident light should be converted into a local field as much as possible. The intense local field should be absorbed by the optical sensitive part of the device instead of being dissipated as loss. For the most popular metal-graphene-metal architecture, since the p-n junctions required for photocurrent generation are close to the contacts, the nano photonic structure not only needs to create the intense local field close to the contact but also needs to extend the contact borderline for a better signal collection.

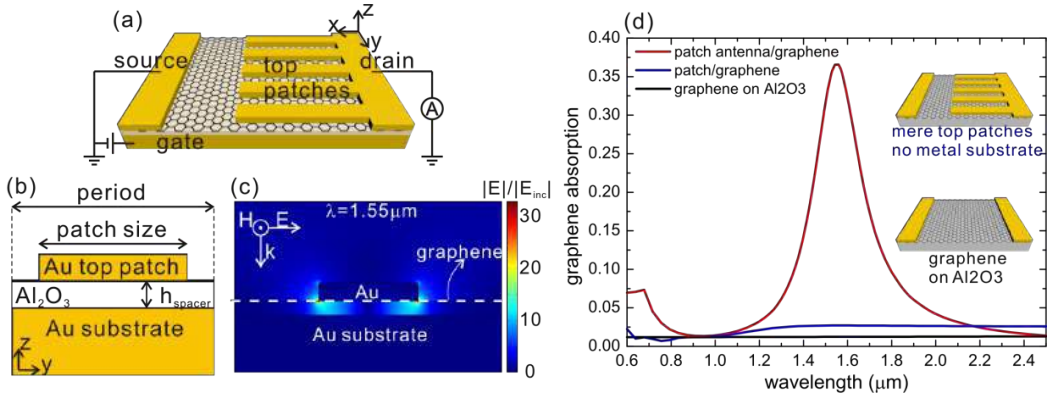

Fig. 1 (a) Sketch of the patch-antenna-graphene PD. (b) One period of the patch-antenna-graphene combination in the *z*-*y* cross section. (c) Simulated electric field distribution of the patch-antenna-graphene combination at the

resonant wavelength of 1.55 μm. The colored surface represents the electric field intensity normalized to the incident light. The patch width is 218 nm; the patch height 40 nm; the period 588 nm; and the spacer thickness 30 nm. (d) Graphene absorption spectra of the patch-antenna-graphene PD, the bare graphene layer on Al_2O_3 and the graphene layer with metal patch array. The metal patches are designed to have a resonance at 1.55 μm. The patch width is 290 nm; the patch height 40 nm; and the period 800 nm.

Based on these considerations, we propose a graphene infrared PD integrated with an optical patch antenna, as shown in Fig. 1 (a). A single layer graphene is transferred onto a metal plane (Au) coated with a dielectric spacer (Al_2O_3). Above the graphene, the contacts and some metal patches are fabricated. The patches together with the bottom metal plane and the dielectric spacer form an optical patch antenna. The cross section is shown in Fig. 1 (b). Due to the Fabry-Perot like resonance of the metal-insulator-metal waveguide mode, the incident light with TM polarization is mostly coupled into a local field as shown in Fig. 1 (c). In this way, the graphene layer just beneath the top patch overlaps with the most intense field and hence has a big absorption. For demonstration, the patch antenna's geometry parameters are designed for the resonance at 1.55 μm. The peak absorption is 37%, ~29 times higher than that of a bare graphene layer on a Al_2O_3 substrate, and ~14 times higher than that of a graphene layer with a common plasmonic structure. The plasmonic structure is represented by a metal patch array (Fig. 1 (d) inset). The geometry parameters are designed to make the resonance around 1.55 μm. Besides the improvement in optical absorption, the patch antenna structure also benefits the signal generation in an electrical manner. First, the top patches serving as the tentacles of the contact greatly extend the borderline and hence increase the optical sensitive area. Second, the asymmetrical distribution of the top patches (all at one contact) induces much stronger light absorption at one contact and thus makes the photocurrent collected by this contact overwhelms the other, leading to a net signal under uniform flood illumination on both contacts of the device. This patch-antenna-graphene PD is suitable for a wide range of wavelengths in the infrared range.

Nonperturbative theoretical description of graphene saturable absorption

Abstract-We theoretically investigate saturable absorption in extended graphene by developing a semi-analytical nonperturbative approach and solving the electron dynamics nonperturbatively. We find a remarkably low saturation intensity along with a large modulation depth that can be electrically manipulated through an externally applied gate voltage. Our results are relevant for the development of graphene-based optoelectronic devices, as well as for application in mode-locking and random lasers.

Saturable absorption (SA) is an inherent property of photonic materials that manifests itself as an absorption quenching at high light intensities and is a key element for passive mode-locking (PML) in laser cavities, where continuous waves break into a train of ultrashort optical pulses. Currently, state-of-the-art semiconductor-based SA mirrors are routinely employed for PML lasers. However, these mirrors operate in a narrow spectral range, are poorly tunable, and require advanced fabrication techniques. Graphene overcomes these limitations thanks to its peculiar conical band structure, providing a universally-resonant wavelength-independent SA at low light intensity [1] that can be further electrically tuned be means of an externally applied gate voltage, thus enabling PML ultrafast laser operation [2]. Here, we calculate intraband and interband contributions to SA of extended graphene by solving non-perturbatively the single-particle Dirac equation for massless Dirac fermions in the presence of an external electromagnetic field. Further, we investigate the dependence of the intensity-saturated graphene conductivity on doping, temperature, and optical frequency. We find a remarkably low intensity-threshold for SA, which is consistent with reported experimental findings. In addition, our calculations indicate a strong quenching of absorption depth ensuing from doping through an externally applied voltage, and a weak dependence on electron temperature. We envisage that our results will be relevant for the engineering of graphene-based PML fibre lasers and single-mode random lasers [3].

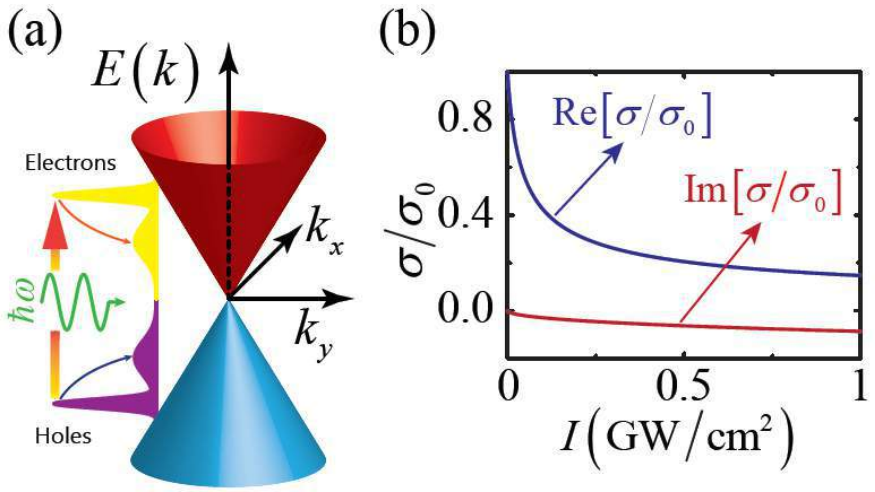

Figure 1: (a) Conical band-structure around the Dirac points. Upper $E_+(k)=+\hbar v_F k$ and lower $E_+(k)=+\hbar v_F k$ energy bands depend linearly on the electron wave-vector k. Interband transitions produced by impinging photons lead to an out-of-equilibrium electron distribution, which then relaxes via electron collisions. After an initial transient time, optical pumping and electron relaxation compensate with each other, and absorption is saturated due to partial Pauli blocking. (b) Intensity-dependent conductivity $\sigma(I)$ normalized to the universal conductivity $\sigma_0 = e^2/(4\hbar)$.

Low-Loss Non-Reciprocity in Spatiotemporally Modulated Hybrid Dielectric-Graphene Photonic Structures

D. Correas-Serrano[1], D. L. Sounas[2], A. Alù[2*], and J. S. Gomez-Diaz[2*]

Abstract-We introduce the concept of magnet-less non-reciprocal photonic devices based on spatiotemporally modulated graphene embedded in dielectric structures. Compared to non-reciprocal graphene plasmonic devices based on similar bias schemes [1], graphene is now used as a perturbation of low-loss photonic modes. This approach has important benefits, including significantly reduced losses, much relaxed biasing requirements, and large non-reciprocal responses. We envision that this technology will pave the way to a future low-loss, magnet-free, non-reciprocal photonic platform with wide applications in communication systems, sensing, imaging, and on-chip networks.

Modulating the physical properties of a system in space and time has allowed in recent years the engineering of magnet-less non-reciprocal responses in electromagnetics and acoustics [2], [3], but the use of this concept in practical applications beyond RF remains challenging due to the high modulation frequencies required and the difficulty of modulating the permittivity of silicon [4], [5]. Recently, gated graphene structures with time-varying gate voltages have been introduced as a promising plasmonic platform to implement this paradigm at THz and IR [1], owing to the ultrafast modulations it can support [6] and the numerous attractive features of graphene plasmonics [7]. The most significant challenge in this approach lies in the necessity of high quality graphene able to support plasmons with low damping. To lessen this constraint, here we propose to break reciprocity by using spatiotemporally modulated graphene as a *perturbation* of high-Q photonic modes in dielectric structures. The resulting hybrid graphene-dielectric photonic devices are low-loss, silicon-compatible, robust against graphene's imperfections, and exhibit large non-reciprocal responses using a realistic biasing scheme.

We illustrate this concept through a simple waveguide isolator based on the fundamental transverse electric (TE) mode in a dielectric slab loaded with a closely spaced graphene bilayer, as depicted in Fig. 1a. This configuration allows fast modulation of the effective stack conductivity by applying a time-varying voltage between them [6], [8]. If different voltages with adequate phases are applied along the propagation direction z, an effective linear momentum is imparted to the propagating modes due to the (weak) interaction of the graphene stack with the z-component of the photonic mode. We study the response of the system by (i) analytically solving the eigenmodes of the modulated structure, (ii) using coupled mode theory together with the unmodulated states, and (iii) using coupled multi-harmonic frequency domain numerical simulations – full details will be given at the conference. The operation is as depicted in Fig. 1b: power can only propagate from left to right, with any power in the opposite direction being frequency-shifted and reflected. Fig. 1c shows the insertion loss from left to right and from right to left versus frequency, for a graphene relaxation time of $\tau = 0.1$ ps and a modulation frequency $f_m = 20$ GHz, five hundred times smaller than the operation frequency. We stress that all these parameters are

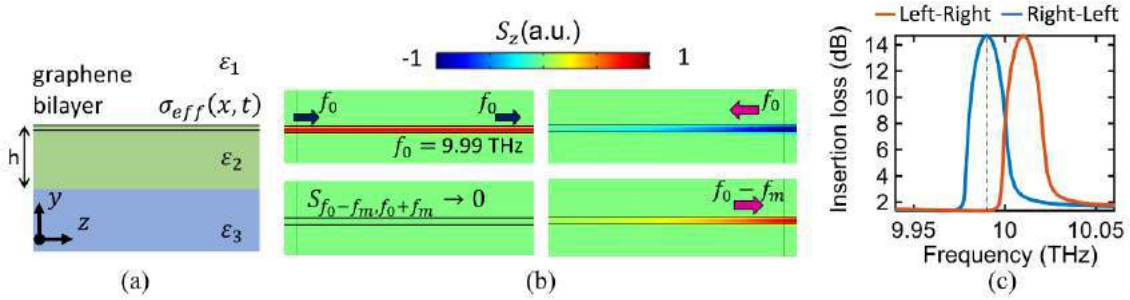

Figure 1. (a) Photonic isolator based on a slab waveguide with relative permittivities $\varepsilon_1 = 1, \varepsilon_2 = 12, \varepsilon_3 = 4$ and $h = 2\ \mu m$, loaded with a spatiotemporally modulated graphene bilayer with effective conductivity $\sigma_{eff} = \sigma_0(1 + M\cos[\omega_m t - \beta_m z])$. (b) Poynting vector for incidence from the left (energy is transmitted to the right) and from the right (energy is frequency converted and reflected). (c) Insertion loss versus frequency for both excitation directions. Dashed line indicates the operation point plotted in panel (b).

easily achieved with state of the art fabrication techniques. Our proposed structure isolates in each direction at different frequencies due to the asymmetric bandgaps opened by the modulation, while loss in the transmitting direction remains very low. These preliminary results are very promising, and they may establish the foundation for a new class of non-reciprocal photonic devices compatible with integrated silicon photonics. We will discuss at the conference alternative implementations based on multimode operation, resonant structures aimed to reduce device footprint, as well as metasurfaces for isolation of plane waves.

Abstract- We have derived analytical expressions for the radiative decay rate of the spontaneous emission of a chiral molecule located near a dielectric spherical particle with a chiral nonconcentric spherical shell made of a bi-isotropic material. Our numerical analyses show that for a chiral molecule near a dielectric spherical particle with a shell made of a chiral metamaterial with simultaneously negative permittivity and permeability, the "right" and "left" enantiomers of molecules can exhibit pronounced differences between the radiative decay rates.

The scattering of electromagnetic radiation by a chiral spherical particle was previously investigated [1,2]. However, the problem of scattering of light by an asymmetric chiral particle has not yet received the attention of researchers. In this paper we consider the spontaneous radiation of a chiral molecule located near an asymmetric chiral nanoparticle and as a model of such particles we investigate a spherical dielectric particle with a nonconcentric spherical shell made of a chiral material.

In describing the electric and magnetic fields in the shell of a chiral medium, we use constitutive equations for a bi-isotropic material in the Drude-Born-Fedorov form [3]. We have obtained analytical expressions [4] for the radiative decay rate [2] of the spontaneous emission of such a chiral system. To understand physics of these effects, we also performed independent numerical simulations by using the finite element method as implemented in COMSOL Multiphysics® software [5], as shown in the insets of Fig.1.

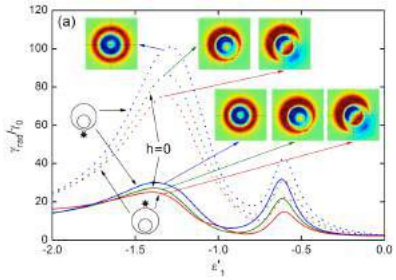

Figure 1. Radiative decay rate of the spontaneous emission of a chiral molecule located close to the surface of a spherical nanoparticle with a dielectric core and a chiral shell as the function of the real part of the permittivity

$\varepsilon_1 = \varepsilon_1' + i0.1$. The solid lines correspond to the "right" molecule ($\mathbf{m}_0 = 0.1\mathbf{d}_0$), and the dashed lines correspond to the "left" molecule ($\mathbf{m}_0 = -0.1\mathbf{d}_0$). The colors represent the cases of the molecule position near the thin (blue), thick (red) parts of a shell, and the case of concentric shell (green). The insets show near-field patterns Re(E_z) at $\varepsilon_1' = -1.33$ on the z=0 plane.

Optical sensing of chiral molecules using metamaterials

S. Yoo, and Q-H. Park*
Department of Physics, Korea University, Republic of Korea
*corresponding author: qpark@korea.ac.kr

Abstract- We present a theory for the microscopic origins underlying the chiroptical spectroscopy using metamaterials. When optical resonators are coupled to chiral molecules, the inherent circular dichroism (CD) of chiral molecules are modified by local fields near resonators, whereas chiral molecules perturb resonant modes of the resonators. We show two origins of CD simultaneously contribute to the CD enhancement in the chiral molecule/resonator coupled system. We propose a design route for the optical resonators that enhance CD of chiral molecules.

Naturally occurring circular dichroism (CD) signals of chiral molecules are inherently weak because the chirality of molecules is much smaller than the wavelength of circularly polarized plane waves, but chiral molecular CD signals can be strongly enhanced when chiral molecules are coupled to optical resonators. In recent years, resonant metamaterials have been applied to the enhancement of molecular CD signals [1]. Unfortunately, however, it has been a significant mismatch between experimentally observed CD enhancement factors and theoretical predictions [1]. Here, we explain two simultaneously contributing mechanisms of the CD enhancement in the chiral molecule/metamaterial coupled systems [2,3].

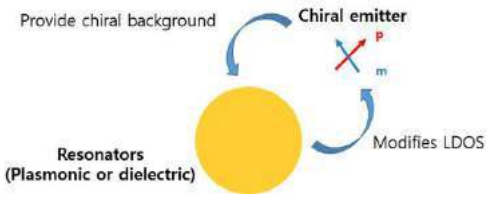

Figure 1. Schematic of two mechanisms for the CD enhancement.

When the chiral molecules are adsorbed on the optical resonators, CD signals can be strongly enhanced. As shown in Fig. 1, the enhancement of CD signals by resonators is originated from two major mechanisms: the chiral Purcell effect and the circular differential scattering effect. The chiral Purcell effect describes the modification of the helicity-dependent spontaneous decay of chiral molecules. Inside the resonator, both the energy and the helicity of light can be strongly localized. As a result of localization of optical energy and helicity, the circular difference in the spontaneous decay rate $\Delta\Gamma$ can be significantly enhanced compared to that in the free space $\Delta\Gamma_0$, as shown in Fig 2 [2,4]. The figure of merit for the resonator to enhance CD signals is called as the chiral Purcell factor F_C, and it is defined by

$$F_C = \frac{1}{4\pi^2}\left(\frac{\lambda_0}{n}\right)^3\left(\frac{Q}{V_C}\right) \quad (1)$$

with the resonance wavelength λ_0, refractive index n, the quality factor Q of the resonator, and the chiral mode

volume V_C [2]. On the other hand, the presence of chiral molecules in the vicinity of optical resonators perturbs the optical response of the resonators [3]. We find that scattering cross sections of light by the optical resonator embedded in chiral medium is different upon two opposite circular polarized incident light although the optical resonators are achiral.

In this presentation, we show that both the chiral Purcell effect and the circular differential scattering effect can simultaneously contribute the measured CD signals. We present a microscopic theory to completely describe the multiple origins for the CD enhancement in the chiral molecule/optical resonator coupled system [5]. We expect that our theory can overcome the limitations of the conventional theory that have a mismatch between experimentally observed CD enhancement factors and theoretical predictions. Our theory also enables analysis and design of the surface-enhanced chiral molecule sensing experiment.

Enhanced Circular Dichroism of Isotropic Au-core/Ag-shell Nanoparticles due to Fano Resonances

J.-W. Park*
Boston University, United States of America
*corresponding author: jwonpark@gmail.com

Abstract-Optical activity of individual Au-nanospheres and Au-core/Ag-shell nanoparticles was observed in aqueous solution. Possible mechanisms are discussed, including the excitation of volume plasmons, multiple scattering, and electron spin polarization. Given the left-handedness of dipolar localized surface plasmons (LSPs) of Au-nanospheres, spherical Au-core/Ag-shell nanoparticles exhibit sign reversal. Strong positive ellipticity from core-shell nanoparticles is attributed to Fano resonances between dipolar and quadrupolar LSPs whereas negative ellipticity of dipolar LSPs originates from nonlocality. Plasmon enhancement via ligand chirality was not observed.

Recent chirality research in nanoparticles concerns only structural dissymmetry, including chiral transfer of ligand molecules to nanoparticles[1] as well as helical arrangement of assembled nanoparticles. This is based on the quantum mechanical theory of optical activity, which is one-electron model associated with formulating the scalar product of electric/magnetic dipole transition moments.[2] Metal nanoparticles are many-body systems, and their dimensions are larger than the Fermi radius of electrons, and thus a direct application of the one-electron model of optical activity to individual nanoparticles may lead to unphysical consequences. Except for helical assemblies of nanoparticles exhibiting dominant CD responses, spatial dispersion (nonlocality) should be considered for individual nanoparticles. In crystals, optical activity is the first order spatial dispersion of electromagnetic waves,[3] which has been neglected since chirality studies of plasmonic nanoparticles gained great interest a decade ago. I experimentally demonstrate that spatial dispersion for individual Au nanosphers leads to optical activity of dipolar LSPs with having left-handedness, although measured ellipticities are generally weak. Longitudinal volume plasmons excited along the direction of light propagation[4] likely generate a electric field gradient, leading to dephasing[5] of the electromagnetic wave. For nanoparticles having strong quadrupolar LSPs such as core-shell structures,[6] however, Fano resonances enhance CD responses,[7] resulting in large positive values of ellipticity. Plasmon enhancement of nanoparticle CD was not observed for L-ascorbic acid functionalized Au-nanospheres, due to homogeneous distribution of the ligands or screened Coulomb interactions between conduction electrons and ligand electrons by the positive jellium background. The CD sign reversal is not related to possible phase variation via multiple scattering as well as possible electron-spin polarization via coupling of Shockley surface states to bulk conduction electrons. The latter effects, which would produce a constant sign of ellipticity, were safely excluded. Under spatial dispersion, Fano resonances produce noticeable CD responses, which is not negligible for optical activity of individual nanoparticles.

Abstract- Chiroptical activity serves as an important tool for manipulating light or for characterizing spatial arrangements in molecules, proteins (and other polymers) crystals and nanostructures. Due to the weak intensity of Circular Dichroism (CD) measurements of CD are all done on an ensemble of particles either in solution, in crystals, or on a large array of meta-particles on a substrate. Here we present an experiment in which the CD spectroscopy of individual, fabricated Gammadions were studied.

Recent studies to measure CD of individual nano-objects have been made, by using near field techniques[1], or dark-field[2] of randomly generated non symmetric structures . Here, we present a study in which CD absorption spectroscopy of individual fabricated (left and right chirality) Gammadions was carried out**.**
Our experimental setup for measuring the spectroscopy of individual nanostructure follows the approach of Sandoghdar and coworkers[3] who demonstrated single molecule detection by optical absorption. Here, we expand the spectral range to the entire visible spectrum together with accurate polarization control to enable CD spectroscopy. We use a broadband Supercontinuum source (SC) filtered by Acousto-optic tunable filter (AOTF). A 50:50 beam-splitter to split the light beam to a probe beam and a reference beam. The reference beam is used to monitor light intensity fluctuations, while the probe beam is passed through the LC retarder and then focused on the sample. We use a moderately high NA polarization maintaining objective to increase the interaction between the beam and particles while still keeping the polarization as pure as possible. . We scan through the spectral range, and spatially over the sample of interest and preform spectroscopic absorption and reflectance measurement on individual particle. The LC retarder cycles 30-100 times between Left/Right circular polarization states to differentiate between the corresponding absorptions and thus measure dissymmetry caused by a single nanoparticle.

Transmission and spatial dissymmetry maps for a 160 nm right handed gold Gammadion, taken at 600 nm, is shown in Figure 1. We show that the chiral gammadion shape leads to a negative dissymmetry value at the shapes center as determined by the transmission data. The dissymmetry shown here is of the order of 10^{-4} and is presented after subtracting the small surface dissymmetry, is attributed to residual dissymmetry-response of the experimental setup. The distinct CD, is reversed in sign when measuring CD on an equivalent left handed Gammadion.

Wide spectral range measurements were performed on 500nm Au Gammadions. For each wavelength the sample was scanned using only right handed circular polarization, and at the end of each such scan the center of the particle was identified by finding the point giving a minima in the transmission. At that point the polarization was square-wave modulated, between right and left circular polarization for 30 cycles. The difference between the left and right set of measurements represents the CD at a specific wavelength. The experimental spectra of the CD of left handed and right handed Gammadions show distinct similarity to our FDTD simulations (See Figure 2)

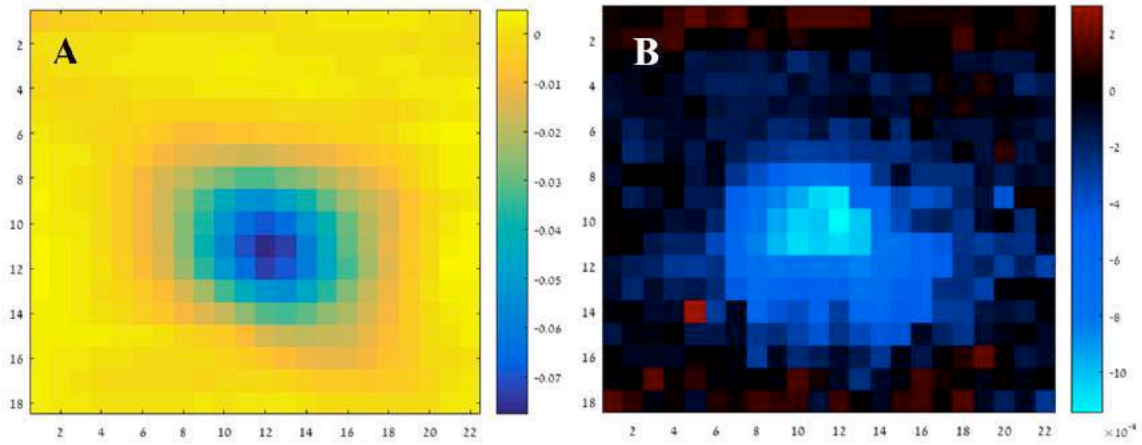

Figure 1 – Transmission and spatial dissymmetry scans at wavelength of 600nm. (**A**) – Transmission scans for a 160nm right handed Gammadion. (**B**) - Dissymmetry scans for the same Gammadion.

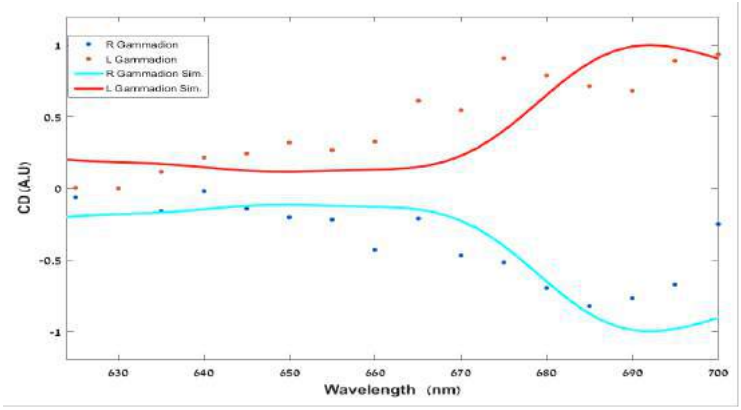

Figure 2 – dissymmetry spectra for 500nm Gammadions. The dots represent measurements on Right/Left handed Gammadions while the solid line is the simulated spectra calculated using FDTD.

In summary, we have successfully shown bright far-field CD spectroscopy of single nano-objects, with a distinct ability to distinguish between the CD responses of two enantiomers and to map the spatial CD distribution on the nanoscale.

Abstract- Here we demonstrate that mechanically-tunable, nondispersive optical activity can be achieved in quasi-planar, bi-layered chiral metamaterials where an enhanced magnetic coupling between front- and back layers is present. It is experimentally shown that the polarization state of the transmitted electromagnetic waves through the metamaterial layer is rotated by 30°, regardless of their frequencies in a broad frequency range.

Extremely large optical activity can be realized by chiral metamaterials consisting of strongly-resonant, subwavelength-scale chiral particles. The large optical activity of the chiral metamaterials allows them to be used as ultra-thin polarization rotators. However, the most of chiral metamaterials have highly dispersive optical properties due to their resonant nature, which leads to the narrow operating bandwidth in terms of transmission and optical rotatory power. Recently, nondispersive, strong optical activity has been reported in three-dimensional meshed helical metamaterials [1].

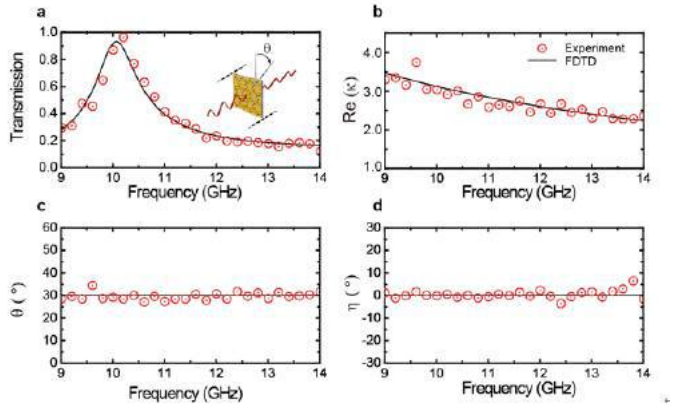

Figure 1 Characterization of the proposed bi-layered chiral metamaterial in the microwave range. (a) Numerically calculated and experimentally measured total transmission amplitude. (b) Numerically- and experimentally retrieved chirality parameter. (c) Nondispersive polarization rotation of the transmitted wave and (d) nearly-zero, flat ellipticity.

Here we demonstrate that mechanically-tunable, nondispersive optical activity can be achieved in quasi-planar, bi-layered chiral metamaterials where an enhanced magnetic coupling between front- and back layers is present. It is experimentally shown that the polarization state of the transmitted electromagnetic waves

through the metamaterial layer is rotated by 30°, regardless of their frequencies in a broad frequency range (see Fig. 1). It is also found that the amount of polarization rotation can be further increased by adding more layers. Furthermore, the rotation angle can be dramatically tuned by changing the interlayer spacing distance. This tunable optical activity seems to originate from the change in interlayer magnetic coupling, which is reasoned by its asymptotic scaling with increasing spacing distance. Since the proposed chiral metamaterial consists of planar structures, we expect that the chiral metamaterials with tunable, nondispersive optical activity at higher frequency regime might be realized by using conventional micro- and nano fabrication techniques.

Abstract- We experimentally demonstrate an electrical tuning of the polarization state of terahertz waves with a graphene integrated chiral metamaterial. We validated that the graphene integrated chiral metamaterial achieves a high-intensity modulation depth up to 63% for the RCP wave at the small gate voltage with maintaining high transmission of the LCP wave up to 52%.

Controlling circular polarization states is important in the field of quantum computation and information, optical communication of spin information and circular dichroism spectroscopy. Conventionally, chiral materials such as quartz have been used for the purpose of modifying the state of polarization of light. However, naturally occurring chirality in the form of circular dichroism (CD) and optical activity (OA) is extremely weak, requiring a substantially long propagation length to observe chirality[1]. To overcome this problem, artificial structures called "chiral metamaterials" composed of sub-wavelength metallic building blocks have been proposed for enhancing CD and OA enabling various potential applications such as broadband circular polarizers and wave plates[2].

In this study, it is shown that the transmission of a right- handed circularly polarized (RCP) terahertz wave can be strongly modulated when a voltage is applied to the gate, due to a critical transition followed by the change in the optical conductivity of the graphene.

We used a conjugated double Z metamaterial (CDZM) to control the circular polarization state of the terahertz wave. The metamaterial was fabricated through a general MEMS process. Single layer graphene grown by chemical vapor deposition (CVD) was transferred thereon, and gate voltage was applied to the graphene by side-gate method using ion gel (Figure 1). The fabricated graphene CDZM structures are characterized by THz time-domain spectroscopy (THz-TDS). As shown in the figure 2a, T_{RCP} can be dramatically reduced when we applied gate voltage of $\Delta V(=V_{CNP}-V_G) = 1.8V$, but almost leaves T_{LCP} unchanged at the resonance frequency of 1.1 THz. The maximum modulation depth for the RCP wave, defined as a relative transmission of RCP change $\Delta T_{RCP} / T_{RCP, Min}$ for graphene CDZM, is measured to be 63 % at the resonance. To clarify the mechanism of electrical control of one circular polarization observed in the experiments, we perform numerical simulations and employ the temporal coupled-mode theory (CMT) involving two resonant modes with two ports[3].

Abstract-We fabricated unprecedented three dimensional chiral plasmonic nanostructures by integrating organic-inorganic interaction in nanoparticle growth. Depending on the functional group in organic molecule, binding energy onto gold surface was modulated and we use this control over shape to address fabrication of asymmetric structure with nanometer controllability. Fabricated chiral gold nanoparticle exhibited extremely high dissymmetry factor at visible range (~0.2 at 622 nm) superior to any other structures produced by bottom-up approaches and showed macroscopic color transformation even in random dispersion.

Nature has remarkable ability to control the shape of inorganic material. Direct contact of biomolecule with inorganic surface at specific site significantly modifies the direction of crystal growth resulting in macroscopic shape change. Inspired from organic modifier in nature, we developed organothiol assisted growth system which is capable of directing morphological development through distinctive interaction between organothiol and gold surface.[1-2] Using rationally designed organothiol molecules, here, we demonstrated unprecedented morphologies with exceptional optical properties. By changing spatial configuration of functional group in organothiol molecule, we constructed nanoparticle with strong optical activity at visible range. The nanoparticle exhibits outstanding anisotropy dissymmetry factor ~0.2 and optical rotatory dispersion effect. In addition, tunable optical response was achieved through tailoring the structure of nanoparticle modulated by spatial control of functional groups.

Abstract

A chiral metamaterial (CMM) based on a complementary metal strip in a single dielectric layer is proposed for achieving broadband asymmetric transmission (AT) of linearly polarized electromagnetic waves. The proposed CMM exhibits AT efficiency of 90% over a bandwidth of 1.15 GHz (8.58 GHz to 9.73 GHz) for forward/backward linearly polarized excitations. Surface current analysis and electric field profiles of the structure elaborates the non-identical interaction of electromagnetic radiation for forward and backward excitations that resulting in the AT effect. Proposed CMM is ultrathin over the operational AT bandwidth and hence it may be useful to replace conventional ferrite based devices for microwave applications.

1. Introduction

Efficient manipulation of polarization state of electromagnetic radiation has always been highly desirable due to its potential applications in molecular biology, analytical chemistry and optoelectronics[1]. Although, conventional chiral materials which lacks mirror symmetry in the propagation direction possess optical activity, its magnitude is very weak. On the other hand, metamaterials which are artificial materials formed by periodic metallic inclusions came out as an excellent candidate for the polarization manipulation. Metamaterial with twisted metal inclusion is sufficient enough to break the mirror symmetry along the direction of propagation and such composite possesses giant optical activity known as chiral metamaterials (CMM). CMM exhibit tailored chiral response which is several magnitudes higher than the natural conventional chiral materials. Initially three-dimensional helical metamaterials were employed for polarization manipulation but due to the difficulty in fabrication and thickness the focus has been shifted to planar CMMs. Twisted rosettes[1], cross wire pairs[2], gammodian structures[3], fractal geometries[4], cut-wire pairs[5], asymmetric split ring resonators including square and V-shaped constituents[6] are few examples of planar CMMs. Apart from giant optical activity CMMs can also show some exciting properties such as polarization transformation, circular or elliptical dichroism and asymmetric transmission (AT).

Asymmetric transmission (AT) is a remarkable effect exhibited by CMMs due to circular conversion dichroism. It is the capability of the structure to allow the electromagnetic wave to propagate in one direction while blocking it completely in the opposite direction. This can be compared to a diode which allows the current in forward direction while blocks it in the backward bias[7]. AT effect in CMMs is different from the non-reciprocity of the Faraday Effect in magneto-optical media and can be explained by de hoop reciprocity as explained by Jones matrix formulation [8]. AT effect is useful in designing non reciprocal devices such as isolators and circulators, especially in the microwave region and also in optical interconnects, ultrafast information processing and integrated photonic circuits [9]. AT effect in metamaterial can be a good replacement for bulky ferrite based conventional ones to help in microwave circuit miniaturization. Hence, over the last decade much research has been carried out to develop metamaterial based AT structures [10-13]. However, many of the designs exhibited only narrow operational bandwidth that restricted its practical applications. Therefore, designs with broadband, high magnitude AT effect is highly desirable.

In this work, we present a novel, broadband asymmetric transmission structure for a linearly polarized wave at microwave frequencies. The designed structure is based on complementary strips patterned on a dielectric substrate. The optimized design is almost transparent for a broadband of 1.15 GHz in one propagation direction while the same polarization is blocked from the other direction. The mechanism of the asymmetric transmission by the proposed design is explored with surface current analysis and electric field maps.

2. Design

Fig. 1 shows the unit cell layout of the proposed AT structure. It is a single dielectric layer design with metal patterns on both the sides of it. The metal patterns are designed to be complementary strips which are kept at an angle of 90° with respect to each other. This rotated geometry breaks the symmetry in the propagation direction and thus gives the asymmetric transmission from the structure by giving different polarization conversion from the two opposite incident directions. Rogers RT 5880 with dielectric constant 2.2 and loss tangent 0.0009 is used as a

substrate and the metal patterns are realized with copper of thickness 0.034 mm and conductivity of 5.8×10^7 S/m.

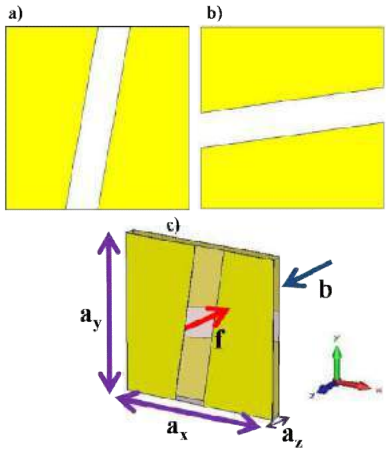

Figure 1: Unit cell of the proposed AT structure. a) Front layer b) back layer c) Perspective view

The geometry of proposed structure is analyzed and optimized by full-wave electromagnetic simulations using CST Microwave studio. In the frequency domain solver, unit cell boundary conditions are applied in the Y and X direction, and electromagnetic radiation is excited along the Z direction. The optimized dimensions of the unit cell parameters are a_x=11.5 mm, a_y=11.5 mm, a_z=0.787mm.

3. Simulation Results

For transverse electric (TE) and transverse magnetic (TM) polarization excitation, all components of co- (T_{xx} and T_{yy}) and cross-polarized (T_{yx} and T_{xy}) transmission coefficients are computed in the frequency range of 4-14 GHz. Transmission coefficients T_{ij} is defined as the ratio of complex amplitude of transmitted electric field to the incident electric field. The subscripts i and j corresponds to the polarization of the transmitted and incident electromagnetic radiation which is either TE (Electric field is oriented along y) or TM (Electric field is oriented along x) linear polarization.

Fig. 2 shows the transmission coefficient from the structure when the electromagnetic radiation incident on it in the a) forward and b) backward directions. For the entire spectrum the cross- polarization terms T_{yx} and T_{xy} show different magnitudes whereas the co-polarization terms T_{xx} and T_{yy} are equal. It is observed that T_{yx} shows a broad, strong peak with values above 0.9 from 8.48 GHz to 9.86 GHz. At the same frequency range co-polarization transmission magnitudes are less than 0.015. This indicates strong cross polarization conversion of the structure. When X-polarized wave is incident on the structure from the forward direction, most of it gets converted to Y polarization and transmitted to the other side. But for Y-polarized incidence, this effect is absent. This large difference in polarization conversion for different incident polarization makes the structure suitable for asymmetric transmission. When the propagation direction is reversed the cross-polarization terms exchange its values (fig. 2 b). That is from the backward direction, the incident Y-polarization gets converted to X-polarization and transmitted to the other side while blocking the incident X-polarization. Also, the co-polarization terms are less than 0.136 for the entire spectrum. The equal magnitudes for T_{xx} and T_{yy} make the asymmetric transmission for circularly polarized light as zero making the structure suitable for asymmetric transmission of linearly polarized wave.

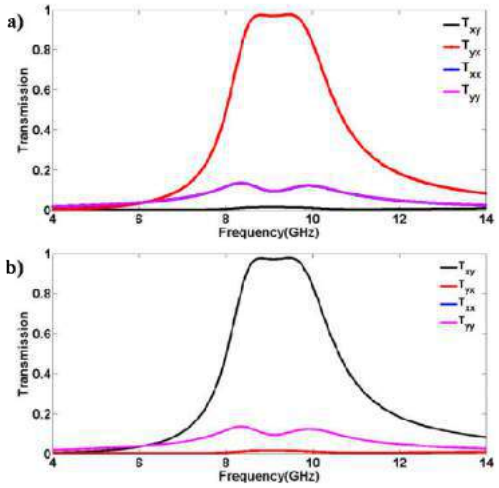

Figure 2: The co- (T_{xx} and T_{yy}) and cross-polarized (T_{yx} and T_{xy}) transmission coefficients of linearly polarized wave in a) forward and b) backward directions.

The large difference in the cross polarization terms causes large difference in the total transmission for a linear polarization from the two propagation directions. Total transmission is calculated as the sum of cross-polarization and co-polarization terms as [14]

$$T_x = |T_{xx}|^2 + |T_{yx}|^2 \qquad (1\ a)$$

$$T_y = |T_{yy}|^2 + |T_{xy}|^2 \qquad (1\ b)$$

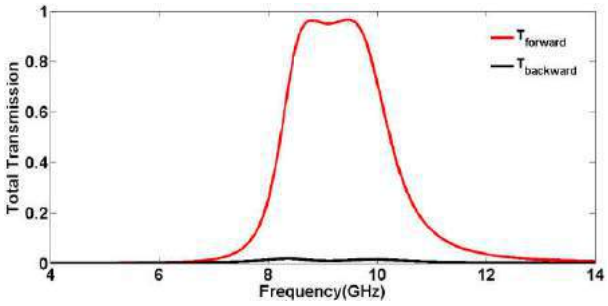

Figure 3: Total transmission for an X- polarized wave from forward and backward directions

From Fig. 3, it is observed that in the forward propagation direction X-polarization shows a peak from

8.56 GHz to 9.75 GHz with a maximum value of 96.6% and in the backward propagation direction it is less than 1.6%. In the opposite propagation direction, Y polarization shows a strong peak in the same frequency band.

Asymmetric transmission is generally characterized by the parameter Δ, which is defined as the difference between the cross-polarization terms [9].

$$\Delta^{x}_{lin} = |T_{yx}|^2 \quad |T_{xy}|^2 = \Delta^{y}_{lin} \qquad (2)$$

Fig.4 shows the calculated asymmetric transmission parameter Δ in the frequency range 4-14 GHz. A Strong, broadband response is observed from 8.58 GHz to 9.73 GHz with magnitude more than 0.9 with a maximum value of 0.95. This strong AT is a result of difference in the partial polarization conversion which is asymmetric in the two propagation directions.

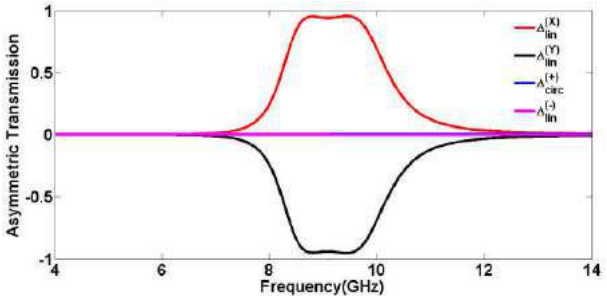

Fig.4 The asymmetric transmission parameter Δ for X and Y polarizations.

The existence of opposite peaks for Δ^x and Δ^y in the spectrum signifies that the asymmetric transmission is contrary for X and Y polarization. That is, in one propagation direction X polarization is allowed while Y polarization is forbidden and in the opposite direction this reverses. Further, owing to the equal magnitudes of the co-polarization terms, Δ for the circular polarizations is observed to be zero.

To elucidate the mechanism of asymmetric transmission, the surface current generated under e-m wave excitation on the structure is analyzed. Surface current distribution of the two metallic layers at 8.78 GHz when X-polarized wave incident on it in the forward direction is presented in Fig. 5. The applied electric field is in the X-direction and magnetic field in the Y direction. From the figure it can be seen that anti parallel currents exist between the front and back layers. This constitute a circulating current in the structure resulting in induced magnetic field which has components in both X and Y directions. The Y component of the induced magnetic field which is perpendicular to the applied electric field does not contribute to the polarization conversion. In contrast, the X component of the induced magnetic field which is in the direction of applied electric field couples strongly with the incident electric field and result in the X to Y polarization conversion. Also, there are induced electric fields along X and Y directions and the induced electric field along the Y direction which is perpendicular to the applied filed contribute in cross polarization conversion.

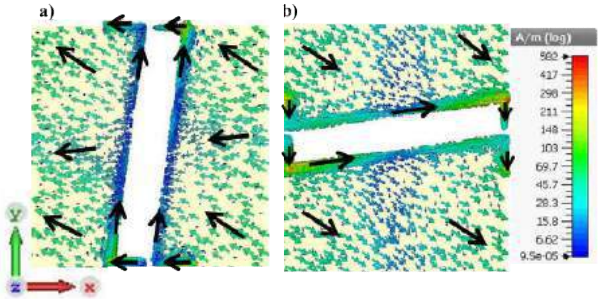

Figure 5: Surface current distribution on the proposed metamaterial structure at 8.78 GHz a) front b) back layers

To substantiate the cross polarization mechanism the electric field profiles of the structure is presented (Fig. 6). When Y polarized wave is incident on the structure in the forward direction (a) most of the incident radiation get reflected and no cross polarization conversion occurs. When Y polarization incident in the backward direction (b), it get converted to X polarization and transmitted to the other side. The change in the field patterns in the structure is noticeable and caused by the cross coupling resulting in the polarization conversion.

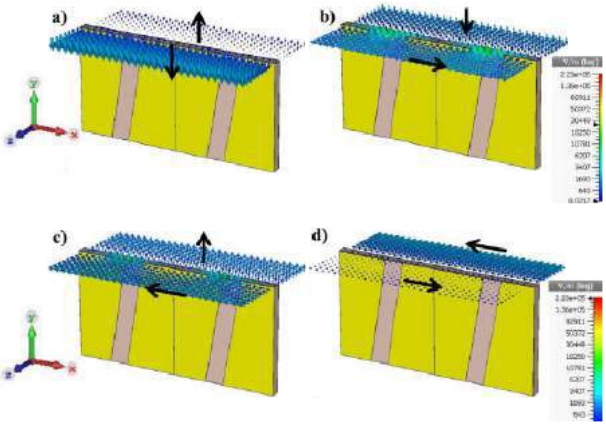

Figure 6: Electric field evolution for X and Y polarization incidence

Similarly when X polarized wave incident in the forward direction (c) cross coupling happens in the structure and the wave gets transmitted to the other side as Y polarization. But when incident in the backward direction (d), most of the radiation gets reflected and no cross polarization conversion occur.

4. Conclusion

In summary, the design and analysis of a metamaterial based broadband asymmetric transmission structure at microwave frequency is presented. In addition to

being planar, simple and ultra-thin, the structure exhibits broadband nature which makes it excellent for practical applications. Full wave simulations show that for a bandwidth of 1.15 GHz from 8.58 GHz to 9.73 GHz, the design produces strong asymmetric transmission for linear polarizations with magnitude more than 0.9. Also, from the calculated total transmission it is found that 96.6% of the incident polarization gets transmitted in one propagation direction while from the other direction the same polarization is restricted to 1.6%. The mechanism of cross polarization conversion is explained with the surface current analysis. Further the electric field profilesof the structure gives a clear visualization of the cross polarization occurring in the structure.

Abstract— Here we design a new SERS-active plasmonic nanostructure. Selected enhancement of Raman signals is achieved by this device. We found that the SERS enhancement factor corresponding to the resonant frequency exhibit about one magnitude larger than the enhancement factor mismatched with the resonant frequency.

Structures with one or two plasmon resonant mode have been widely used to realize higher enhancement of Raman signals[1]. Here we design a new SERS-active plasmonic nanostructure with period silver nanoholes upon metallic film separated by a layer of silica spacer. The introduce of silver and silica spacer provides a higher enhanced electric field for the interaction of the LSPR mode and SPP modes with their mirror's resonant modes, respectively.[2-3] The structure we investigate here combines a LSP resonant mode and two SPP resonant modes. Theoretical and experiment studies have been made to realize the selected enhancement of Raman signals. We successfully achieve the enhancement of Raman signals by strengthening the exciting mode and selected enhancements of several specific Raman signals matching with the other two resonant frequencies. Period nanohole without metallic film upon the substrate was introduced for comparison. The SERS enhancement factor (EF) of period silver nanoholes upon metallic film separated by a layer of silica spacer was observed to be more than one order of magnitude larger than that of a regular silver nanohole array on a glass substrate. Besides, we found that the SERS enhancement factors corresponding to the plasmonic resonant modes exhibit more than two times larger than that mismatched with the plasmonic resonant modes, which was almost the same in the period nanoholes with silica substrate only.

In conclusion, we propose a SERS-active substrate with selected enhancement property. Compared to the single layer nanoholes device, the multilayer device possesses not only higher SERS enhancement factors, but also a selective enhancement of specific Raman frequency corresponding to the plasmon resonant mode. This device can also be applied to several molecules with characteristic Raman vibrational frequency detection. Besides, measures like self-assembled[4] or UV nanoimprint lithography[5] can be introduced to reduce the cost of time and economy.

Abstract - We demonstrate that a conventional polarization-insensitive multilayer absorber can be switched to a highly polarization sensitive perfect absorber by replacing the metallic reflecting layer with a plasmonic grating. Active control of light absorption based on this concept is experimentally and numerically demonstrated for both narrowband and broadband of wavelength.

Perfect absorber, which is a device that neither reflects nor transmits the incident light, has drawn great interest due to many possible applications in photovoltaic solar cells, spatial imaging or highly sensitive detectors. Recently, polarization dependent perfect absorbers, where only lights with specific polarization are perfectly absorbed, have been realized by introducing anisotropy in the design structure. For example, for narrowband polarization sensitive perfect absorber, designs with botte-line and cub-like structures are numerical demonstrated in [1], and the one consisting of arrays of three-dimensional standing U-shaped resonators are fabricated and realized in [2]. Since the control of light absorbance plays a fundamental role in photonics technology with strong impact for light emitting and sensing components, metamaterial designs that can enable active control of light absorbance are necessary.

Here, we report a demonstration of polarization sensitive perfect absorbers for both narrowband and broadband of wavelength based on plasmonic grating, including numerical investigation of the design, fabrication and measurements. We show that a polarization sensitive perfect absorber can be realized by simply replacing the bottom metallic thin film with an appropriate plasmonic grating. The design structures for broadband and narrowband polarization sensitive perfect absorber are presented respectively in Fig. 1a and Fig. 1b. We perform numerical investigations for both cases with different incident angles by using finite element method (FEM) with Lumerical. In fabrication, evaporation for multilayers coating and e-beam lithography technique with parameters optimized for plasmonic grating have been used. Performance of the designed broadband perfect absorber under normal incidence is presented in Fig. 1c. When the incident light is s-polarized, since the permittivity of Cr is closed to the idea metal permittivity in the visible and NIR range, multi-resonance frequencies are created when the beam reflects back to the dielectric layer after approaching the grating [3], leading to high absorption (above 85%) over broad wavelength range of 0.4-1.4 μm. For p-polarized incidence, we can see that absorption decreases rapidly and becomes smaller than 25% for wavelength range of 1.2-1.6 μm. The device is therefore sensitive to the polarization state for a range of 1.2-1.4 μm. In case of narrowband perfect absorber, for s-polarized light, three absorption peaks, denoted as Peak 1 (absorption above 98%), Peak 2 (absorption above 85%) and Peak 3 (absorption above 68%), corresponding to the wavelength of 722 nm, 870

nm and 950 are observed respectively. Similar to the case of the broadband absorber, when the p-polarized light is applied, we can see that all of 3 absorption peaks are diminished. Especially, guided mode resonance absorption (Peak 2) is depleted to below 5%.

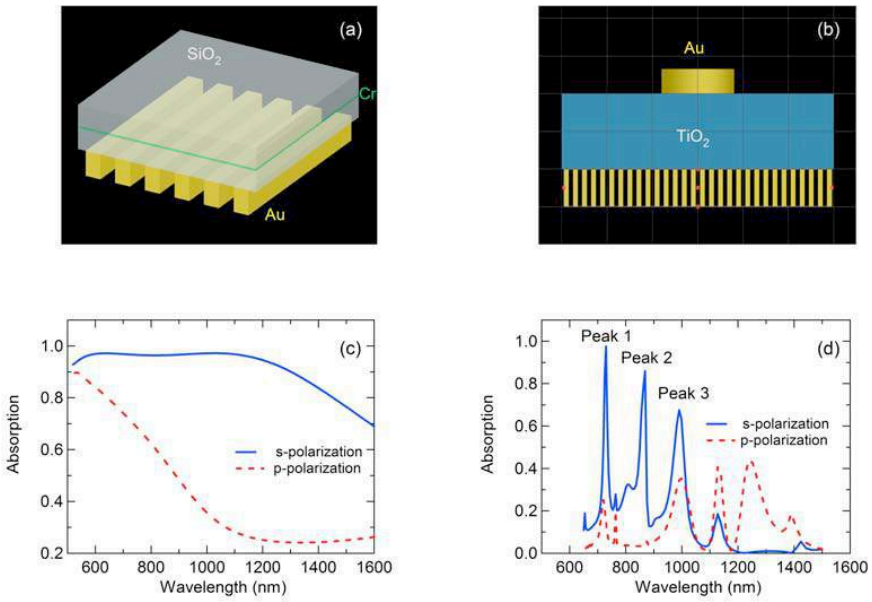

Fig. 1. Design of polarization sensitive perfect absorber for (a) broadband and (b) narrowband range of wavelength. (c) and (d) are absorption under s-polarized and p-polarized incidence for the designed broadband and narrowband perfect absorber respectively.

Overall, this study shows that a conventional multilayer perfect absorber can be switched to polarization sensitive perfect absorber by simply replacing the metallic thin layer with a plasmonic grating. A broadband and a narrowband perfect absorber based on the above concept are designed, fabricated and demonstrated to be polarization dependent. Challenges remain, including the fabrication of grating with tinny period, especially for sizes below 50 nm. The performance tolerance of the absorbers on the grating sizes is therefore also investigated in our work. The proposed absorbers may have potential applications in polarization detectors, polarizers etc.

Hybrid plasmonic waveguides by cladding hyperbolic metamaterials

Ruey-Lin Chern

Institute of Applied Mechanics, National Taiwan University, Taipei 106, Taiwan
chernrl@ntu.edu.tw

Abstract— We propose a new type of hybrid plasmonic waveguides by cladding hyperbolic metamaterials, consisting of mutlilayers of metal and dielectric, on a cylindrical plasmonic waveguide. The proposed metal-dielectric-hyperbolic waveguides share the merit of hybrid plasmonic waveguides, that is, a relatively large ratio of propagation length to mode area. We analytically solve the propagation constant, the most important waveguide feature, by locating the complex roots of the multilayered anisotropic cylindrical waveguide dispersion relations.

In the present study, a new design of plasmonic waveguides with the dielectric-coated metal wire as the inner core structure and the hyperbolic metamaterial as the outer cladding, is proposed. The inner core structure is one of the standard optical waveguides for guiding waves in one dimension [1]. The outer cladding is a strongly anisotropic medium, which is carefully arranged to adjust the distribution of field energy within the waveguide. On the one hand, adding an outer cladding on the coated structure forms the so-called metal–dielectric–hyperbolic cylindrical waveguides. The field energy is shown to be highly confined within the dielectric layer as in the metal–dielectric–metal planar [2] or cylindrical [3] waveguides, with minimal interference to nearby optical components. On the other hand, the propagation loss will be reduced because of the somewhat less confinement of the field energy along the transverse (to propagation) direction as in the hyperbolic–dielectric–hyperbolic planar waveguides [4]. The proposed waveguides thus behave in the spirit of hybrid plasmonic waveguides that combine the advantages of two different types of waveguides to reach an optimal performance. Regarding the hyperbolic metamaterial as an effective medium, the radial component of the permittivity tensor is positive in the present configuration, as opposed to being negative for the axial component.

The propagation characteristics of the proposed waveguides are analyzed by the dispersion relation of a multi-layered anisotropic structure in cylindrical coordinates. By taking into account the evanescent nature of surface plasmon waves in the cladding, the dispersion relation can be well approximated by a three-layered compact formula, based on which the propagation constant, propagation length, mode area, and figure of merit are determined in an analytical manner. An optimal waveguide performance is achieved when the propagation loss is substantially reduced at the expense of slight mode confinement. For the plasmonic cylindrical waveguide made of Ag and ZnO at the telecommunication wavelength, the mode area is comparable to that of the metal–dielectric–metal waveguide, while the propagation length is about twice as large.

Abstract— We proposed and evaluated a functional layer, a composite of plasma and dielectric, which compensates the propagation of electromagnetic waves for loss in the shadow of an object. The layer hides the object inside the layer from electromagnetic waves like an invisibility cloak. Using the layer, we observed by numerical analyses that electromagnetic waves propagate in the shadow. This layer consists of a dielectric layer and a plasma layer which has a spatial gradient of electron density, and so the structure is simpler than the invisibility cloak composed of metamaterial.

The methods of controlling propagation paths of electromagnetic waves by metamaterial, for instance, cloaking, have been studied extensively[1]. An invisibility cloak decreases scattering from the hidden object and its shadow[2]. In other words, the cloak compensates propagation of electromagnetic waves for loss in the shadow of an object. Metamaterial, which can achieve the cloaking is complex, which is a drawback for future industrial uses. Here we propose that plasma can replace metamaterial in some cases. We observed that the plasma layer and the dielectric layer hide an object roughly like an invisibility cloak without metamaterial by numerical analysis[3]. In addition, combination of plasma and metamaterial works well to make the property tunable[4], which is an advantage of plasma.

In this study, we evaluate this functional composite layer which compensates propagation of electromagnetic waves for loss in the shadow of an object and hides the object from electromagnetic waves. Its structure is simpler than an invisibility cloak of metamaterial.

The two-dimensional model of the layer is shown in Figure 1. We calculated the distribution of the scattered and the total one, which is a sum of vectors of incident and scattered electric fields, by finite-difference time-domain method (FDTD) when the incident plane wave (3.0 GHz) entered the layer. The plane wave is in the TM mode, therefore the electric field is normal to, and the magnetic field is parallel to the plane. The numerical model is shown in Figure 2. Central electron density of plasma n_{e0}, the relative permittivity of dielectric ε_g, the thickness of dielectric d_g and the inner radius of the functional layer r_{in} are model parameters. The observed point is on the circle whose center is the same as the layer and whose radius is $r_{in} + d_g + \lambda$, where λ is the wavelength of the incident filed. We evaluated the layer by the value $E_{trms}(r_{in} + d_g + \lambda, \phi)/E_{irms}(r_{in} + d_g + \lambda, \phi)$, where ϕ is the observed angle, E_{trms} is the root mean square value (RMS) of the total field, and E_{irms} is RMS of the incident field.

RMS distribution of electric field calculated by FDTD and the evaluation value are shown in Figure 3. Figure 3(a) shows the case with the functional layer. In this case, electromagnetic wave cannot propagate in the plasma layer because of its overdense property. This case indicates that the functional layer can hide an object inside the plasma layer. Compared with Figure 3(b), Figure 3(a) shows that electromagnetic waves can propagate behind the layer. Therefore the functional

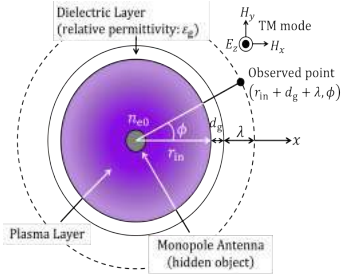

Figure 1: Functional layer.

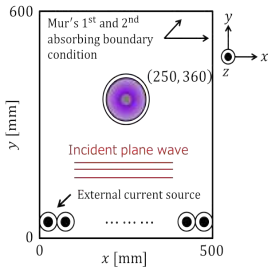

Figure 2: Numerical model

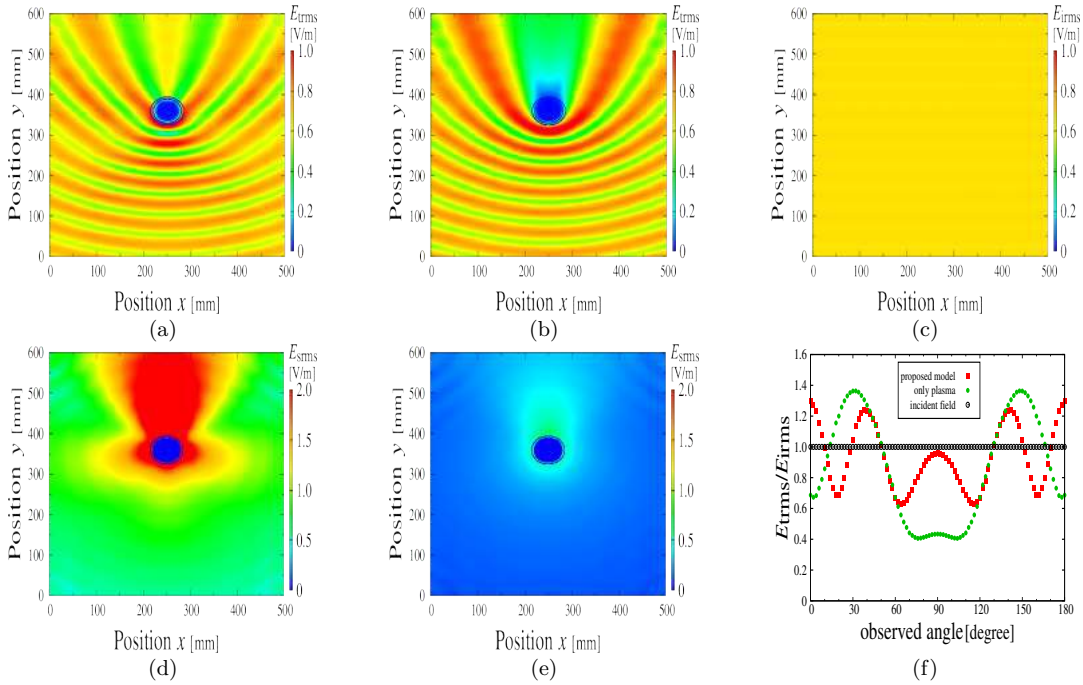

Figure 3: RMS distribution of electric field and evaluation value. Two circles describe inner or outer radius.(a)-(c): total field distribution and (d)-(e): scattered field distribution. (a) and (d): case with the functional layer. n_{e0} is 2.0×10^{19} m^{-3}(overdense plasma), ε_g is 9.0, d_g is 5.0 mm and r_{in} is 30.0 mm. (b) and (e): case with plasma only. Parameters are same as (a) except ε_g. (c): incident electric field. This case corresponds to free space propagation. (f): evaluation value.

layer can hide an object and compensate the propagation for loss in the shadow of the object.

RMS distribution of the scattered field of the functional layer is shown in Figure 3(d). Compared with Figure 3(e), the scattered field in the case with the functional layer is larger than the case of plasma only. In spite of large scattered field, the total field behind the layer is larger than that in the case of plasma only.

Figure 3(f) summarizes the results as an evaluation value. This figure shows that electromagnetic waves can propagate almost as much as the incident field by using the functional layer around 90°. Compared with the case of plasma only, the evaluation value in the case of the layer is bigger than that for plasma only. Therefore the compensation for loss in the shadow is successful.

In conclusion, we proposed the functional layer composed of plasma and dielectric. Its structure is simpler than the invisibility cloak of metamaterial. We observed the layer compensates propagation of electromagnetic waves for loss in the shadow of an object and hides the object from electromagnetic waves by numerical analysis.

Observation of resonance mode in a MIM plasmonic waveguide with a rectangular resonator

S. Kamada[1], **T. Okamoto**[1], **and M. Haraguchi**[1]

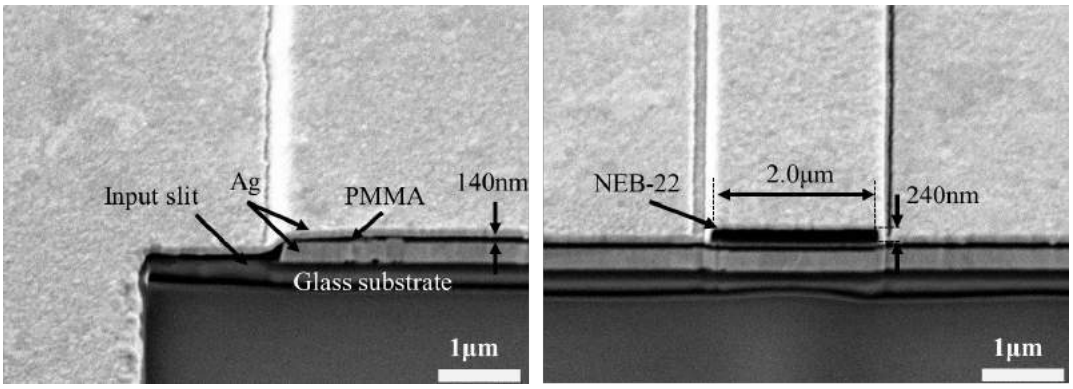
[1]Tokushima University, Japan
c501648001@tokushima-u.ac.jp

Abstract— We proposed a metal/insulator/metal plasmonic waveguide with a rectangular resonator for a compact pressure or refractive index sensor. Transmission spectra of fabricated structure were measured to confirm the resonance mode. Transmission dips by rectangular resonator are appeared at the fabricated structure. It is assume that the transmission dips due to resonance mode in the rectangular resonator.

Plasmonic waveguide poses a potential to realized tiny and simple optical devices, because of strong light confinement [1], [2], [3]. We are working on plasmonic devices for integrated optical circuits based on Metal-Insulator-Metal (MIM) plasmonic waveguides (PWGs). We proposed a MIM PWG with a rectangular resonator. Our rectangular resonator is sensitive to modification of its shape and changing of the refractive index [4]. Therefore, our device is available for pressure and/or temperature sensor.

Our rectangular resonator device could be fabricated by Electron beam lithography techniques. MIM PWGs consist of Ag/PMMA/Ag on a glass substrate. An Ag pattern (thickness: 300nm) of 1st layer is fabricated by EB lithography and lift off process. PMMA films and Ag film (thickness: 20nm) are formed by spin coating and thermal evaporation, respectively. A rectangular resonator was negative type electron beam resist (NEB-22) fabricated by electron beam exposure. Ag films (thickness: 300nm) are deposited on the structure. Finally, the output slit was milling by focused ion beam.

SEM images of the cross section of a part of input slit and PWG with rectangular resonator device are shown as Fig.1 (a) and (b), respectively. As shown in Fig.1 (a), the thickness of PMMA film is approximately 140 nm. The surface plasmon polariton (SPP) can be confined and propagating within the thicknesses PMMA with Ag cladding. The incident light is irradiated from glass substrate for exciting SPP at the MIM PWGs. The height and width of rectangular resonator are 240nm and 2.0μm, respectively.



(a) Input slit of plasmonic waveguide (b) Rectangular resonator device

Figure 1: SEM image of cross section of fabricated structures.

Optical setup for measurement of transmission spectra is shown as Fig.2. Xe lamp has been utilized as an incident light source. The TM polarized incident light is irradiated to the input slit from a glass substrate for excitation of the SPPs at a MIM PWG. A distance between input and output slit of a PWG is 20μm.

Transmission spectra of a straight PWG and a PWG with a rectangular resonator are observed in the wavelength range from 600nm to 1000nm. The transmission spectra are shown as Fig.3. Light intensity is decrease to shorter wavelength in the transmission spectrum of a straight PWG as shown Fig.3. It is because of shorter propagation length of SPP in MIM PWGs. There are no dips in this spectrum. On the other hand, there are many dips are appeared in the spectrum of a PWG with a rectangular resonator. Transmission dips appeared at the wavelength 780nm, 840nm and 890nm. When standing waves are occurred in a rectangular resonator, optical energy propagating in PWGs is consumed at a part of the rectangular resonator. Therefore, we believe that transmission dips as shown Fig.3 are resonance modes in a rectangular resonator.

In this study, we proposed a rectangular resonator device, and experimental measurements of transmission dips are succeeded. The device is available for on-chop sensor device.

Abstract-Active and reconfigurable plasmonic devices are expanding their applications. To combine such devices on optical fibers, one easily excites and detects signals from the optical element. We report the design, fabrication and demonstration of active plasmon device on fiber facets. From visible to near- infrared spectral range, we could control the transmission from the device by applying electrical signal.

Plasmonic devices, including sensors, optical filter, ultra-thin lenses, and optical tweezers and so on, are expanding their application based on their strong electric field enhancement and nano-scale localization. However, their properties are determined by the material and structure design, so it is difficult to change the properties after the devices are fabricated. Active and reconfigurable plasmonic devices are paid attention to overcome the difficulties. These device structures can be changed after the fabrication using electric voltage, material expansion, and refractive index change and so on. Yamaguchi et al. proposed and demonstrated the active plasmon filter [1] and the active plasmon lens [2] using micro/nano electro-mechanical system (MEMS/NEMS) technologies.

Optical fibers are the central element of optical information and communication technology and can deliver light energy to long distance with low loss and are easy to handle and connect to other optical elements. Recently, the research areas called “Lab on Fiber [3]” are paid attention due to their advantages. Lab on Fiber technologies covers optical function inside of optical fiber (“Lab in fiber”), and on fiber facet for controlling input and output. To disperse the functionalities of optical network including sensors and switches, such technology is one solution. In this presentation, we propose MEMS/NEMS-based active plasmonic devices on fiber facet for the Lab on fiber technology. We designed and fabricated active plasmon device which control the transmission from the fiber by applying electric signals shown in Fig.1. From optical measurement, we could control the transmission from the visible to near-infrared.

First, we designed the active plasmon device using the finite difference time domain (FDTD) method. Figure 2 show the transmission spectrum for a designed structure. We designed the structure consist of 4 slit grating with slit width is (400, 400, 400, 400) nm. Using electro static MEMS mechanism, the slit width change to (200, 600, 600, 200) nm when we applied the voltage to the structure. As figure 2 shows, around 570 nm the transmission decrease, on the other hand, around 780 nm the transmission increase. These changes come from slit width and plasmonic resonance of slit structures.

Next, we fabricated the active plasmon device on fiber facet using focused ion beam (FIB) milling and selective wet etching. First, we deposited Au/Cr thin film (300 nm/ 5nm) on cleaved fiber facet. We used the dispersion compensated fiber (DCF) for the telecom wavelength. Next, using FIB we milled a part of slit on the fiber core position. These slit act as the window for the following wet etching of optical fiber. Then, the structure was immersed to buffered fluoric acid (BHF). The etching rate for the core and clad of the fiber are different

because of their Ge doping difference. In this case, the etching rate for the core is faster than for the clad, we could release the plasmonic structures above the fiber core. Finally, grating structures were expanded for the decreasing driving voltage and the electrode pads using FIB milling. Figure 3 shows the scanning electron microscope (SEM) image of the fabricated device.

We conducted the transmission measurement of the active plasmonic device. White light incident from the fiber end and the outputted light were collected by optical microscope using 100X objective. The collected light entered the fiber-coupled spectrometer and the transmission spectrum was measured. Figure 4 shows the transmission spectrum of the active plasmonic device. The black point shows the spectrum without applying voltage and the blue point shows the spectrum when we applied 21 V DC voltages to the device. Comparing with the simulated data, the results suggest the grating arms moved about 200 nm to outer by electrostatic force and transmission could be changed by the MEMS mechanism.

In conclusion, we proposed and demonstrated the active plasmon device on the optical fiber. Our device could connect to other fiber or waveguide devices easily and make bundles for the parallel optical processing. In presentation, we will also discuss the combination with the in-fiber ("Lab in fiber") device [4].

Abstract- We propose and analyze a novel detector structure for linear polarization detection in the mid-infrared regime. 1-dimensional subwavelength grating atop a dielectric layer offers enhanced transmission for transverse magnetic polarized light, thereby enabling a higher extinction ratio as compared with conventional structure. Numerical simulations based on a finite integration technique were used to find the optimized geometric parameters for the structure. Our work can pave the way for practical, easy-to-fabricate detectors, which are highly useful for polarimetric imaging applications.

Infrared (IR) polarimetric imaging has been widely used in remote sensing, military applications and environmental protection[1]. 1-dimensional (1D) subwavelength grating integrated IR sensors have advantages such as polarization discrimination and a significant reduction in cost and complexity of IR camera systems. However, conventional 1D grating structures have low transmission efficiency for transverse magnetic (TM) polarized light due to unwanted reflections. Our design uses a 1D grating on top of the dielectric film, which can be integrated with a Type-II superlattice (T2SL) detector, thereby enabling enhanced responsivity for the TM polarization and thus giving rise to higher figure of merit (extinction ratio), as the measure of linear polarization detection performance than a conventional 1D grating[2]. T2SL structures have been the focus of significant interest recently because of a high device performance and bandgap engineering capabilities[3]. In this study, we employed both the commercial software (CST Microwave Studio[4]) based on a finite integration technique and a rigorous coupled wave analysis[5] for designing the structure of 1D grating atop the dielectric layer. Figure 1(a) shows the calculated extinction ratio color map (1D grating on substrate) as a function of grating parameters (periodicity p and duty cycle r). The grating period p and the ratio r are varied continuously from 0.2 – 2.0 μm and 0 – 1 with fixed gold thickness at 100 nm. The extinction ratio (ER) at 4 μm is found to be from 1 - 10^5 for linear polarized light. The ER for the grating period p = 0.4 μm and duty cycle r = 0.7 can reach up to ~10^3 while maintaining TM transmission higher than 50%. Next, we use SU-8 as the spacer between the 1D grating (p = 0.4 μm and r = 0.7) and substrate. ER is represented in the color map as a function of wavelength and SU-8 dielectric thickness (t_{SU8} is varied from 0 to 2 μm with a step of 0.2 μm) as shown in Figure 1(b). In order to satisfy high TM transmission (>70%) and ER (>10^3) simultaneously, an optimal SU-8 thickness was found to be ~0.4 μm. As indicated in Figure 1(a) and (b), the 1D grating on SU-8 spacer structures show overall performance enhancement (associated with linear polarization detection) as compared with a single layer 1D grating. Finally,

the 1D grating and 1D grating-SU8 (p = 0.4 μm; r = 0.7; t_{SU8} = 0.4 μm) integrated backside-illumination T2SL detector (Figure 1(c)) were simulated for the overall polarization detection performance. Figure 1(d) indicates that TM absorption efficiency in 1D grating-SU8-T2SL can be improved up to ~87% as compared with 1D grating-T2SL and integration of extinction ratio ($\int ER(\lambda)d\lambda$) is also increased by ~ a factor of 10. We expect our design and analysis can be used for various IR polarimetric imaging applications.

Abstract- In this paper, we study the performance of dual polarized cross bowtie gold nano antenna (nantenna) using COMSOL Multiphysics software [1] for energy harvesting applications [2, 3, 4]. Illuminating the bowtie nantenna with an incident plane wave results in a strong local field confinement in the gap. In this work, the electric field in the inner gap of the cross bowtie nantenna is observed and estimated for different values of the geometrical parameters of the nantenna. As it is challenging to fabricate and obtain sharp-tips for such nanostructures, we focus on the changes in the local field for curved-tips as compared to sharp-tips cross bowtie nantenna. Fig. 1 shows the design of cross bowtie gold nanoantenna and the variation of the normalized electric field against frequency for one of the considered parameters.

Abstract-This paper is focused on analyzing the effect of a two-dimensional metal hole array structure and metal mirror back plane in a surface plasmonic-cavity system. Simulation results clearly show anti-crossing behavior resulting from interaction between the surface plasmon resonance and the Fabry-Perot resonance, depending on the thickness of the dielectric spacer. The simulation method detailed in this paper provides a generalized approach to optimize the design of any type of couplers integrated with backside-illuminate IR devices.

In this work, we have investigated the resonances in the surface plasmon[1-3] coupled cavity system. The system is composed of a dielectric spacer (BCB) of variable thickness t_d (from 0.32 μm to 4.52 μm) sandwiched between a gold mirror back plane (t_{MGP} = 0.2 μm) and surface plasmon resonance structure (a gold film perforated with two-dimensional periodic array of subwavelength sized patterns: pitch p = 3.2 μm, diameter of circular aperture d_m = 1.6 μm, gold thickness t_m = 0.05 μm) as shown in the inset of Figure 1. Finite integration technique based simulations (CST Microwave Studio) were carried out to study the physical origins of coupling between surface plasmon (SP) resonance and Farby-Perot (FP) resonance in the cavity[4]. We gradually varied the BCB thickness t_{BCB} and numerically calculated the reflection of the SP-FP system. We present the spectral reflection data using a colormap to show the spectral changes as shown in Figure 1. For t_{BCB} = 0.32 μm, zero reflection is achieved at 5.5 μm, which is the first order SP resonance. Higher order SP resonances can be found at shorter wavelengths. As t_{BCB} increases, the SP resonance is blue-shifted (up to the t_{BCB} of ~1.72 μm). At t_{BCB} = 1.53 μm, anti-crossing behavior is clearly observed due to two resonances, i.e., SP resonance and a half-wavelength ($\lambda/2$) FP mode. The simulated $\lambda/2$ FP mode shows good agreement with theoretically calculated FP mode (green dashed line) for the system bounded by two mirrors. Note that our SP-FP system is bounded by a mirror at one end and an SP structure at the other end, acting as the quasi-open boundary, thus giving rise to a small discrepancy between simulation and theory. Similar anti-crossing behavior can be also found between λ FP mode and 2nd order SP resonance at 3.12 μm. Understanding the underlying mechanism by means of a simulation may offer guidelines for the design of backside-illuminate IR detectors (including IR focal plane array) integrated with any type of resonators because these device structures (semiconductor and metal ground plane consisting of contact metals, under bump metallization, etc.) are similar to the system used here[5]. We are currently testing various sets of geometric parameters (t_{BCB} = 0.32, 1.21, 1.52, 1.7 and 2.12 μm with fixed p, d_m, t_m, t_{MGP} at 3.2, 1.6, 0.05, 0.2 μm, respectively) for experimental verification.

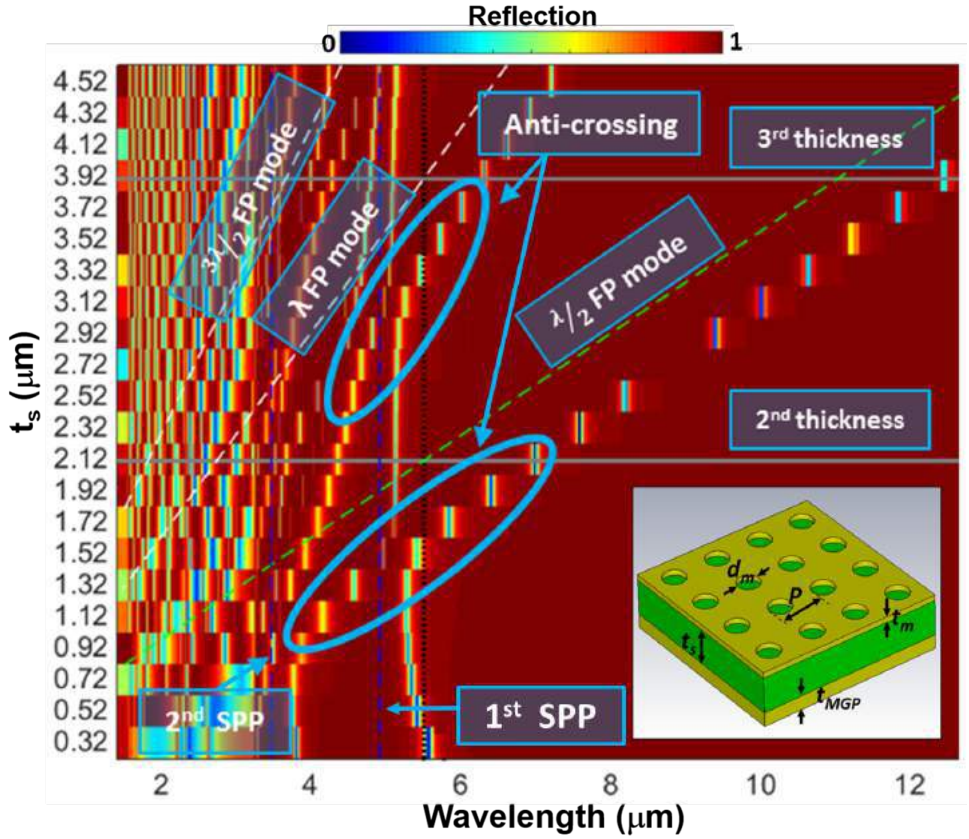

Figure 1. Simulated reflection colormap for SP-FP system (p = 3.2 μm; d_m = 1.6 μm; t_m = 0.05 μm; t_{MGP} = 0.2 μm) as a function of the wavelength and BCB thickness t_d (varying from 0.32 μm to 4.52 μm with a step of 0.2 μm). Inset shows the illustration of unit cell of SP-FP system.

A Monolayer Graphene NIR Plasmonic Super Absorber using High-index Contrast Grating (HCG)

Parag Parashar, Wei-Ming Huang, and Albert Lin*
Department of Electronic Engineering, National Chiao-Tung Univeristy, Hsinchu, Taiwan 30010

Abstract- Quasi-guided plasmonic mode excitation based near infrared (NIR) graphene absorber using high index contrast grating (HCG) has been demonstrated. High-Q (=700) narrow-band plasmonic resonance with enhanced (>80%) absorbance in graphene monolayer is reported without incorporating metallic mirrors. The high absorbance achieved is comparable to the magnetic resonance graphene absorption with metal gratings**.** Also**,** only a single-layer of subwavelength dielectric grating is adopted to achieve high TM NIR absorption without the use of distributed Bragg reflectors or 1D Photonic crystals.

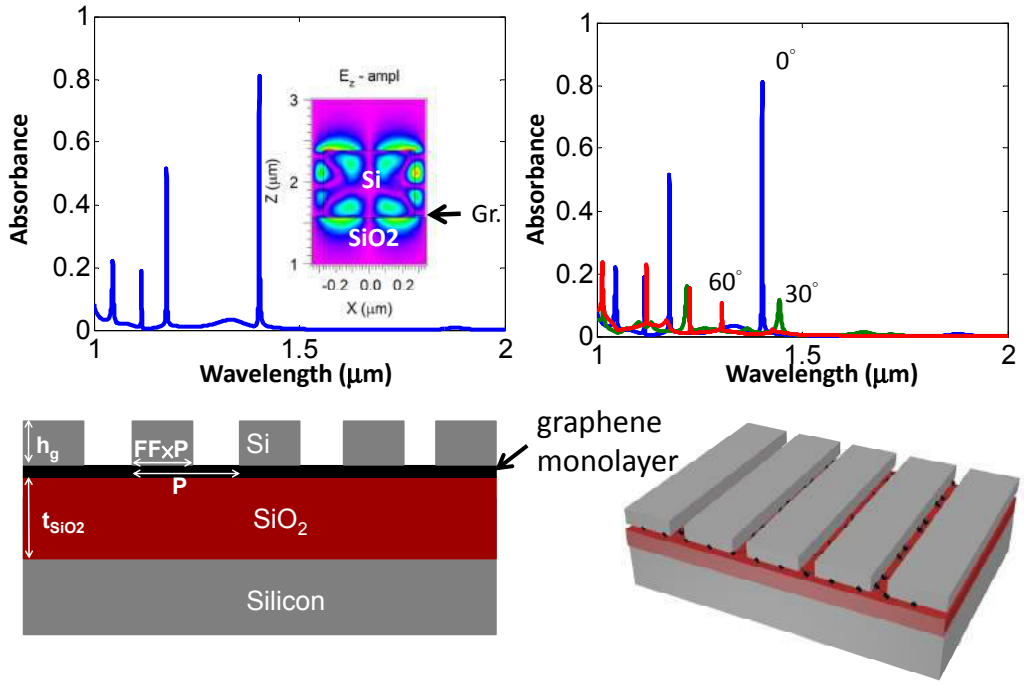

Figure 1 Proposed HCG monolayer graphene plasmonics platform and the corresponding TM spectral absorption curves for the normal and oblique incidences. Surface plasmon polaritons (SPP) are observed at graphene/SiO_2 interface.

Graphene is a 2D monoatomic layer of carbon atoms that possess unique optical and electrical properties. The monolayer graphene absorption enhancement is imperative for optical sensing, photo detecting, and

biomedical applications. High absorption using graphene plasmonics is relatively easy to achieve for a single layer graphene at THz, FIR, and MIR regimes, but the realization of the super absorber at near infrared (NIR) is quite difficult due to the lower free carrier concentration in graphene as compared to noble metals, such as silver and gold. Previously, B. Zhao et al. [1] achieved nearly 70% total absorption in monolayer graphene using metallic gratings to enhance the TM NIR absorption. In contrast to metallic-gratin-based graphene super absorbers, dielectric structures with multiple layers of dielectric gratings, DBR, and 1D PC were also investigated to realize high absorption [2]. Figure 1 shows the structure of our proposed HCG platform for monolayer graphene plasmonics. The graphene monolayer has been sandwiched between top Si grating and bottom SiO_2 spacer.

In the present work, we demonstrated that only one layer of HCG is capable of achieving >80% TM absorption via plasmonic mode excitations. The absorption value achieved here is analogous to the work done by B. Zhao et al. [1] that implemented localized strong electric field resulted from magnetic resonance. However, the quality factor (Q- factor) achieved in our proposed structure is higher than B. Zhao et al. work. As compared to the past dielectric grating structures [2], we have used only a single-layer of subwavelength dielectric grating to achieve high TM NIR absorption without the incorporation of DBR or 1D PC.

RCWA simulations have been conducted for the structure, and high-Q (Q=700) resonance at λ=1.4μm has been achieved for normal incidence through plasmonic mode excitations. The inset shows the field profile variation that manifests the plasmonic nature of the quasi-guided mode. Here, surface plasmon polariton (SPP) at graphene surface is evident at the resonating wavelength. Also, high angular selectivity exists for this structure as <20% absorption is observed at 30^o and 60^o incidences due to the high geometry and angle sensitivity associated with the high-Q narrow band resonances and the ultrathin graphene absorption layer. A very thin etch stop layer above the graphene monolayer could also be included in this design so as to prevent damage to the graphene layer during dry etching process**.**

Abstract

A novel implementation of spoof surface plasmon transmission line (SSP-TL) with loaded capacitors is proposed in this paper. It has been demonstrated that SSP-TL with capacitors can be an alternate candidate of flexible dispersion properties control. As an example, a smaller-line-width SSP-TL with loaded capacitors is designed and its measured performance is compared to the conventional one without capacitors but in larger-line-width configuration. The new method provides design flexibility without any geometrical dimensions modification of the SSP-TL.

1. Introduction

In optics, surface plasmons (SP) are propagating waves along the interface between a conductor and a dielectric medium. These waves decay exponentially in the direction perpendicular to the interface and give rise to highly field confinement near the surface supporting the surface electromagnetic waves [1]. In 2004, Pendry *et al*. has demonstrated that a similar surface plasmonic phenomenon, known as spoof surface plasmon (SSP), can be observed by perforating the conductive surface by parametrical holes [2]. Since then, the SSPs are widely being explored for their potential in microwave and terahertz circuits design, such as low crosstalk SSP transmission lines (SSP-TL), filters, leaky-wave antennas and etc [3-6].

In recently reported works on SSP-TL design, it has been demonstrated that the dispersion properties of such SSP-TL structure can be adjusted by modifying their geometrical dimensions and/or dielectric material parameters [3]. A novel implementation approach of SSP-TLs with loaded capacitors is proposed in this work. The value of capacitors brings another design degree freedom, which can control the dispersion properties of the fabricated SSP-TL structure without any geometrical dimensions modification.

2. SSP-TL Design

The conventional structure of SSP-TL consists of an ultrathin metallic strip with uniform periodic slots without ground plane. The dispersion properties of such SSP-TL can be realized in two ways: by modifying the geometrical parameters or by loading capacitors in the structure. In [3], an electrical equivalent model was proposed according to geometrical parameters as shown in Fig.1(a). The parameters *d*, *h*, *a* and *w* denote the periodic pitch, the slot depth, the slot width and the line width respectively (see Fig.1(b)). Fig.1(c) shows the dispersion curves for conventional SSP-TL with various slot depth *h* and the proposed SSP-TL with loaded capacitors. As expected, the confinement of electromagnetic wave is enhanced as the depth of slots increases. Although a high corrugation depth is good for filed confinement, it inevitably increases the line width which is not preferred in a compact system. To overcome this drawback, we propose the capacitor-loaded SSP-TL in Fig.1(b). As shown in Fig.1(c), the additional loaded capacitors ΔC along the surface brings in an extra

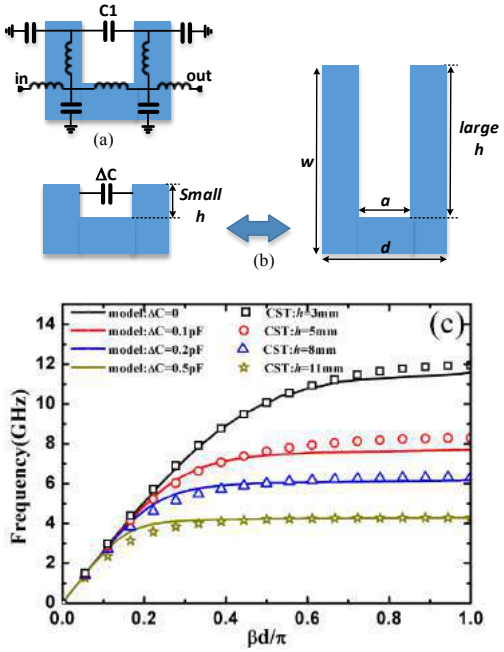

Figure 1: (a) Equivalent circuit model presented in [3]. (b) Proposed SSP-TL and geometrical dimensions. (c) Dispersion curves of conventional SSP-TL and capacitors-loaded SSP-TL.

capacitance, in equivalence to the extra capacitance brought by the increased corrugation depth in conventional SSP-TLs. For a given conventional SSP-TL, one can find a corresponding SSP-TL with smaller line width loaded by capacitors ΔC to analyze a similar dispersion behavior, leading to a control of dispersion properties.

Fig.2 shows the fabricated prototypes of SSP-TL with (Fig.2(a)) and without loaded capacitors (Fig.2(b)). The CPW-SSP transitions are required to achieve momentum, impedance matching and highly efficient SSP mode conversion [4]. The SSP-TLs were implemented on a 1.52 mm-thick Rogers 4003C substrate with ε_r=3.38 and tanδ=0.0027. The geometrical dimensions of SSP-TL in Fig.2(a) are *h*=3 mm, *w*=5 mm, *a*=1 mm, *d*=5 mm and ΔC=0.2 pF (Murata GJM1555C1HR20WB01D), whereas its comparison counterpart in Fig.2(b) were with *h*=8 mm, *w*=10 mm, *a*=1 mm, *d*=5 mm. Fig.2(c) shows the measured performance of both SSP-TLs. From 2 to 6 GHz, the measured S-parameters of proposed SSP-TLs are similar with |S21| and |S11| around -3 dB and lower than -11 dB respectively. The measured cutoff frequency of both SSP-TLs is around 5.8 GHz, corresponding to the one extracted from Fig.1(c). From the graph, it can be clearly seen that the proposed SSP-TL structure with less line width and loaded capacitors is validated, and it can be used as an alternative solution for SSP-TLs with large line width for compact system applications.

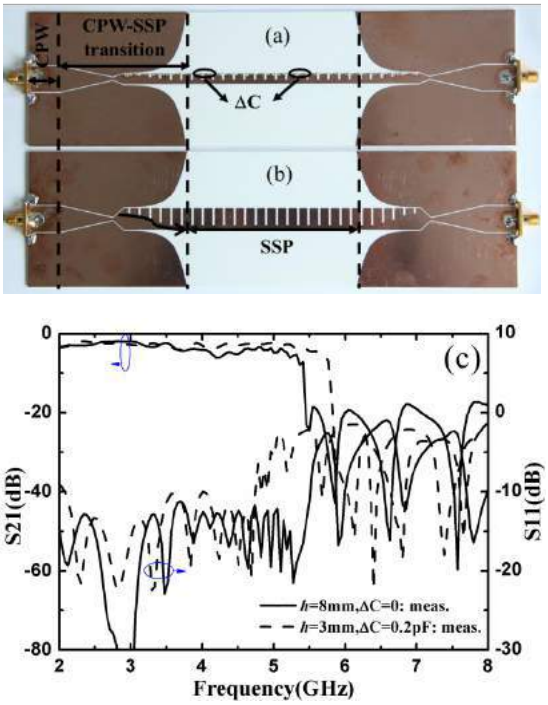

Figure 2: Prototype of SSP-TL (a) with ΔC=0.2pF and *h*=3mm/*w*=5mm, (b) without capacitors and *h*=8mm/*w*=15mm. (c) The measured S-parameters of the fabricated prototypes in (a) and (b).

3. Conclusions

In this paper, we have demonstrated that the use of capacitors in SSP-TL structures is a good solution for systems where large line width SSP-TLs are required. Indeed, the smaller line width SSP-TLs can be employed instead of large line width ones when the capacitors are used. In microwave frequency band, the measured performance of both SSP-TLs is quite similar. Furthermore, with this method, the control of dispersion properties can be done without any geometrical dimensions modification of the fabricated SSP-TL structure, making the SSP-TL design more flexible. In addition, with the proper scaling-down of the dimensions, various and reconfigurable SSP-TLs in terahertz band can be expected.

Abstract – Although metamaterials have shown many extraordinary phenomena, most of the metamaterials have been demonstrated in a passive type which acts as obstacle of its real applications. A few works of active metamaterials have been done, but modulation in the visible region is still challenge. Hereby, we suggest an active mechanism enabling high speed modulation in the visible region and tunable perfect absorber by using this mechanism.

Metamaterials have been explored due to their extraordinary optical properties and unprecedented phenomena such as negative refractive index [1,2], invisibility cloak [3,4], super-resolution imaging [5], artificial chirality [6], electromagnetically induced transparency [7], perfect absorber [8] and so on. Although many interesting phenomena have been introduced, there are technical limitations. Most of the metamaterials demonstrated before were passive type, so their optical properties cannot be changed after fabrication. This limitation is a critical obstacle of conventional metamaterials to outperform typical optical and electronic devices. A few works to control the optical properties of fabricated metamaterial devices by using electrical, optical, thermal and mechanical methods have been reported. However, they have severe problems to solve such as low working frequency, low modulation speed and insufficient integration feasibility.

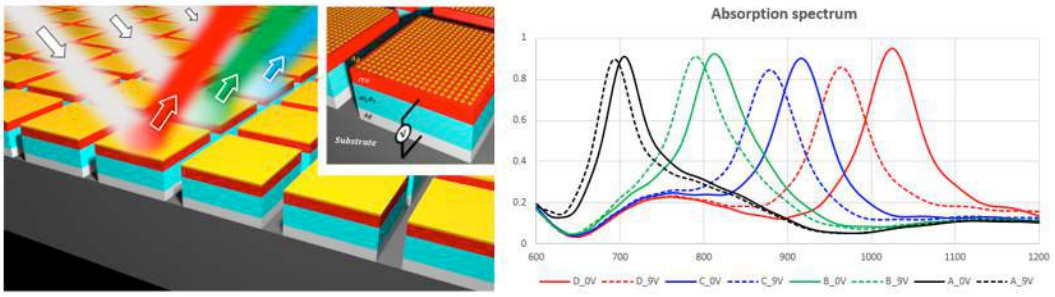

Figure 1. Schematic of the device and simulation result of the voltage application

Hereby, we suggest ITO as an active layer of the tunable metamaterial perfect absorber to solve aforementioned issues. Intrinsic ITO is not suitable for tuning in the visible wavelengths, so its carrier concentration has to be tuned to appropriate value by optimizing fabrication conditions such as annealing process. According to the simulation result, the suggested device can perfectly absorb a certain wavelength and handle the absorption wavelength within the visible region. It has many potential applications such as optical logic elements, ultrafast visible tunable band-pass filter, reflective display and military stealth technology.

Moreover, tuning mechanism of ITO at visible region can convert the past passive metamaterials to the active metamaterials, for example, tunable meta-hologram, ultrafast optical modulation and active wavefront manipulation opening a new generation of photonics beyond metamaterials.

Broadband and Thin Electromagnetic Absorber Based on Non-Foster Metasurface

Jinchao Mou and Zhongxiang Shen *
School of Electrical and Electronic Engineering, Nanyang Technological University, 50 Nanyang Avenue, Singapore
*corresponding author: ezxshen@ntu.edu.sg

Abstract-An ultra-wideband and extremely-thin electromagnetic absorber is presented, containing a grounded magnetic sheet coated with a non-Foster metasurface. The non-Foster metasurface can tailor the dispersion property of the magnetic material for reactance neutralization and compensate the loss in the substrate for power absorption over an ultra-wide band. Experimental measurements demonstrate that a nearly decade-wide absorption bandwidth can be achieved with a total thickness of only 1/255 wavelength at the lowest frequency, effectively breaking the Rozanov limit for passive absorbers.

Manipulating the absorption of electromagnetic (EM) waves is a fascinating and important theme, which can be realized by artificially engineering the dispersion properties with metamaterials or metasurface [1]. However, broadening the absorption bandwidth and thinning the thickness of an EM absorber is always a pair of contradictory propositions, which originates from the natural essence of causality and passivity [2]. To break the theoretical thickness-to-bandwidth ratio formulated as the Rozanov limit [3], active inclusions that can break Foster's limitations are necessary [2], [4]. By tailoring the dispersion property and compensating the loss in a magnetic sheet with a non-Foster metasurface, an ultra-wideband and extremely-thin absorber can be designed.

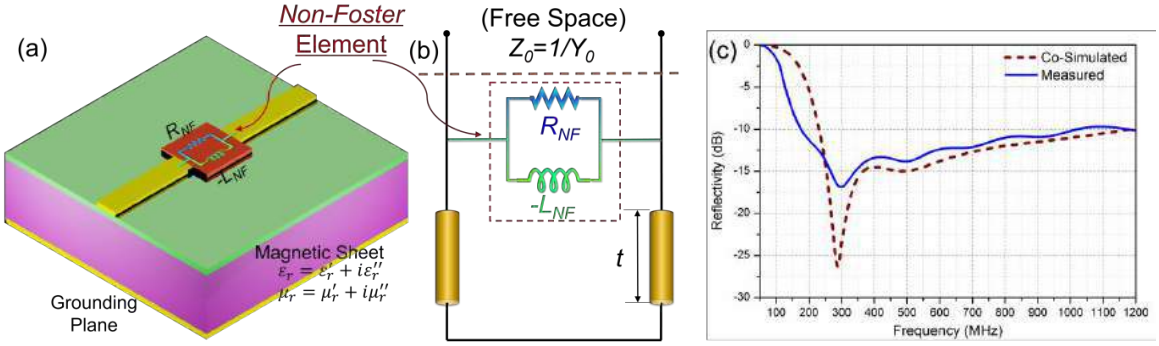

Figure 1. (a) Elementary cell of the proposed non-Foster absorber. (b) Equivalent circuit model of the absorber; (c) Measured and simulated reflectivity of the non-Foster absorber with physical implementation.

Figure 1(a) shows the elementary cell of the proposed absorber, which contains a grounded magnetic sheet topped by a non-Foster metasurface. The non-Foster element with ($-L_{NF}||R_{NF}$) may *re*-phase the current that is induced from the incident plane wave by the metallic gratings, which will then *re*-radiate out-of-phase to facilitate the destructive interference. Therefore, little energy will be reflected back and good absorption can be achieved over a wide frequency range. As the periodicity of the metasurface is smaller than the operating

wavelength, the absorber can be equivalent to a circuit in Figure 1(b). The non-Foster matching condition corresponding to the perfect absorption is L_S-L_{NF}=0 and ($1/R_{NF}$+$1/R_S$)=$1/Z_0$, where Z_0 is the characteristic impedance in free space.

A fabricated non-Foster absorber is demonstrated experimentally for validation, which is optimized with a co-simulation method [4] and fabricated using standard lithographic etching and plated through-hole technology. A test setup based on parallel-plate waveguide is employed for characterizing the fabricated absorber, which is particularly useful for long-wavelength band [5]. In this case, the fabricated absorber placed inside the parallel-plate waveguide will be imaged and equivalent to an infinite array. Figure 1(c) plots the measured reflectivity that is in a good agreement with the co-simulated result. The results exhibit that a reflectivity less than -10 dB can be obtained from 160 to 1000 MHz. The total thickness of the absorber including the non-Foster metasurface is only 7.35 mm, corresponding to 1/255 λ_0 at the lowest frequency of 160 MHz. This thickness is only one sixth of the theoretical minimum from the Rozanov limit [3].

The above analysis and results have validated the concept that the non-Foster metasurface can tailor the dispersion characteristics of a magnetic film for reactance cancellation and loss compensation for wide-band absorption. It may be mentioned that the same concept can be applied to other absorbing structures and readily scaled to other frequency bands.

Metasurface electrode light emitting diodes for directional emission

Yeonsang Park[1*], Jineun Kim[1], Young-Geun Roh[1], and Q-Han Park[2*]
[1]Device lab., Samsung Advanced Institute of Technology, Korea
[2]Department of Physics, Korea University, Korea

Abstract-Metasurfaces have attracted great attention in recent years due to their diverse properties. However, the application of metasurfaces to optical source devices has been limited by difficulties in fabrication and the inefficient coupling of unit elements to light due to their small sizes. Here, we present quantum dot light emitting diodes with metasurface-integrated metal electrode and demonstrate direction control of LED emission. By incorporating slot-groove array structures into the metal electrode, we show that LED emission can be directed towards a specific direction determined by metasurfaces.

Metasurfaces are planar structures that can change the polarization, phase, and amplitude of electromagnetic (EM) waves abruptly within thin and planar interfaces.[1,2] Based on their diverse properties and practical advantages, the application of metasurfaces has been extended from long-wavelength regime to optical regime. However, most previous works about optical metasurfaces dealt with passive type such as lens and beamsplitters[3,4] because the small size of optical scatterers causes not only fabrication difficulties but also low coupling efficiency with light emitters such as quantum wells (QWs), quantum dots (QDs), and molecule dyes. In view of practical applications, integrating metasurfaces with electric-driven light devices would provide unprecedented submicron-scale control to achieve improved performance or new functionalities in nanophotonics.

In this report, we present metasurface electrode light emitting diodes (LEDs) that control the direction of emission. Figure 1a shows the schematics of the metasurface electrode LED. Red-emitting colloidal quantum dots (CQDs) are used as a light emitting materials.[5] Its top electrode is made of Al-Ag-Au multilayer metals for the simultaneous operation as optical metasurfaces and electrode. Successful operation of the LED with the multilayer metal electrode was demonstrated by measuring the representative current-voltage (IV) curve and electroluminescence (EL) of the LED as shown in Figure 1b. As optical metasurfaces for direction control, we engraved slot-groove array structure on the top metal electrode. A scanning electron microscope (SEM) image of the fabricated slot-groove unit is given in left of Figure 1c. We demonstrated the control ability of metasurfaces by measuring optical and Fourier-space images of emissions from the LED. The optical image of Figure 1c shows surface emission from metasurface electrode LED. On the contrary, the Fourier-space images of Figure 1c corresponds to each pixel for 4-directional emission and clearly show that EL from the metasurface electrode LED is deflected in four distinct directions. From these results, we conclude that metasurface-integrated electrode not only actuates LEDs but also steers the emission into a directed beam.

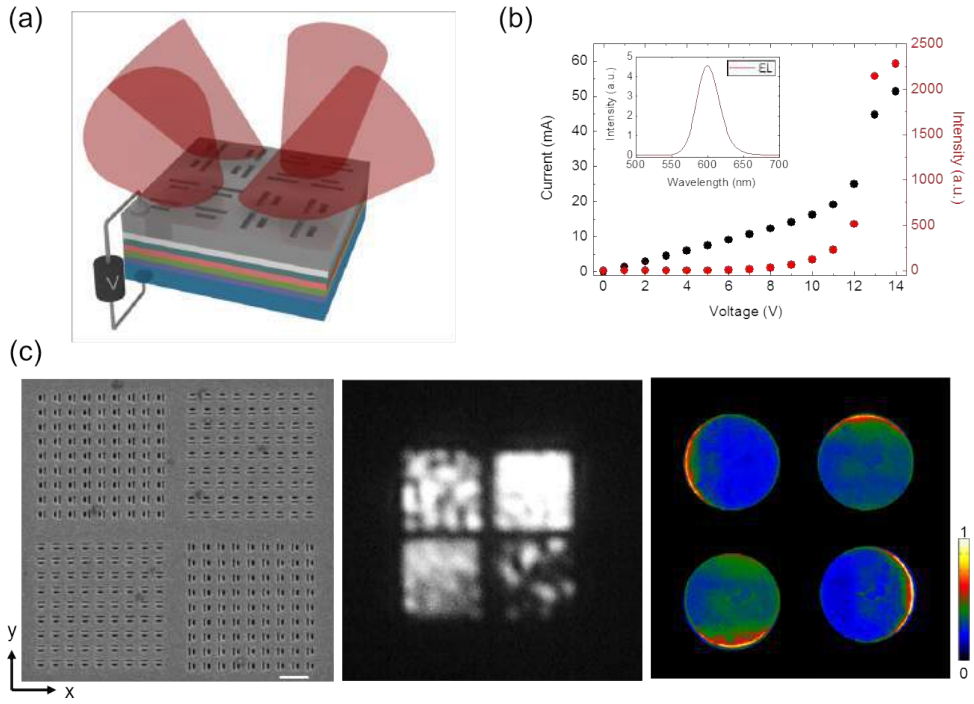

Figure 1. (a) Schematics of metasurface electrode LEDs (b) IV curve and EL spectrum (inset) of metasurface electrode LED (c) SEM image (left), optical images of EL from metasurface electrode LED (middle), and Fourier-space images of 4-directional emissions from metasurface electrode LED (right). White bar in SEM corresponds to 1 μm and the intensity in Fourier-space images are normalized by the maximum.

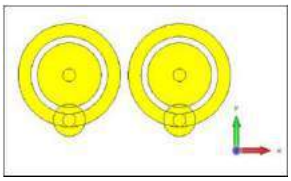
Abstract- Metamaterial structure of Electromagnetic Band Gap (EBG) incorporated onto dual band array antenna operate at 2.45 GHz (lower band) and 5.8 GHz (upper band) is proposed. The three EBGs with different diode states introduces dual band gap (S21) properties at 2.45 GHz and 5.8 GHz which is verified using Suspended Transmission Line (STL) method. The EBG successfully realize frequency reconfigurable array antenna which able to configure to operate exclusively at both bands, lower band or upper band.

Introduction

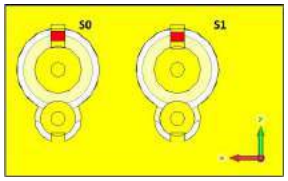
EBG is a High Impedance Surface (HIS) of metamaterial which exhibits unique properties in suppressing the propagating wave within its structure [1]. This characteristic can use to realize a filter [2] for the antenna design in which certain frequency can be block from propagating through the antenna feeding network. In this paper, a dual band array antenna is incorporated with EBG cells at various positions at the feeding network to realize dual band frequency reconfigurable antenna. The antenna has a maximum realized gain of 6.27 dBi and 7.84 dBi at 2.45 GHz (lower band) and 5.8 GHz (upper band respectively).

Result and Discussion

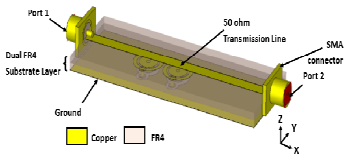
Figure 1(a)-(b) shows the front and back view of EBG cells with region "S0" and "S1" which can be "ON" and "OFF" with connection or removal of copper strips respectively. The "ON" and "OFF" are represented by "1" and "0" respectively. STL method in Figure 1(c) is used to analyzed the band gap, S21 of EBG and the result is shown in Figure 1(d). It can be observed that EBG produces band gap at lower band (2.45 GH) and upper band (5.8GH) with different EBG configurations. EBG is then incorporated to array antenna as shown in Figure 1(e) and 1(f). Different EBG configuration at EBG1, EBG2 and EBG3 as depicted in Figure 1(g) successfully achieve frequency reconfigurability for the array antenna as shown in Figure 1(h) and Figure 1(i). The proposed antenna is very useful to reduces the interference in wireless communication service (WCS) which operate at similar operating frequencies because the proposed antenna with metamaterial can be selectively operates at single band of lower band and upper band or simultaneously at both bands depending on dynamic requirement of the WCS.



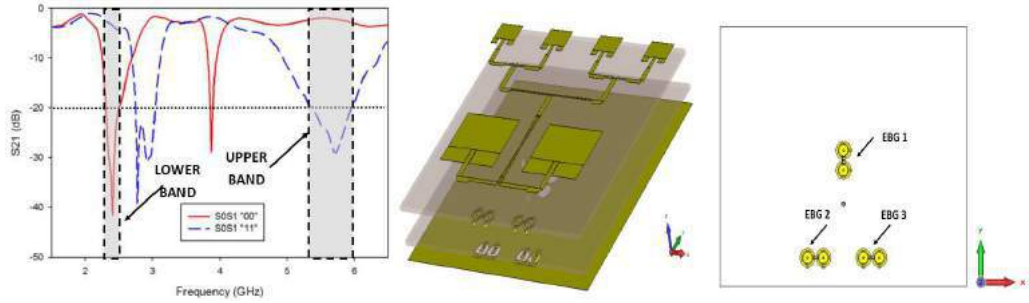
(a)



(b)

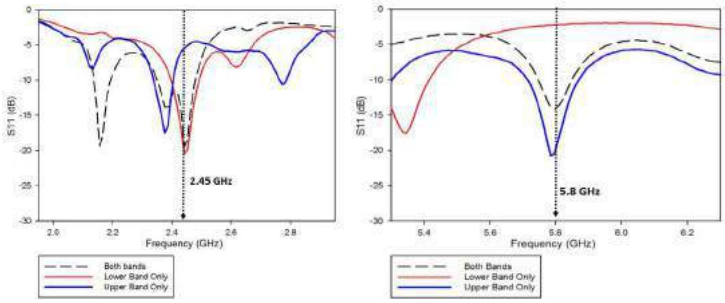


(c)



(d) (e) (f)

EBG 1		EBG 2		EBG 3		Frequency
S0	S1	S0	S1	S0	S1	Reconfiguration
0	0	1	1	1	1	Both bands
1	1	1	1	1	1	Lower band only
0	0	0	0	0	0	Upper band only



(g) (h) (i)

Figure 1. (a) Front and (b) back view of EBG cells. (c) STL method to analyze band gap (S21) with the corresponding (d) band gap (S21) simulated result. The (e) 3-dimensional and (f) EBG cells at the bottom substrate view of the array antenna. (g) EBG configurations at the array antenna with the corresponding frequency reconfigurability at (h) lower and (i) upper band of 2.45 GHz and 5.8 GHz respectively.

Conclusion: Dual band frequency array antenna using metamaterial EBG is proposed. EBG with different configuration produces band gap at 2.45 GHz and 5.8 GHz. By varying the configuration of EBG1, EBG1 and EBG3, the array antenna successfully achieves frequency reconfigurability to operate either at 2.45 GHz, 5.8 GHz or at both band simultaneously. The potential applications of the proposed antenna are in RFID, WLAN and WiMAX applications.

Abstract In this work, we enhanced the functionality to metatronic nanocircuits by adding real time tunability feature. We change the surface structure of the ITO surface using nanoimprint lithography. Hence, we will obtain RLC nanocircuits which operates at NIR region. Then, we change the dielectric constant of the nano-gap region dynamically. The capacitance value and the resonance wavelength of optical nanocircuits changes when the dielectric constant of the gap region the nanoscale gap region changes.

In microelectronic devices, radiofrequency signals are controlled and manipulated by 'lumped' circuit elements (i.e., resistors, capacitors, and inductors). It is essential to integrate radiofrequency electronic systems with nanoscale platforms for high speed information processing and high density data-storage technologies. In 2005, Engheta proposed metamaterials inspired optical lumped circuit elements. Properly designed and suitably arranged nanostructures exposed to optical signals function as lumped circuit elements. The optical material dispersion determines the type of lumped nanostructure, with dielectric leading to capacitive behavior and plasmonic materials leading to inductive behavior. Instead of conduction current these optical nanocircuits based primarily on the use of optical displacement field current. This concept of metamaterial-inspired optical nanocircuitry, named as ''metatronics''.

It is shown that an optical circuit is effectively a "stereo-circuit", exhibiting different properties simultaneously for multiple optical signals with different incident angles and polarizations, and thus can significantly improve our capability in parallel information processing at the nanoscale. Recently, 3D lumped nanocircuitry at visible wavelengths by using individually loaded nanoantennas has been experimentally demosntrated.

These state of the art studies shows optical frequency circuit elements in which circuit operations are based on photons rather than electrons. They open up possibilities for optical information processing at the nanoscale. It is possible to tailor the metatronic nanocircuits by changing the geometry or the load of the circuitry as suggested previous works. However, these approaches are lack of enabling real-time control. The ability to tune the values of the lumped circuit element will enable the real-time control of the circuits and add more functionality.

In this work, we fabricate ITO nanorod structures which act as optical RLC nanocircuits and add more functionality to the metatronic nanocircuits changing the dielectric constant of the gap region dynamically. The capacitance value of optical nanocircuits changes when the dielectric constant of the gap region the nanoscale gap region changes. We have changed the resonance of the metatronic circuit by the control of the outside medium. We tuned the optical element values by changing the substrate filling the nanoscale gap region in

real-time Finally, we have tested dielectric materials such as PDMS, glucose and CEMS. Hence, tune the capacitor value and resonance wavelength of the RLC circuitry.

Abstract – Although metamaterials have shown many extraordinary phenomena, most of the metamaterials have been demonstrated in a passive type which acts as obstacle of its real applications. A few works of active metamaterials have been done, but modulation in the visible region is still challenge. Hereby, we suggest an active mechanism enabling high speed modulation in the visible region and tunable perfect absorber by using this mechanism.

Metamaterials have been explored due to their extraordinary optical properties and unprecedented phenomena such as negative refractive index [1,2], invisibility cloak [3,4], super-resolution imaging [5], artificial chirality [6], electromagnetically induced transparency [7], perfect absorber [8] and so on. Although many interesting phenomena have been introduced, there are technical limitations. Most of the metamaterials demonstrated before were passive type, so their optical properties cannot be changed after fabrication. This limitation is a critical obstacle of conventional metamaterials to outperform typical optical and electronic devices. A few works to control the optical properties of fabricated metamaterial devices by using electrical, optical, thermal and mechanical methods have been reported. However, they have severe problems to solve such as low working frequency, low modulation speed and insufficient integration feasibility.

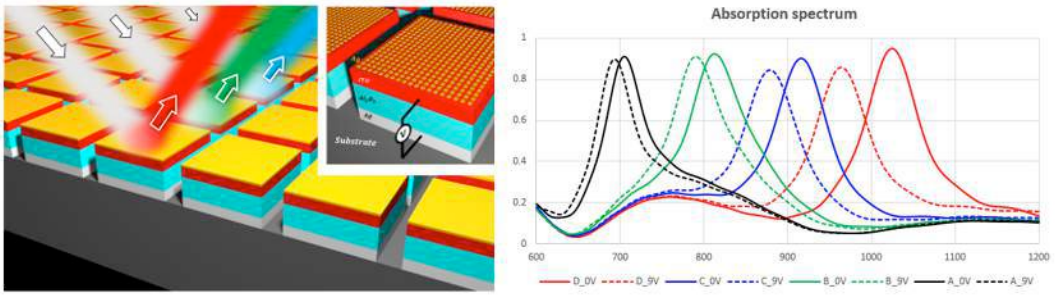

Figure 1. Schematic of the device and simulation result of the voltage application

Hereby, we suggest ITO as an active layer of the tunable metamaterial perfect absorber to solve aforementioned issues. Intrinsic ITO is not suitable for tuning in the visible wavelengths, so its carrier concentration has to be tuned to appropriate value by optimizing fabrication conditions such as annealing process. According to the simulation result, the suggested device can perfectly absorb a certain wavelength and handle the absorption wavelength within the visible region. It has many potential applications such as optical logic elements, ultrafast visible tunable band-pass filter, reflective display and military stealth technology.

Moreover, tuning mechanism of ITO at visible region can convert the past passive metamaterials to the active metamaterials, for example, tunable meta-hologram, ultrafast optical modulation and active wavefront manipulation opening a new generation of photonics beyond metamaterials.

Abstract- Phase change metamaterial (PCM) is a potential candidate to be assimilated in planar structures to make a new generation of tunable optical devices. We developed a tunable perfect absorber based on PCM, which also works as a non-volatile optical memory. By exploiting the advantage of switching the PCM between amorphous and crystalline states, we designed and fabricated a flexible programmable perfect absorber. The suggested device reflects the basic requirements of a re-writable and non-volatile memory by absorbing the light into a thin film of a PCM.

MMs as electromagnetic illustrative with artificial operations can get attained by configuring on the sub-wavelength scale.[1] Because the resonant optical characteristics of plasmonic MMs depends on the near-field dielectric circumstances, they specify a vigorous and an adjustable substitute for metals. Although various MMs has been introduced with a representative reflection to induced stimuli such as light and electric field, but the majority of them showed volatile switching state.[2, 3]

To overcome this bottleneck, we integrated a phase change metamaterial (PCM) in the nanophotonic device structure. We take benefits from the loss elements of the optical constant (real components) to establish an elevated absorber. A near-zero reflectivity is achieved by controlling the μ and ε resonances and matching MM impedance to the free space.[4, 5]

Metamaterial-based programmable perfect absorber (MPA) is a reconfigurable device with an absorbance near unity. It has been shown that optically- stimulated PCM specifies a non-volatile MM modulator of transmission and reflection for near- infrared (NIR) to mid-infrared (MIR) wavelengths with a subwavelength thickness.[2] MPAs have been earned appeal owing to their polarization independency, widespread-angle occurrence, high amount of light absorbency, exotic properties, and unity absorptivity of EM waves.[6]

Our design consists of three main layers in a simple metal-insulator-metal (MIM) structure including a dielectric thin film (spacer) which is sandwiched between two metallic layers (Figure 1a-d). The structure is analogous with Fabry-Perot (FP) etalon with an ultrathin cavity according to the top electrode (TE) arrayed nanoparticles. TE is a patterned metallic layer which conveys an electric reply relevant to the grounded bottom electrode (BE) by intensely coupling to the electric field at a specific resonance frequency.[1]

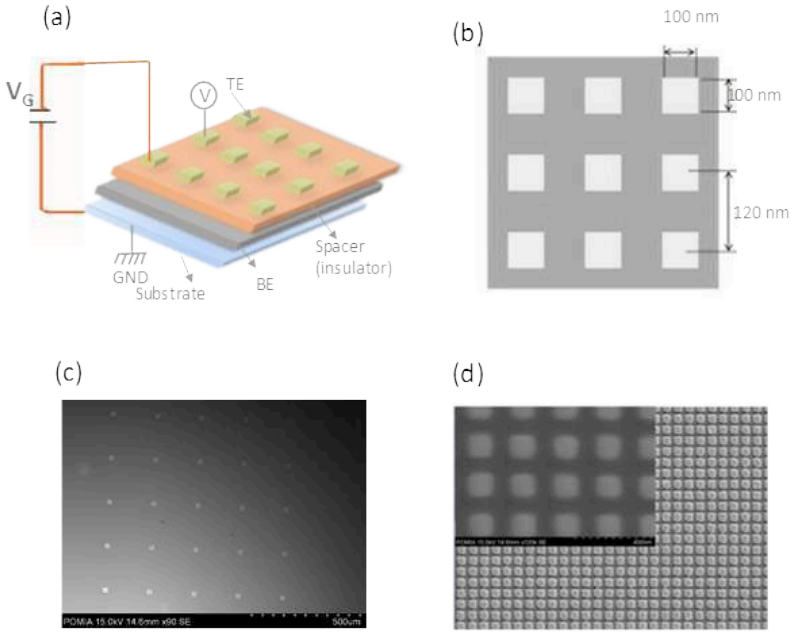

Figure1. (a) Schematic illustration of the dual functional device; the MPA and ReRAM. (b) The device consists of a 100 nm Pt as a BE, an ALD deposited PCM (25nm) and an array of Ag nanoparticles with a 100 nm thickness. The SEM images of the fabricated (c) device with MIM structure, (d) nanoparticles on the MPA.

We demonstrated a reconfigurable and rewritable MPA with two resistance states, which works as a memory device as well. The metal-insulator transition is done opto-electrically in both of the amorphous and insulator states. This programmable MPA device, potentially provides an enhancement in the future digital approaches of optical devices.

A New Meta-atom-based Stop-Band Filter for Ultra Wideband Applications

S. S. Islam[1], M. R.I. Faruque1*, S Abdullah[1], M. M. Hasan[1] and M. T. Islam[2]
[1]Space Science Centre, Universiti Kebangsaan Malaysia, Malaysia

Abstract-. In this study, a meta-atom-based ultra wideband stop-band filter is presented. Initially, a pi-shaped metamaterial was designed. The metamaterial shows wide band negative refractive index and near zero refractive index property. The metamaterial was then utilized in designing a filter that performs stop-band operation over an ultra wide band region. Measured results were provided for the metamaterial and the filter.

Artificially constructed metamateraial have become a promising field for the researcher. Metmaterial unit cell (meta-atom) can be utilized in designing a wideband filter. In the field of filter design, very few works are found with metamaterial in stop-band applications. For example, a metamaterial-based cut-band filter was proposed in [1] for C-band applications. They utilized different array of same metamaterial for increasing the resonance, but all in C-band of microwave spectra. They also increased bandwidth by increasing the metamaterial array. A split ring resonator (SRR) metamaterial-based microstrip filter was proposed in [2] where stop band performance was achieved from L-band to X-band. Actually, in their work, they obtained sharp resonances for each band with consecutive SRR increment, but their filter could not produce ultra wideband stop-band characteristics. A compact stop-band filter was proposed in [312] for radar application, but the filter was designed for X-band operation only and no metamaterial characteristics were shown.

In this paper, a new pi-shaped metamaterial introduced that was designed on $10\times10mm^2$ FR-4 substrate material with dielectric property 4.3 + j0.002. Finite integration technique (FIT) based CST-microwave studio software was utilized for the calculation of the complex S-parameters S_{21}(transmission co-efficient) and S_{11} (reflection co-efficient) of the metamaterial. The transverse electromagnetic wave was propagated through *z*-axis of the metamaterial unit cell using two waveguide ports. The metamaterial unit cell shows transmittance in the frequency of 8.31 GHz and 12.81 GHz as seen in Figure-1. The effective medium parameters permeability (μ) and permittivity (ε) were extracted from the simulated complex S_{21}(transmission co-efficient) and S_{11} (reflection co-efficient) parameters using Nicolson-Ross-Weir method.

In further step, a filter was constructed using the metamaterial unit cell for stop-band operation. The 20×10 mm^2 filter were designed for the same substrate material. However, in the filter design the copper arms of the unit cell structure were extended up to ending border on two opposite sides. The Figure.2 displays fabricated filter and the numerical and measured results of S-parameters for the filer operation. The stop band region has started from the frequency of 1 GHz to 12.04 GHz. The rejection level was found greater than 20dB from 1GHz to 10 GHz. The return loss was found below -10 dB from the frequency of 12.07 GHz to 12.55 GHz. A small pass band is visible from the frequency of 12.15GHz to 12.28 GHz.

Abstract- In this paper, the proposed absorber structure shows a wide bandwidth of 4.66 GHz and applicable for C-, X- and Ku-band applications. The absorber is developed by electric-inductive-capacitive resonators that are capable of not only high absorption, but also channelling almost all the absorbed power to a resistive load. The size of every unit cell of the absorber unit cell is 10×10 mm^2 and array slab is 150×200 mm^2. FIT-based CST Microwave Studio has been used for design and analysed purpose. From result analysis, it has been shown the simulated and measured results are well matched together. The measured result show resonance at 5.35 GHz (C-band), 11.85 GHz (X-band), and 16.45 GHz (Ku-band) and the effective medium ratio is 9.85. However, the absorption of the proposed meta-surface absorber at 2.06, 5.05, 9.26, and 13.23 GHz, are respectively, 60%, 95%, 78%, and 93%.

As advances in low power design, power consumption of electronics becomes smaller increasingly, which opens the possibility to harvest energy from the environment to power directly to the electronics or recharge a secondary battery. This kind of new techniques is called energy harvesting. In 2003, a metamaterial by capacitor loaded strips and split ring resonators, which exhibited negative permittivity and negative permeability both at the X-band frequencies developed by Ziolkowski et *al*. [1]. The first perfect metamaterial absorber was introduced by Landy et *al*. in 2008. The absorber with a classic sandwiched structure composed of a split ring resonator, a dielectric substrate, and a metallic cut wire achieved its peak absorption of 88% at 11.50 GHz [2]. A compact square split z-shape meta-atom with left handed features, wide bandwidth for S-, C-, X- and Ku-band applications by Faruque et *al*. presented. The presented meta-atom was investigated at 0^0, 15^0, 30^0, 45^0, 60^0, 75^0 and 90^0 rotation angle. The designed structure shown resonances at S-, C-, X-, and Ku-band with 5.67 GHz wide bandwidth. The compact meta-atom had an effective medium ratio 9.10 and exhibited left handed characteristics at 8.50 GHz [3]. Almoneefa et *al*. presented a metamaterial slab comprised of 13×13 electrically small cells, each loaded with an 82Ω resistor. The designed structure shown power absorption efficiency of 97% and 93%, respectively in 2015 [4].

The designed structure consists of a square outer and an inner metallic resonator, where the circular rings are in the center of the inner resonator. There is splits in every resonator and the circular metallic rings, which formed the capacitance and shift the resonance points toward higher frequency shown in figure 1(a). The simulation results show transmittance (S_{21}) resonance at 4.13, 8.19, 12.01, and 16.63 GHz. The measured result show resonance at 4.16 GHz (C-band), 8.18 GHz (X-band), 12.03 GHz (Ku-band), 16.61 GHz (Ku-band) and the effective medium ratio is 5.50 in figure 1(b). Further, from figure 1(c) the effective permittivity, permeability and refractive index curves show negative values from 9.42 to 11.55 GHz. According to the left handed characteristics, if the permittivity and permeability are simultaneously negative, then the refractive index will be

negative. As a result, the designed structure can be called as a left handed meta-surface absorber. The absorption rate of 2.06, 5.05, 9.26, and 13.23 GHz are, respectively, 60%, 95%, 78%, and 93% exhibited in figure 1(d).

Abstract-The aim of this investigation is to analyze the effects of mobile casing on the specific absorption rate (SAR) in the human head. The effects were analyzed with the variation in casing materials and its thickness. The results show that the SAR values are reduced significantly after using a mobile casing at 0.9 GHz. The maximum SAR reduction can be obtained by using silicon mobile casing (97.8 percent at 0.9 GHz and 24 percent at 1.8 GHz).

Nowadays, the mobile phones are the most popular devices all over the world. But the electromagnetic (EM) radiation from mobile devices is a matter of threat to the human health as it can penetrate the body tissues when the phone is used in the vicinity of human body [1, 2]. The defined parameter for the absorbing power calculation in the human body tissue is SAR, which is directly related to the electric and magnetic field distribution in the human body tissues. Several factors may affect SAR values such as EM source geometry and frequency, the user body tissue size and their properties. SAR values also depend on the medium and distance between source and user body [3]. In [4] effects of mobile component and casing on antenna performances were analyzed. The results showed that the mobile casing with metal ring significantly affected the antenna performances. On the other hand, the cell phone casing also processes significant effects on the SAR values. In [5], a study of materials to reduce the SAR values has been presented. The numerical results showed that the cell phone case box made of materials with higher conductivity produces higher SAR in the human head. In this paper, a study of the effects of mobile casing materials on SAR is presented. This investigation will provide the detail information about the effects of different casing materials on SAR values and antenna radiation efficiency. Six different casing materials comprising Polyimide, Polycarbonate, Aluminium, Rubber, Silicon and Glass are used in this analysis.

Figure 1(a) indicate the geometry of dual band PIFA operates over 900 MHz and 1800 MHz. The casing box is indicated in Figure 1(b). The dimensions of mobile casing are 104 mm × 44 mm × 15.4 mm, where the glass sheet dimensions are 84 mm × 44 mm × 1 mm. The simulation setup of mobile phone with human head and hand phantom is indicated in Figure 1(c) considering cheek position of talk mode. Figure 1(d) indicates SAR values in the human head due to mobile phone with silicon casing. The obtained results indicate that all the cell phone casing can reduce SAR values to the human head significantly at 0.9 GHz. At upper frequency band, SAR values increase for some of casing materials (Polyimide, Polycarbonate, and Rubber) and decrease for other materials (Aluminum, and Silicon). The maximum SAR reduction can be obtained by using silicon mobile casing (97.8 percent at 0.9 GHz and 24 percent at 1.8 GHz).

Designing High Gain WiMAX Antenna Using Metamaterial Inspired Technique

M. I. Hossain[1*], **M. R. I. Faruque**[2], and **M. T. Islam**[3]
[1]Department of Electrical & Electronic Engineering, International Islamic University Chittagong, Bangladesh

Abstract- In this paper, a high gain microstrip antenna with double negative metamaterial (DNG) is proposed for WiMAX application. The experimental and numerical results show that the proposed metamaterial loaded antenna operates over a wide frequency range about 2 GHz (2.95 to 5 GHz). The DNG metamaterial loading leads to enhance antenna gain more than twice compared to conventional one at 3.5 GHz WiMAX band. The metamaterial loading does not affect the radiation efficiency of antenna.

Nowadays, the wireless communication technology has been spread all over the world and the demand of low profile and high performance antenna is increasing day by day. Although, different types of antennas have been proposed in recent years for WiMAX and WLAN applications, there are still some performances need to be improved. However, metamaterials are being used in antenna engineering due to its extraordinary electromagnetic properties. Recently, metamaterials are proposed to enhance antenna performances and to reduce electromagnetic (EM) radiation toward human [1]. In [2], a metamaterial based helical antenna is designed to get improved radiation characteristics and directivity. The gain improvement of microstrip patch antenna is obtain in [3] using left-handed metamaterial (LHM) structure at 2.4 GHz. The application of proposed LNH detunes the resonance points and alters the radiation pattern greatly. In [4], a microstrip-patch antenna with metamaterial reflecting surface was introduced to improve the antenna gain at 2.4 GHz WLAN frequency. A single layer split ring resonator was utilized with an antenna to enhance gain [5]. This configuration reported significant gain enhancement, but 66.5 mm distance between antenna and metamaterial layer is not applicable for modern compact devices. In this paper, a double negative metamaterial loaded microstrip antenna is presented to enhance antenna gain for WiMAX application. Three-layer planar metamaterial array is proposed as a superstrate of antenna. The presented metamaterial loaded antenna design is compact in size and it is highly suitable for the compact electronic devices.

Figure 1(a) shows the geometry of proposed antenna and Figure 1(b) shows the structure metamaterial unit-cell and array (planar one dimensional array). Figure 1(c) indicates the reflection coefficients for the antenna with and without metamaterial superstrate. The results show that the metamaterial superstrate layers affect resonance points of antenna slightly. The optimized distance between antenna and superstrate is determined 10 mm based on the facts that with metamaterial superstrate does not reduce the bandwidth of antenna. Figure 1(d) exhibits the values simulated and measured gain for the antenna with and without metamaterial superstrate configurations. The results also exhibit that the antenna gain is dramatically increased

due to the influence of proposed double-negative metamaterial layer.

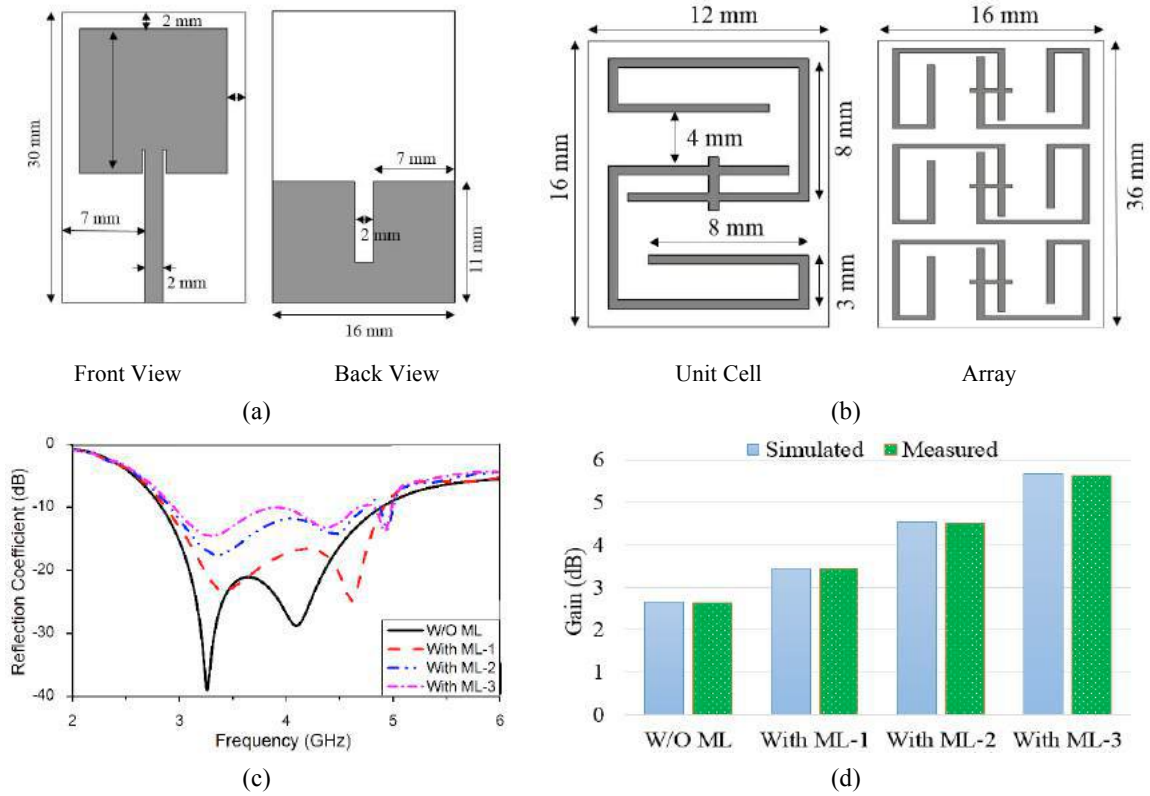

Fig. 1. (a) Geometry of proposed antenna (dimensions in millimeters), (b) metamaterial unit-cell (dimensions in millimeters), (c) return loss characteristics of antenna with and without metamaterial, and (d) antenna gain of proposed antenna with and without metamaterial.

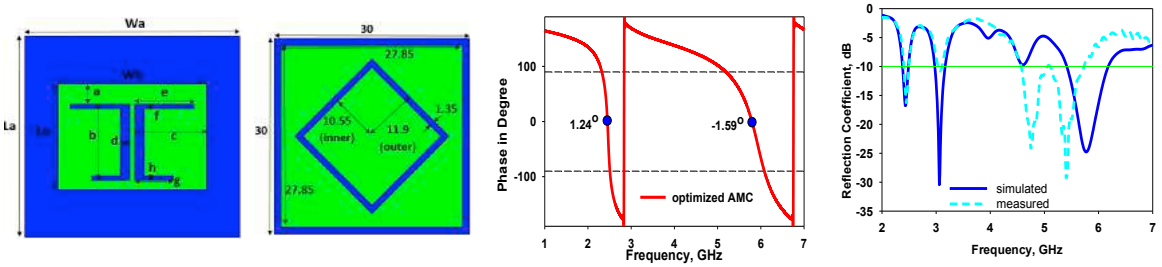
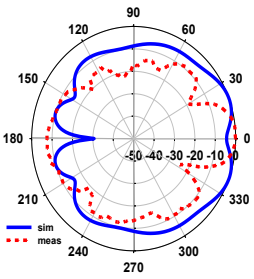
Abstract- This paper is presents an optimized structure of a slotted dual-band textile antenna integrated with an optimized artificial magnetic conductor (AMC) plane made using felt and ShieldIt Super. These structure operates at 2.45 GHz and 5.8 GHz for WBAN applications. The realized gain of this structure is about 2.38 dB and 6.53 dB at 2.45 GHz and 5.8 GHz, respectively. The antenna has a satisfactory reflection coefficient, bandwidth, and high front-to-back-ratio (FBR) and exhibit properties suitable for wearable applications.

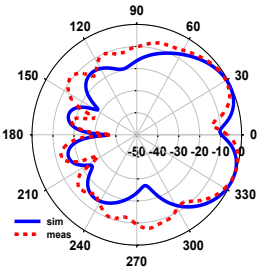
Summary: From our previous research in [1], a planar slot antenna made from textile has been initially proposed, with unsatisfactory gain levels. This paper describes the optimization of a planar C-slotted dual band textile antenna plane with improve antenna performances, especially in terms of gain. The topology of the proposed optimized antenna and the diamond-shaped slotted AMC unit cell are illustrated in Figure 1. Felt was used as its substrate and ShieldIt Super as its conducting element. The 6.51 mm thick overall structure is build using five layers: a ground (bottom), two layers of substrate, a layer of AMC plane in between substrate and patch (top). As shown in Figure 1(c), the optimized AMC indicated a phase response of 1.24^{o} and -1.59^{o} at 2.45 GHz and 5.8 GHz, respectively. The antenna also exhibited a satisfactory simulated reflection coefficient with -15.69 dB at 2.45 GHz and -24.55 dB at 5.8 GHz. The bandwidth of the antenna for lower and upper frequency is 109 MHz and 766 MHz in the lower and upper band, respectively. Besides that, the FBR for both frequencies are more than 19 dB. The directivity of the antenna is 7.31 dBi and 9.88 dBi in the lower and upper frequency, respectively. Deformations in terms of bending when placed on the chest and upper arm are investigated and their SAR values calculated. The detailed results will be presented in the full paper.



(a) (b) (c) (d)



(e)



(f)

Figure 1: (a) Topology of the proposed antenna, (b) optimized diamond-shaped slotted AMC, (c) reflection phase of the optimized AMC unit cell, (d) reflection coefficient results, and radiation pattern in the yz-plane (e) at 2.45GHz, (f) at 5.8 GHz. The dimensions of the optimized antenna are La=90mm, Wa=90, Lb=47, Wb=62, a=9, b=34, c=26, d=4, e=21, f=2, g=12, h=2. The dimensions of optimized AMC unit cell are L=30, W=30, L1=27.85, W1=27.85, inner=10.55 and outer=11.9. All dimensions are in mm.

Conclusion: An optimized wearable planar slotted dual band textile antenna integrated with an AMC plane to improve the realized gain and performances of antenna is presented. This structure operates in dual band mode at 2.45 GHz and 5.8 GHz for WBAN and WLAN. The performance of proposed antenna is satisfactory as a wearable antenna in terms of reflection coefficient, bandwidth and gain.

Abstract- A 4x4 (16 element) planar array antenna for Ku-band satellite communication is presented in this paper. The proposed antenna is a two layered structure where the top layer consists of rectangular microstrip patches while the bottom layer consists of corporate feeding structure energizing the antenna patches through aperture. The concept of microstrip feeding array antenna structure was presented in [1] which was improved by various groups [2-4]. In this work, we have used composite right-left hand (CRLH) material to introduce phase-shifts in the feeding lines which can help controlling the direction of the main beam as well as reducing the side-lobe levels. A progressive phase-shift of 0°, 90°, 180°and 270° is achieved by introducing lumped-elements based CRLH lines in the feeding structure [5-6] which reduces the overall size of the feeding structure. The gain of the antenna is approximately 7 dB in the azimuth plane. The design of the proposed antenna is shown in Figure 1.

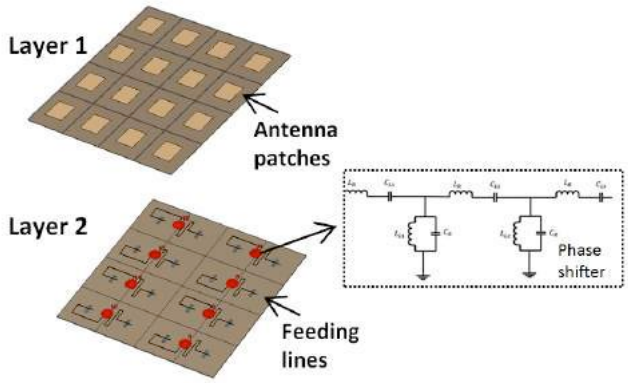

Figure 1. Design of the 4x4 array antenna

CST-MWS is used to design and simulate the proposed antenna. The overall length and width of the antenna is 65mm x 65 mm. RT5880 with the permittivity of 2.2 and thickness of layer 1 = 0.55 mm and layer 2 = 0.25 mm is used as the substrate.

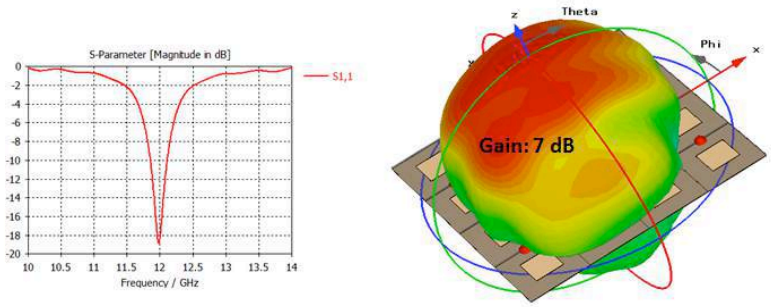

Figure 2. Simulated results of the return-loss and 3D farfield pattern

The simulated results including return-loss and 3D farfield pattern is shown in figure 2.

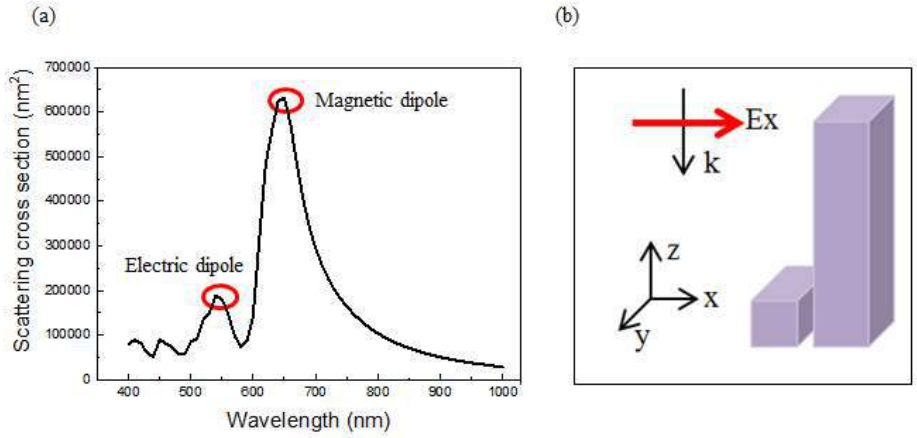
Optical switching of scattering direction in Si rectangle -dimer

Bona Ku[1] , Seokhyeon Hong[1]
and Soon-Hong Kwon[1*]
[1]Dept. of Physics, Chung-Ang University, Seoul 06974, Korea
[*]E-mail: soonhong.kwon@gmail.com

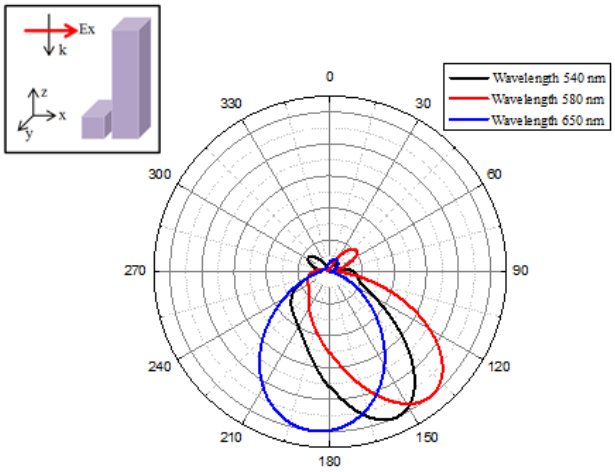
Abstract- Resonant scattering of nanodimer composed of silicon enables controlling of scattering direction depending on the wavelength of incident light. Silicon has two representative resonance based on Mie resonance, called electric and magnetic dipole. We make a dimer structure consisting of silicon rectangles. In this study, the direction of forward scattering in proposed dimer is tuned by changing the wavelength of incident light. The maximum angle of forward scattering is shifted 45°when the wavelength of incident wave is changed 30 nm.

Nanodimer consisting of dielectric particles hold the control of optical scattering for switching and sensing [1]. we simulated scattering cross-section and far-field of scattering light in the dimer as the wavelength changes from electric dipole wavelength to magnetic dipole wavelength of silicon nanorectangle as shown in Fig. 1 (a). In contrast to strong forward scattering with same direction of incident light in the single nanorectangle, the scattering in the hybrid dimer shows deflections of incident light depending on the wavelength.



Figures 1: (a) Scattering cross-section by wavelength of rectangle nanodimer (b) Scheme of hybrid dimer composed of rectangles

We simulated hybrid dimer composed of silicon rectangles by using finite-difference time-domain method as shown in Fig. 1 (b).



Figures 2 : Scattering direction transition when the wavelength of incident wave is changed from 580 nm 650 nm

When height of two rectangles exist, switching of scattering direction by wavelength is especially prominent. we observed that maximum angle of forward scattering is shifted 45° when the difference of height between two rectangles is 400 nm as shown in Fig. 2.

Abstract- In this study, we propose an intriguing metamaterial design method to achieve actively customized tuning of terahertz resonance properties. The proposed metamaterial devices are based on the inter-atomic bonding of meta-atoms, which is referred as 'moleculization' of meta-atoms, and realized by controlling the conductance of interconnected graphene bridges. Based on the numerical and experimental results, we confirm that the proposed moleculization system successfully exhibits a broad tuning range of resonance frequency in terahertz regime.

In the past decade, many researchers have attempted to realize the actively tunable metamaterials within the fixed array structures, so that their exotic resonance properties could be controlled in the wide spectrum range [1]. Graphene based metamaterials have recently received extensive attentions as one of the promising tunable metamaterials in THz and optical ranges with various ways [2-4]. However, due to the limited conductivity variation range of graphene materials, they suffered from the unsatisfied tunability of the resonance properties. In this paper, we propose resonance frequency tunable terahertz metamaterials by interconnecting the meta-atoms with the ion-gel gated graphene bridges along the incident polarization direction.

Figure 1a shows the schematic view of our proposed metamaterial array. In this design, the H-shaped meta-atoms are adopted to generate fundamental resonance frequency of the metamaterials with the designated width-to-length ratio of the gap between the adjacent meta-atoms. The graphene bridges are formed between the meta-atoms and connected to two outer electrodes to control their conductivities. One isolated electrode is used as an ion-gel gating electrode.

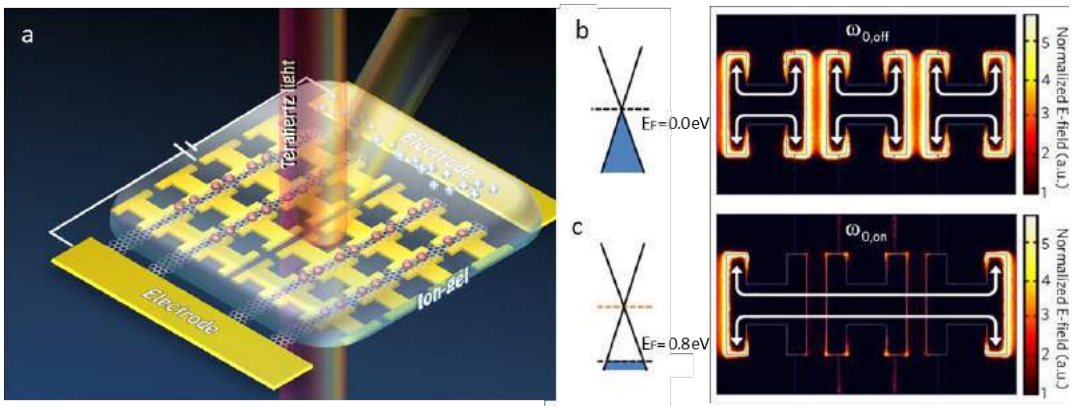

Figure 1. (a) Schematic view of the proposed active meta-atom moleculization system using graphene bridges. (b, c) band structure of the graphene and electric field distribution of the proposed metamaterials at (b) E_F = 0.0 eV and (c) E_F = 0.5 eV.

As shown in Figure 1b, when the fermi energy of graphene bridges E_F is 0.0 eV (V_G = 1.0 V), there are no electrical bridging between the meta-atoms and therefore the proposed metamaterials merely exhibit the resonance of the individual H-shaped meta-atoms ($\omega_{0,\,off}$). However, for the electrically p-doped graphene bridge (E_F = 0.8 eV or V_G = -3.0 V) as shown in Figure 1c, the conductivity of graphene bridges increases and can form electrical connections between adjacent meta-atoms, so that the resonance path of the meta-atoms can be extended as they are connected to each other. Consequently, this extended resonance path makes the resonance frequency red-shifted ($\omega_{0,\,on}$).

Figure 2a shows the optical microscope image of the fabricated graphene bridge metamaterials and the inset shows the position of the graphene bridges between the H-shaped meta-atoms. As shown in Figure 2b, measured transmission spectra of our active moleculization system successfully show that the resonance frequency can be adjusted from 0.8 to 1.28 THz by controlling the conductance of the graphene bridges. These results indicate that the proposed metamaterials can be used as tunable and switchable terahertz and optical meta-surface platforms. Moreover, we can expect that their resonance tuning range can be even extendable and alterable by changing the numbers of interconnected graphene bridges.

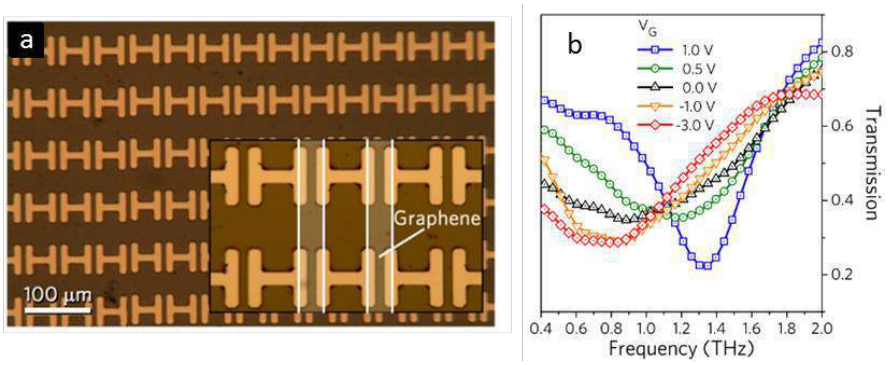

Figure 2. (a) Optical microscope image of the proposed metamaterials. The inset shows the position of the fabricated graphene lines. (b) Measured transmission spectra of proposed meta-atom moleculization system.

Abstract- We demonstrate a tuneable metamaterial device for gas sensing. The transmission peak of this metamaterial is tuned to over a wide frequency band in the mid-infrared. Upon inducing a structural phase transition in the chalcogenide, the transmission peak is red-shifted by 333 nm. We further engineered the peak transmission wavelength by controlling the geometry of the metamaterial's features. The tuneable chalcogenide metamaterial-based filters will have extensive applications in sensing, displays, and spectroscopy.

Metamaterials have aroused enormous interest in the past decades due to their unusual interaction with electromagnetic waves. The optical properties of these metamaterials can be tailored according to specific requirements for various applications, such as perfect absorbers[1], invisibility cloaking[2] and negative refractive index materials[3]. Our objective here is to use phase change chalcogenides to tune mid-infrared sensors for sensing of pollutant gases, such as SO_2, NO_2, NO, N_2O, HCl, HCHO, CH_4. We demonstrate a tuneable phase change metamaterial that can be tuned over a wide frequency band in the mid-infrared. Upon inducing a structural phase transition in the chalcogenide, the transmission peak is red-shifted by 333 nm. We engineered the peak transmission wavelength by controlling the geometry of the metamaterial's features. The relatively large dimensions of the matamaterial features will enable fabrication of devices over a large area using inexpensive methods such as nano imprinting. Compared with most other metamaterial designs that are passive and show transmission peaks at a fixed frequency, tuneable chalcogenide metamaterial-based filters will have extensive applications in sensing, displays, and spectroscopy.

Abstract- This study proposes a diamond shaped microstrip patch antenna for ultra-wideband applications. The antenna is made up of a diamond shape radiating patch, partial ground plane, and three asterisk shaped parasitic elements. The parasitic elements are positioned above the ground plane to enhance the bandwidth and gain. The proposed antenna has a compact dimension of 30 x 25 x 1.6 mm^3 and achieves an overall bandwidth (S11<-10dB) is 5.8 GHz from 2.7 GHz to 8.5 GHz. The antenna attains more than 4 dBi realized gain and 80% efficiency over the bandwidth with omnidirectional radiation pattern. The design and simulation of the proposed antenna is performed in CST Microwave Studio. The observation during the analysis of the simulated data reveals that the proposed antenna is suitable for UWB applications where high gain is required.

In recent years, UWB communication has been attracted in wireless communication system for its special features like extremely high data transmission rate, low interference and low spectral power density. It is still a challenge to design a proficient compact UWB antenna. Azim *et al.* proposed tapered-shape slot antenna for UWB application with an overall dimension of 22 × 24 mm^2 [1]. Gautam *et al.* proposed a 25 × 25 × 1.6 mm^3 CPW antenna for achieving UWB bands in [2]. In this study, a diamond shaped UWB antenna is proposed using asterisk shaped parasitic elements. The geometric layout of proposed antenna is shown in Figure 1. The proposed antenna is designed on Rogers RT/duroid 5880 substrate material having 2.2 dielectric constant and 0.0009 loss tangent.

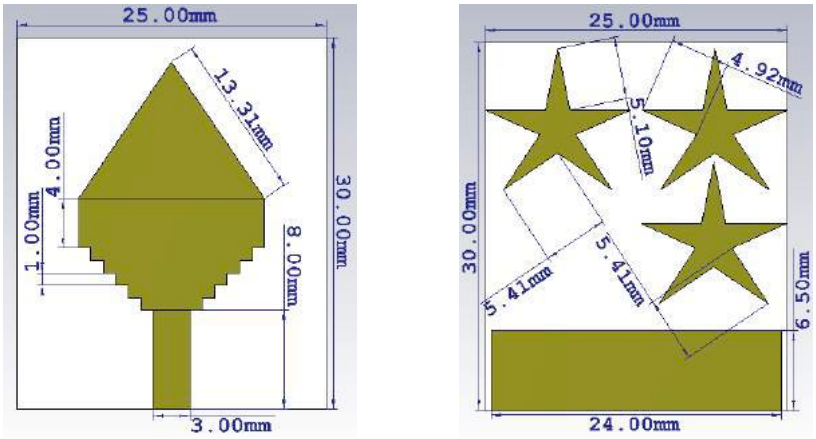

Figure 1. Geometric layout of the proposed UWB antenna-Top view (left) and bottom view (right).

The proposed antenna is designed with a diamond shaped patch, partial ground plane and asterisk shaped parasitic elements on the bottom side of the substrate. The existence parasitic elements and staircase diamond

shape of patch and optimum ground plane has strong effect for the impedance matching. The proposed antenna is feed by a 50 Ω microstrip line.

The reflection coefficient of the proposed diamond shaped antenna is depicted in Figure 2(a). The antenna achieves -10dB impedance bandwidth of 5.8 GHz (2.7- 8.5 GHz).

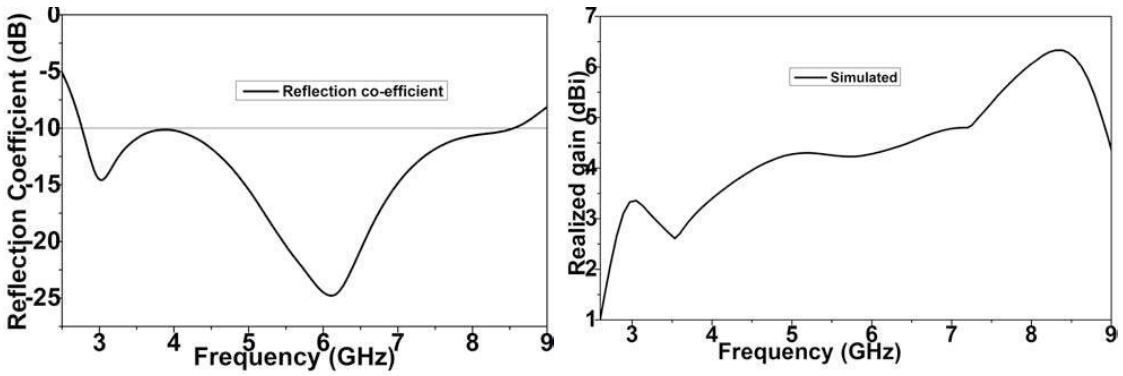

Figure 2. (a) Reflection coefficient (b) Realized gain

Figure 2(b) shows the gain of the proposed diamond shaped antenna. The result reveals that the antenna maintain a more than 4 dBi gain over the entire band with maximum realized gain of 6.2 dBi. Higher gain made the antenna a suitable candidate for the use of UWB applications where high gain is required.

Abstract-This paper presents a metamaterial, based on a digit 8-shaped resonator. The resonator is encompassed by a partial ground plane and excited by a microstrip feeding transmission line. As the digit 8-shaped resonator, partial ground plane, and the feedline are all on a microstrip, the measurement can be executed by using the common laboratory facility instead of using the waveguide. The resonator and the ground are placed on the similar part of the microstrip and the microstrip feeding line is placed on the other part of the microstrip. In metamaterial design, normally numbers of unit cells are needed, whereas this paper presents only one cell which can achieve the metamaterial properties. The characteristic parameters of the metamaterial are fetched and analyzed to find the concurrency between the simulated and measured results. The presented metamaterial is also applied in sensor applications where the simulated and measured results reveal considerable agreement. The presented prototype can be used for several applications where metamaterial properties are required.

From the introduction of the metamaterials, they became popular with the researchers who are working with materials that exhibits negative permittivity and negative permeability. Many researchers suggested different types of resonators for different resonance frequencies and parametric characteristics [1-2]. Currently metamaterials are used in sensors because metamaterial based sensors provide miniaturization facility and large Q-factor values. These advantages make the metamaterials highly sensitive to the environment and for this reason metamaterials are used in sensing applications [3].

In this paper, a metamaterial on a planar surface based on only one unit cell is presented. In the proposed structure, the digit 8-shaped resonator and partial ground frame are placed on the one side of the lossy FR4 substrate, and the feeding transmission line (FTL) is placed on the opposite side of the substrate. This structure provides some advantages and flexibility to design and implementation of the metamaterial. Figure 1 shows the geometric layout of the proposed metamaterial.

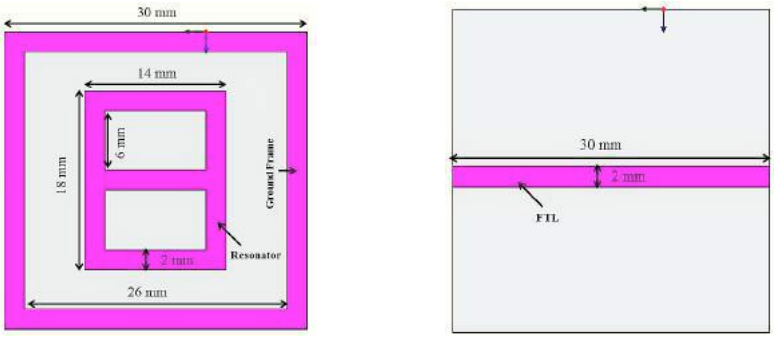

Figure 1. Geometric layout of the proposed UWB antenna-Top view (left) and bottom view (right).

The simulated S-parameters of reflection coefficient and transmission are shown in Figure 2. The figure shows multiple resonances throughout the frequency from 2 GHz to 12 GHz. The resonance at 3 GHz covers highest transmission peak, which is called the left-handed peak.

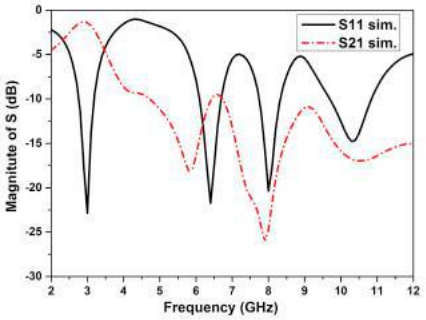

Figure 2. Transmission and Reflection coefficient of the proposed antenna

The metamaterial characteristics of the proposed metamaterial are displayed in Figure 3. From the figure the electromagnetic characteristics of the metamaterial can be observed.

Microstrip Patch Antenna Loaded with Reactive Impedance Surface

A.N. Suraya[1], T.Sabapathy[2], and M.Jusoh[3]

Radio Engineering Research Group, School of Computer and Communication Engineering,[1,2,3]
Universiti Malaysia Perlis, Bangunan Pengkalan Indah, Jalan Pengkalan Asam, 01000, Kangar, Perlis, Malaysia.
Email: mira_anssa@yahoo.com.

Abstract- An investigation on the use of reactive impedance surface (RIS) for wearable antenna is presented. The investigation is conducted with wearable patch antenna that design using RIS at different frequency of unit cells, namely 1.8GHz, 2.45GHz and 5.12GHz. The aim of this project is to observe the miniaturize of antenna if it integrates with RIS. This antenna operates at 2.45 GHz.

In recent years, wearable antenna designs have gained a lot of attention from researchers and industries. Wearable antenna design plays important characteristics such as ease of fabrication and integration, conformal, low profile and high efficiency [1]. Generally, the substrate used to design wearable antenna to have low relative permittivity, εr. According to antenna design theory, this will increase the antenna size. The problem could be further challenging when multi element antenna has to be designed for wearable application that could support emerging communication technologies such as beam steering [2] and MIMO [3].

A two-dimensional (2D) equivalent of metamaterial is basically a surface distribution of electrically small scatters is called metasurface [4]. The RIS is also referred as meta-surface or artificial magnetic surface and used to provide a zero degree reflection phase for further improving the antenna radiations and miniaturization [5-7]. The RIS has a simple design that is composed of metallic patches. In this paper, a miniaturization wearable patch antenna loaded with RIS is proposed. At first, a conventional microstrip patch antenna is designed and optimized with good performance in terms of bandwidth and gain. RIS is introduced as a substrate to miniaturize the size and performance is observed and compared to the RIS operating at different frequencies.

Firstly, the metamaterial unit cell is the initial step of the study based on full structure which is generally consists of unit cell and substrate. A unit cell is design with different dimension based on frequency used; see Figure 1(a). To miniaturize original antenna, RIS is apply as a substrate. The RIS layer consists of 5 × 5 cross-shaped metallic unit cell patch array printed periodically on a grounded low-cost felt substrate. The proposed antenna structure in figure 2(b) is a two layered dielectric geometry made up of felt substrate with the same thickness. As a result, the bandwidth of the all design shows better performance, see Figure 2(c). Felt is used as substrate, this material was chosen because it is easy to cut and sew. As conclusion, the gain and bandwidth is improved as the size of patch is decreased. Overall performance is better compared to original patch antenna.

Abstract- We present a novel three-dimensional chiral metamaterial design for chiroptical spectroscopy. Utilizing the chiral light-matter interaction between the designed metamaterial and molecule that is chiral in the same wavelength range, we demonstrate chiroptical sensing at the molecular level.

Previously, off-resonance chiroptical sensing has been demonstrated using a planar chiral metamaterial [3]. It was shown that optically active biomolecules can be detected by a planar chiral metamaterial by studying the dissymmetry in the resonance shifts induces on the two enantiomers. The measured change in CD, in this experiment, was fairly modest due to the small chirality of the proposed planar metasurface, as well as the mismatch between the chiral resonance of the metamaterial and that of the target molecules. It has been suggested that in order to achieve a significant CD, at least a bilayer nanostructure, with three-dimensional arrangement of plasmonic nanoantennas is needed [4]. In this paper, we demonstrate a new three-dimensional chiral metamaterial (Fig. 3.1.a-b) that can be used for sensing applications [5]. We show that the interaction between the metamaterial presented here and biomolecules with significant chirality in the same range can result in a large change in the chiroptical response of the overall system, beyond what could be achieved with a planar nanostructure.

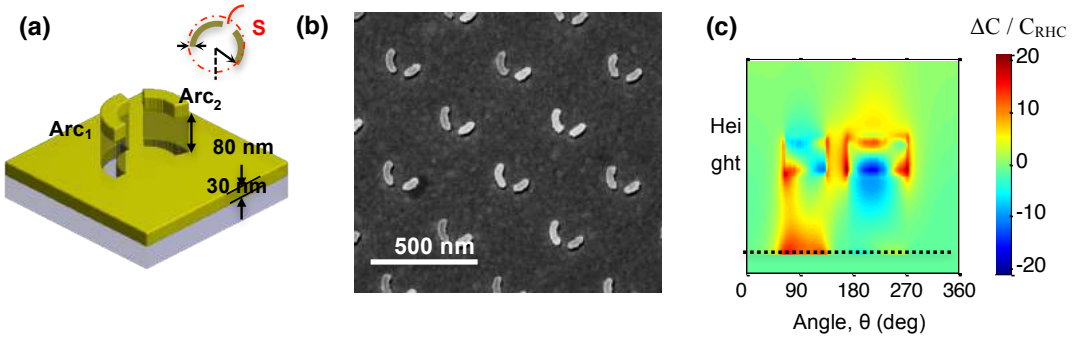

Fig 1. *(a) Schematic view of the bilayer nanoantenna array with geometrical parameters. (b) Scanning electron micrograph from one enantiomer of the designed metamaterial (d) Chirality pseudoscalar over the cylindrical surface 1 nm away form the outer surface of the two arcs.*

In addition this chiral metamaterial can be realized using a simple fabrication process with one-step lithography [6], that preserves the scalability of the embossed nanostructures necessary for practical applications

at lower wavelengths. Figure 1.c shows the chirality pseudoscalar defined in Eq. 1 over a cylindrical surface (S) shown in the inset Fig. 1.a.

$$C(\vec{r}) = \frac{1}{2}\varepsilon_0 \vec{E}(\vec{r}).\nabla \times \vec{E}(\vec{r}) + \frac{1}{2\mu_0}\vec{B}(\vec{r}).\nabla \times \vec{B}(\vec{r}) \quad (1)$$

Figures 2.a-b show the measured change in CD spectra of Enant D and Enant L, when coated by Chlor A and B. As it is evident in the measured ΔCD spectra of Fig. 2, both enantiomers show a giant change of several degrees in the CD in response to the adsorption of the chiral molecules (i.e., Chlor A and Chlor B).

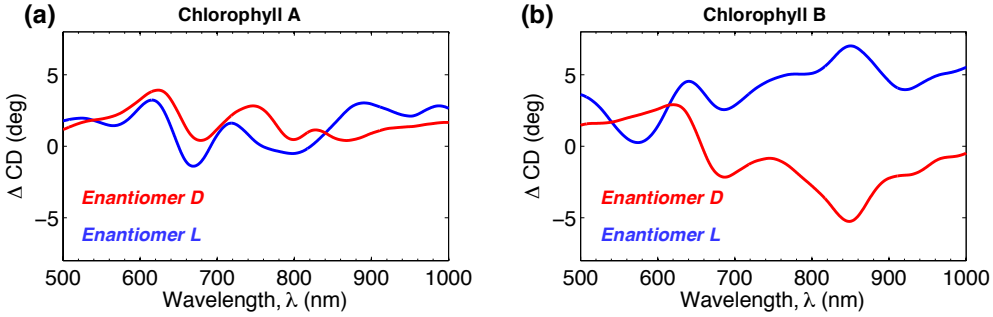

Fig 2. *Differential CD spectra acquired from the two enantiomers of the metamamterial coated with (a) Clor A, (b) Chlor B*

In conclusion, we have demonstrated SECD-based spectral analysis of chiral biomolecules at the molecular level using an on-resonance chiral metamaterial. Using these metamaterials, we measured the superchiral spectra from a monolayer of two biomolecules with very similar atomic compositions, and showed that we can distinguish them from the acquired differential CD. The values of ΔCD reported in this work, show a very large improvement over the non-resonant experiments [7], performed using planar chiral metamaterial, nanoparticle assemblies or non-chiral nanoparticles, owing to the large chirality of the nanostructures and the spectral matching between the CD spectra of the metamaterials and target molecules.

Abstract- The history of manufactured mirror can be traced back to thousands of years ago. Yet people never imagined that the same object can be used as a reflector (mirror) and an absorber by simply rotating its geometrical orientation. In recent decades, as the development of subwavelength optics and plasmonics, optical properties of a structured metal film become extremely diverse. These properties depend not only on the chemical composition of the material, but also on the subwavelength structural designing. In this work, we report on encoding and display based on stereo standing U-shaped resonator (SUSR) arrays. The SUSR serves as a perfect absorber at a structure-dependent frequency when the polarization of incident light is parallel to the bottom rim of the SUSR. When the incidence polarization is rotated for 90^{o} (perpendicular to the bottom rim of the SUSR), SUSR turns to a perfect reflector at all frequencies. Further, the resonant frequency sensitively depends on the height of the arms of SUSR. By introducing SUSRs with different arm height, resonant absorption state may occur at different frequencies. By defining the resonant absorption state as "Dark" and the reflection state as "Bright", we can encode and display binary patterns. Besides, when SUSR rotates with the direction of the standing arms as axis, different reflectivity, hence different shade will be generated. In this way we may realize gray scale display. Experimentally we demonstrate that this encoding and display scheme indeed works.

Polarization and Pattern Reconfigurable Antenna with EBG Structures.

Abstract-This paper presents a design of single patch antenna incorporated with an array of electromagnetic band gap (EBG) structure with pattern and polarization reconfigurability. By tuning the characteristics of the EBG structure and the antenna, the radiation pattern and polarization of the patch antenna can be switched or dynamically controlled. The polarization of the proposed antenna can be switched from linear to circular polarization and vice versa. Meanwhile, the radiation pattern is tuned by controlling the connection between the EBG patches and the ground plane. Five elements of EBG is located at both side and higher from of the antenna to give configuration of -14, 0 and 14 degree of radiation pattern. Full EM wave simulation including the PIN diode equivalent circuit will be discussed.

Figure 1 shows the geometry of proposed antenna where Ls = 100mm, Ws = 70 mm, Lp = 32mm, Le = 12.5 mm, and h = 6.08 mm. The EBG structure was located higher than an antenna for pattern reconfigurability occurs. It is due to the properties of EBG can absorb the surface wave. The antenna is designed on a Taconic RF35 board with a relative permittivity of 3.5, tangential loss of 0.0018 and a thickness of 1.52 mm. A BAR50–02V PIN diode is used as the switch. Computer Simulation Technique (CST) software is used to simulate the designed antenna. In the simulation, the switch is represented by the S-parameters of the BAR50–02V diode, obtained from the manufacturer's website. To obtain the linear polarization, diode D1 to D4 is switched ON to give square shape of patch antenna while switched OFF to obtain circular polarization truncated patch antenna. The axial ratio and S11 parameter of both polarization are shown in Figure 2 (b) and (c). The proposed shape gives good 3dB axial ratio at 2.43 GHz radiating frequency and it's comply the ISM band point to point communication.

Meanwhile, the radiation pattern reconfigurable is obtained by switching the group of array EBG at both side of the antenna. The diode configuration as shown in Figure 2 (a). The radiation pattern was tiled about 14 degree for both condition 0:1 and 1:0. However, when both side of EBG are ON and OFF, the radiation pattern are return to 0 degree. Average gain for all condition are 7.2 dBi. The gain of the antenna can be improve by increasing unit of radiating path in array form. The radiation pattern was tilled when one side of EBG was absorb the surface wave from the antenna. The size of EBG and distance from edge of patch will give major contribution to results.

Ultrafast Terahertz Active Metamaterials integrated with MSM-2DEG Varactors

Ji Hyun Hwang, Muhammad Tayyab Nouman, Kye-Jeong Lee, and Jae-Hyung Jang*
School of Electrical Engineering and Computer Science, Gwangju Institute of Science and Technology, Gwanjgu 500-712, South Korea

Abstract-We propose ultrafast amplitude modulation scheme of terahertz waves based on metamaterials integrated with metal-semiconductor-metal (MSM) two-dimensional electron gas (2DEG) varactors. The MSM-2DEG varactors embedded into the split gap of metamaterials are based on AlGaN/GaN heterostructures, which enable ultrafast modulation. By applying a bias voltage across the split gaps, the effective capacitance of metamaterials changes. This capacitance change leads to resonant frequency shift of metamaterials and amplitude modulation.

The terahertz band of the electromagnetic spectrum (0.3~3 THz) is interesting because of its various applications into imaging, communications, and bio-sensing [1]. Nevertheless, the practical use of the terahertz band is still limited, in the absence of high-performing devices. As one of these, the development of terahertz modulators is highly desirable. Since there are no materials in nature to respond to the terahertz wave, artificially engineered metamaterials have been considered as a solution to manipulate the terahertz wave [2]. In recent years, various modulation techniques have been adopted for metamaterials to actively control the terahertz wave [3]. In particular, electrically controllable metamaterials have received a lot of attention due to its superior characteristics such as the compact size, high modulation speed, and low power consumption.

In this work, we show the full wave electromagnetic simulation result to modulate the incident terahertz wave, as shown in Fig. 1(a). For various bias voltage, the effective capacitance of metal-semiconductor-metal (MSM) two-dimensional electron gas (2DEG) varactors embedded into metamaterials get changed, as shown in Fig. 1(b) [4]. According to this, the resonant frequency of metamaterials is shifted and the amplitude of terahertz wave is modulated for the fixed frequency region. After removing substrate effects, high modulation index (82 %) is obtained from low transmittance (0.15) to high transmittance (0.81). Furthermore, employing AlGaN/GaN heterostructure offers the high speed 2DEG channel by conduction band offset and polarization doping [5]. This high speed 2DEG channel can realize ultrafast modulation of the terahertz wave with reduced RC time constant of the devices. In the optimized design of metamaterials (high Q-factor) and MSM-2DEG varactors (high cutoff frequency), we expect to realize the terahertz modulator with high modulation speed (>10 GHz) and high modulation index (>0.8). Ultimately, the proposed ultrafast terahertz active metamaterials will facilitate seamless terahertz data transmission and real-time terahertz imaging.

thibaut.devaux@eng.hokudai.ac.jp

Abstract— Using the principle of extraordinary transmission through a zero-mass metamaterial, a prototype of a near-field acoustic microscope is proposed and built for the audible frequency range. Experimental results reveal the detection of objects of sub-wavelength size ($\sim \lambda/20$) by use of a simple reflection coefficient measurement. This method allows one to work at high resolution compared to the far-field diffraction limit, and introduces new perspectives in acoustic imaging and non-destructive testing.

Concentrating energy through a spot much smaller than the wavelength, so-called extraordinary transmission (ET), has been a recent subject of much interest for both optical and acoustic waves [1, 2]. In particular, ET acoustic audio energy transmission in air was achieved using zero-mass metamaterials [3]. A transmission of ∼80 % of the incident acoustic energy was demonstrated with a filling fraction of only 1%. Here we demonstrate a prototype of a near-field acoustic microscope based on audio ET that allows $\sim \lambda/20$ resolution near 2000 Hz.

In the setup described in [3], acoustic energy is transmitted through a subwavelength hole containing a tensioned membrane maintained by the acoustic wave at the membrane resonance frequency. Our near-field acoustic microscope, as shown on Fig.1, is based on the same concept.

It is composed of an 100-mm internal diameter acrylic tube closed at one end by an anechoic

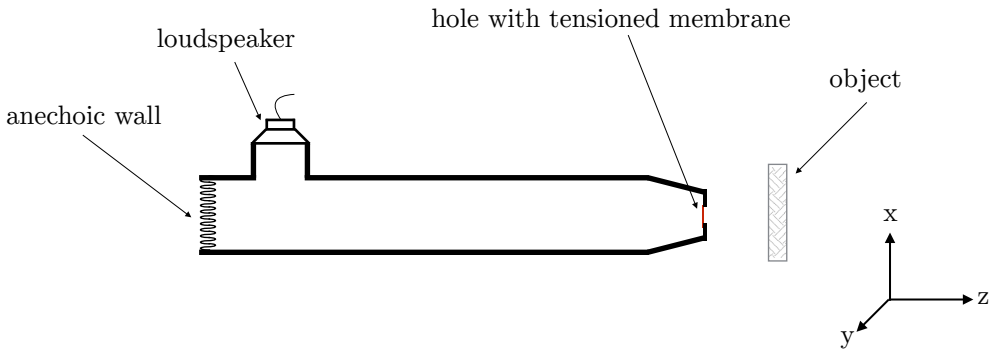

Figure 1: Schematic diagram of the experimental setup. The reflection coefficient of the hole with a tensioned membrane is measured inside the tube with a probe microphone.

wall and at the other end by an hole of diameter 10.5 mm covered with a tensioned membrane. A loudspeaker at the opposite end to the hole provides the audio excitation. The resonance frequency of the tensioned membrane is experimentally determined as $f_r = 1785$ Hz ($\lambda = 0.19$ m), corresponding to a hole diameter of $\lambda/18$.

The principle of microscope is as follows: with no object present in front of the membrane, the zero-mass metamaterial facilities the acoustic energy transmission, so the acoustic reflection coefficient is lowered compared to a bare hole. If an object is placed near the membrane, it frustrates the ET and results in a higher reflection coefficient. To verify this principle, the modulus of the acoustic amplitude reflection coefficient $|R|$ was experimentally determined from the standing wave ratio (SWR) using a probe microphone in the tube.

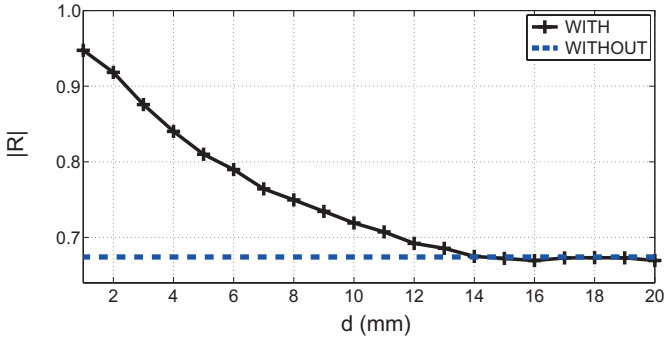

Figure 2: Reflection coefficient of the microscope as a function of the object position d along the z-axis at a frequency of 1785 Hz. The results without any object present are shown by the dashed line.

Figure 2 shows the microscope response when varying the distance between the object position and the membrane (along what we term the z-axis). In the acoustic near-field (i.e. $d \lesssim 15$ mm), the object position influences the reflection coefficient, as expected. $|R|$ decreases monatonically from a maximum value of 0.95 as z increases. For greater object distances, the object position has a negligible influence on $|R|$, and $|R|$ tends to the value (0.67) obtained with no object present. The object position along the z-axis can be deduced by a suitable calibration of these results.

An ET-based scanning acoustic microscope for mapping topography modifications along the x-y-axes can be made by lateral motion of this ET probe. We have demonstrated experimentally that images can be obtained in this way using commonly available materials such as metal, wood and plastic. A lateral resolution of $\sim$10 mm, i.e. $\sim \lambda/20$ could be obtained.

In conclusion, a near-field acoustic microscope based on extraordinary acoustic transmission through a tensioned membrane is proposed with deeply sub-wavelength spatial resolution. By simple measurement of the acoustic reflection coefficient in a tube, one can determine the object position. In future, the use of higher frequencies in the ultrasonic region should expand the possible applications of this microscope.

Abstract— Using a wire medium with high dielectric wires of varying radius, we can sculpt the longitudinal electromagnetic wave profile. Such sculpted wave profiles have applications in signal processing and accelerator physics. The required design modulation of the wires was calculated using concepts of spatial dispersion, and full 3D CST Studio simulations of the structures were run. Predictions and simulations were in excellent agreement, validating our design process.

In a uniform waveguide the mode profiles along the propagation axis are sinusoidal. Here we show how to customize the wave profile, a process with many possible applications [1, 2, 3, 4]: e.g. a flatter profile like that in figure 1(a) enables us to reduce non linear effects. Further, when controlling the bunch properties in particle accelerators, it would mean that more of the bunch receives the same energy boost, so that it could be used to accelerate longer bunches. In contrast, a peakier profile such as that in fig. 1(b) could be used to enhances nonlinear effects; it would also enhance the signal to noise ratio. In accelerators, it would help in the acceleration of short bunches. Another example is the triangular profile in fig. 1(c), which gives a longer bunch a sustained chirp Further, this wave profile shaping could have utility in high harmonic generation [5].

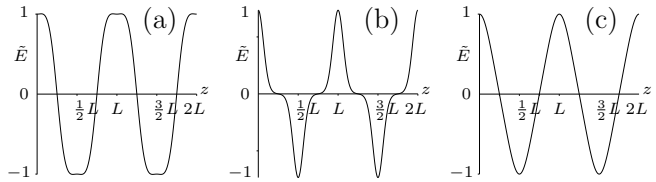

Figure 1: Solutions to Mathieu's equations showing a (a) flatter, (b) peakier and (c) triangular profiles.

Existing methods of mode profile shaping include varying the geometry of the waveguide and adding multiple sinusoidal modes. We consider longitudinal modes in a wire medium with varying radii. The wires had a high dielectric constant. We modelled the three dimensional wire medium using a one dimensional spatially dispersive medium with permittivity of the form

$$\epsilon_{\mathrm{r}}(\omega,k) = 1 + \frac{\omega_{\mathrm{P}}^2}{-\omega^2 + k^2 + \omega_0^2} \tag{1}$$

There exist solutions of the form $\boldsymbol{E} = Ee^{-i\omega t+ikz}\boldsymbol{k}$, $\boldsymbol{D} = 0$ and $\boldsymbol{B} = 0$, so that $\epsilon_{\mathrm{r}}(\omega,k) = 0$. I.e. it is an ENZ medium and the dispersion relation is $\omega^2 - k^2 = \omega_{\mathrm{P}}^2 + \omega_0^2$.

We used CST Microwave studio to examine the modes in a uniform wire. This revelaed a large number of different modes, with a great range of mode profiles and dispersion properties.

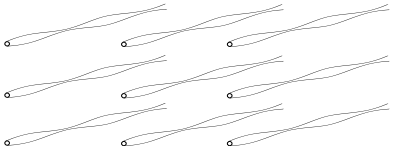

Figure 2: A wire media with varying radii.

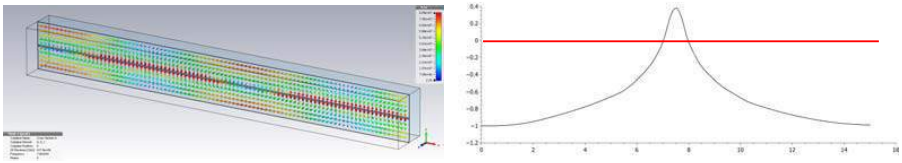

Figure 3: CST simulations of the electric field for a wire medium with fixed radius. This field has the desired properties. (Right) The strength of the electric field as one passes along a line through the wire.

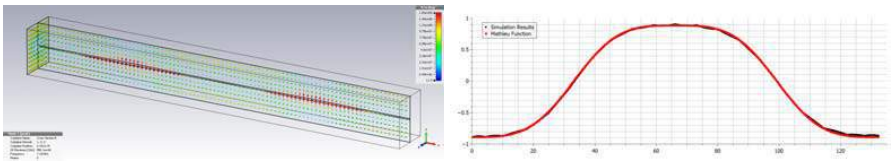

Figure 4: Flat profile: 3D fields from CST simulations (left), and a comparison of predicted (red) and simulated (black) longitudinal electric fields.

A detailed and exhaustive search though these possibilities showed that some of them had the desired properties. It turns out a good case was when the wires are thin and have high $\epsilon_{\rm r}$. We set period $\Delta x = 11$mm, $\Delta y = 15$mm, $\Delta z = 52$mm and $\epsilon_{\rm r} = 1200$. Periodic boundary conditions $\kappa_x = \kappa_y = 360°$, varying κ_z between 0 and 180°. The wire diameter were around 2mm. The wires were in the z-direction. One such is shown in figure 3, in which we can see that:

- The field away between the wires was longitudinal, as needed for on-axis particle acceleration
- Most of the field was between the wires, where it is needed; it is not a wire-localised
- The dispersion relation above is given by to a high degree of accuracy.
- One could control this dispersion by varying the thickness of the wires.

By making the radius depend on position we would get a permittivity that depends both on position z and wave-number k; a scenario that raises interesting issues [2, 6]. We handle it here Fourier transforming the dispersion relation and setting $\Lambda(r(z)) = \omega_{\rm P}(z)^2 + \omega_0^2$; so that we have

$$\tilde{E}'' + \left[\omega^2 - \Lambda\big(r(z)\big)\right]\, \tilde{E} = 0. \tag{2}$$

In all three cases for the wire variation designed to give flat (fig. 4), peakier and triangular profiles, we found very good agreement from frequency domain CST simulations.

Conclusion: We have shown it is possible to sculpt the electric field for longitudinal modes in a 3D wire medium; with results very close to predictions from a 1-dimensional spatially dispersive medium. Our aim is now to verify these modes experimentally.

Multiband band-stop filters for spoof surface plasmon polaritons

Jiandong Li, Xiaopeng Shen*,Haipeng Li, Kui Han, Chuanlei Jia

School of Physics, China University of Mining and Technology, Xuzhou 221116, China
*corresponding author: xpshen@cumt.edu.cn

Abstract-Ultrathin corrugated metallic strip supports the propagation of spoof surface plasmon polaritons (SSPPs). Band-stop filter or band-rejection filter is a filter that passes most frequencies unaltered, but attenuates those in a specific range to very low levels, it's key component and play a very important role in various communication and radar systems. In this report, we will demonstrate a new type of multiband bandstop filters for SSPPs in the microwave frequency regime. The simulated, measured, and the resonator theory calculated resonant frequencies are in good agreement. The proposed planar filters play an important role for filtering surface plasmon polaritons (SPPs) waves in plasmonic circuits and systems.

Frequency Switchable Microfluidic Metamaterial-Loaded QMSIW Bandpass Filter Using a Liquid Metal Alloy

M. U. Memon, and S. Lim*
School of Electrical and Electronics Engineering, Chung-Ang University, Republic of Korea
*corresponding author: sungjoon@cau.ac.kr

Abstract- Frequency-switchable metamaterial-loaded quarter-mode substrate-integrated-waveguide (QMSIW) band-pass filter is proposed. A liquid metal inside microfluidic channel is used for switching. The microfluidic channels are built using the elastomer polydimethylsiloxane (PDMS) and 3D printed channel molds. This structure has two states. Before injection of the liquid metal, the recorded fractional bandwidth and center frequency of filter are 6.80% and 2.205 GHz, respectively. After injecting liquid metal, the frequency changes from 2.205 GHz to 2.56 GHz.

Figure 1 shows the dimensions of the proposed metamaterial-loaded QMSIW bandpass filter, which is composed of two different substrates. The relative permittivity, thickness, and dielectric loss of the Duroid-5880 substrate are 2.2, 0.51 mm, and 0.0009, respectively. The PDMS substrate is attached on top of the Duroid-5880 substrate to form the microfluidic channels. The relative permittivity, thickness, and dielectric loss of PDMS are 2.8, 1 mm, and 0.02, respectively. The resonant frequency of the QMSIW cavity at the TE_{100} dominant mode is given by [1], [2], [3]:

$$f_{100,QMSIW} = \frac{1}{2\pi\sqrt{\mu\varepsilon}}\sqrt{\left(\frac{\pi}{W_{QMSIW}+\Delta W}\right)^2+\left(\frac{\pi}{L_{QMSIW}+\Delta L}\right)^2} \quad (1)$$

A second-order band-pass filter was implemented using metamaterial-loaded QMSIW cavities with a center frequency of 2.205 GHz, fractional bandwidth of 7.71%, and two transmission zeros at 2.19 GHz and 2.25 GHz. An insertion loss of less than 1.65 dB with an in-band and a return loss greater than 19 dB were achieved.

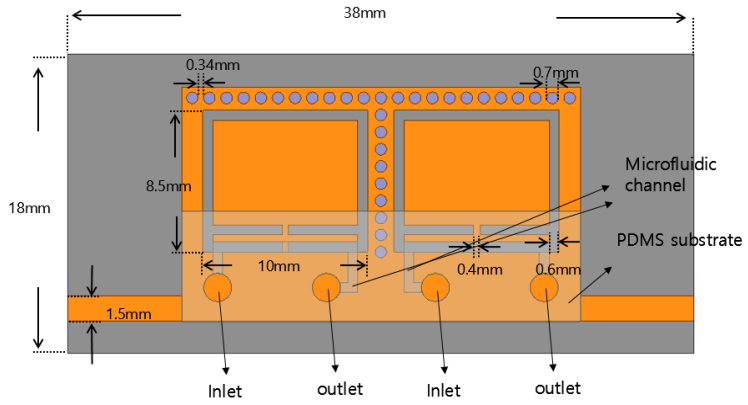

Figure 1. Layout of the proposed metamaterial-loaded QMSIW bandpass filter.

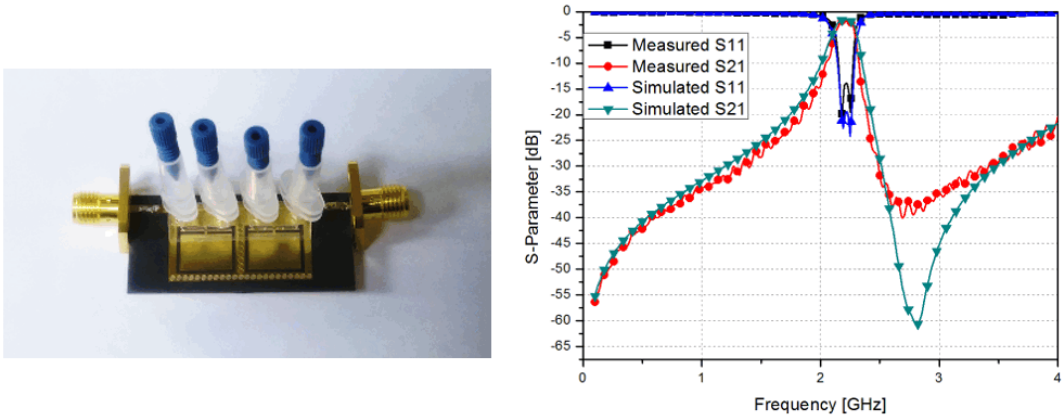
Figure 2a shows the fabricated QMSIW metamaterial filter prototype. The return loss and insertion loss of the filter are recorded using an Anritsu MS2038C vector network analyzer. Figure 2b shows the simulated and measured S-Parameters of the proposed filter along with their comparison. The recorded fractional bandwidths and center frequency are 6.80% and 2.205 GHz, respectively. Two transmission zeros are recorded at 2.18 GHz and 2.25 GHz. An insertion loss of less than 1.8 dB with an in-band and a return loss greater than 14 dB are achieved.



(a) (b)

Figure 2. (a) Fabricated metamaterial-loaded QMSIW filter prototype and (b) simulated and measured S-parameters of the proposed filter.

After the removal of the liquid metal, a small amount of liquid metal remained on the PDMS surface. However, it did not come in contact with the metamaterial directly. Therefore, the measured S-parameter results before and after injecting the liquid metal are practically the same.

Dispersion-free Tunable Beam Splitter with Gate-controlled Graphene Metadevices

Soojeong Baek[1], Hyeon-Don Kim[1], Kanghee Lee[1], Jagang Park[1], and Bumki Min[1]

[1]Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology(KAIST), Daejeon 305-701, Republic of Korea.

Abstract- In this study, we propose a broadband tunable beam splitter, where metamaterials and graphene are hybridized to modulate the splitting ratio in electrically tunable manner.

Terahertz time-domain spectroscopy is dubbed a compelling tool for investigating chemical and physical phenomena. Despite the rapid development of terahertz research, the development of related optical component is still at a late stage. Terahertz beam splitter which is indispensable for interferometers, has recently been suggested. However, in the case of such a beam splitter, the characteristics of the beam splitter are dependent on the specific frequency due to the Fabry-Perot effect. Since temporal distortion of the transmitted terahertz pulse follows such a frequency dependence, the use of a beam splitter with low dispersion characteristics is required. Moreover, once it was fabricated, the splitting ratio could not be changed.

Researches on the modulation of transmission by hybridizing metamaterial with graphene have been proposed. In the case of these studies, there was no focus on modulating the ratio of transmittance to reflectivity even with broadband characteristics. In addition, if the doping concentration of the graphene is changed, the dispersion also changes accordingly. Therefore, it is demanding to modulate the splitting ratio while having nondispersion with transmittance and reflectivity in a wide band. In this regard, we propose broadband THz tunable power splitters based on gated-graphene metadevices. Splitting ratio of the beam splitter can be electrically-modulated. The proposed metadevices were designed to reduce dispersion by combining resonant metamaterials considering the characteristics of transmission modulation according to the Fermi-level change of graphene.

High-efficiency circular polarizer based on dielectric Huygens surface in microwave band

Huan Jiang[1], Wenyu Zhao[1], and Yongyuan Jiang[1, 2]

[1]Department of Physics, Harbin Institute of Technology, Harbin, China

Abstract

Most previously reported circular polarizers are designed by equivalent circuit model in the microwave region. Here, we demonstrate an all-dielectric circular polarizer with high efficiency and broadband response in the microwave region by leveraging the recently developed Huygens surface. Due to the symmetry breaking of structure in the light propagation, right circularly polarized (RCP) light can pass through freely, while left circularly polarized (LCP) light is largely blocked in the broad band of 46.5-54.6 GHz. The high polarization transmission originates from the simultaneous excitation of the Mie-type electric and magnetic resonances in the rotationally twisted strips array with MgF_2 spacer. The device possesses the merits of high efficiency and simple inclusions, which represents a major advance.

1. Introduction

Circular polarizers are the devices who transmit one state of the circularly polarized light (CPL) and completely block the other state CPL. Conventionally, two most common methods to generate circularly polarized light are cholesteric liquid crystals and a combination of linear polarizer with a quarter-wave plate [1]. The performance of cholesteric liquid crystals is further limited by their high viscosity and poor chemical stabilities. To overcome these limitations on traditional circular polarizer, matermaterials based circular polarizers come to researchers' eyes [2-5]. Most circular polarizers are composed of metal components for the advantages of subwavelength thickness and scalability [3-5]. This will inevitably suffer from strong Ohmic loss and the absence of magnetic response. The intrinsic absorptive loss leads to low transmission efficiency and dissymmetry factor, which is defined as $g = 2(T_L - T_R)/(T_R + T_L)$ (T_L, T_R represent the transmission of LCP and RCP light) [6]. For the nature of lacking magnetic response in metal structure, one has to design the polarization devices with complex structures [7], which are difficult to fabricate and preclude further practical application. Another problem is that the principle of circular polarizers in microwave band are limited in equivalent circuit model [8-10].

To solve these problems, we leverage all-dielectric materials, following the principle of Huygens surface rather than equivalent circuit model, to construct high efficiency and broadband response circular polarizers in microwave band. The high efficiency and broadband response of the circular polarizer originates from the simultaneous excitations of electric and magnetic resonances in the all-dielectric rotationally twisted strips. Symmetric breaking of the Huygens metamaterial leads to the significant difference in transmissions between LCP and RCP wave. Furthermore, all-dielectric metamaterial inherently with electric and magnetic resonances extremely simplify the structure compared with previously reported circular polarizers [11,12]. The proposed circular polarizer shows high polarization transmission ($T_{L\max} = 0.99$) and dissymmetry factor ($g = -1.89$), which means the extension of theoretical method for designing circular polarizer by Huygens surface.

2. Design and simulations

Huygens' principle, treating each point on a wavefront as a secondary source of outgoing waves, is developed by Love and Schelkunoff to specify the secondary sources in terms of fictitious electric and magnetic currents fulfilling rigorous boundary condition. In Huygens' surface, certain equivalent electric and magnetic currents are obtained by designing electric and magnetic dipole resonances with suitable surface polarizabilities [13-15]. Since fields are vectorial at the surface, the general forms of electric and magnetic polarizabilities are tensorial [16]. The transmission coefficients of x- and y-polarized incident light can be controlled independently by electric and magnetic surface polarizabilities [17,18]. In other words, arbitrary polarization transmission can be engineered at will by constructing suitable electric and magnetic polarizabilities [19]. To gain polarization transmission selectivity, we arranged a rotational twist between two strips to break the symmetry of the structure.

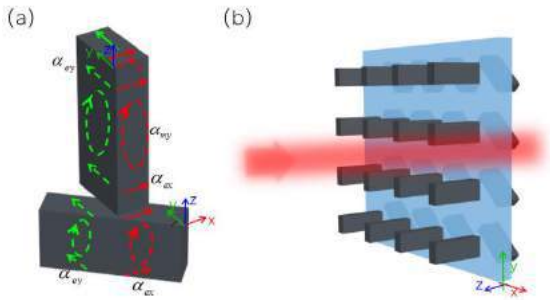

Fig. 1. (a) The design methodology of the circular polarizer. The circles represent the magnetic dipole resonances and the arrows represent the electric dipole resonances. These resonances are excited by the incident waves polarized along x- and y- direction. (b) 3-D scheme of the proposed circular polarizer with two twisted silicon strips arrays on a MgF_2 substrate and the period is 4400 μm.

Figure 1(a) illustrates the design methodology of the circular polarizer. Silicon strips supporting simultaneous excitation of electric and magnetic dipole resonances in each layer for both TE and TM modes are chosen as the basic unit cell of the circular polarizer. The incident CPL can be decomposed into two perpendicular components along x and y directions. Each component will excite corresponding electric and magnetic dipole resonances and they will superimpose together without cross coupling. The fields scattered by orthogonal electric and magnetic dipole resonances can be homogenized by effective electric and magnetic polarizabilities. Fig. 1(b) shows the 3-D scheme of the proposed circular polarizer with two twisted silicon strips arrays on a MgF_2 spacer and the period of the structure is 4400 μm in both x and y directions. The thicknesses of the two strips are 5350 μm and 1650 μm respectively, and the thickness of spacer between two layers is 2000 μm. The Huygens metamaterial is excited by CPL propagating in the direction of -z. Refractive index of silicon strips is 3.5 in the near-infrared range, while the substrate media is MgF_2 (n=1.3) [20]. Transmission spectra and excitations of associated electric and magnetic dipole resonance modes were simulated at the frequency from 46 to 55 GHz using commercial software, CST Microwave Studio. The simulation is based on a frequency-domain finite integration technology (FIT) using a unit cell boundary coupled with the Floquet port, and E-Field monitor and H-Field monitor are used at 54 GHz to detect the distribution of electric and magnetic fields.

3. Results and discussion

Figure 2(a) shows the transmission spectra of the all-dielectric cascaded tensor Huygens surface under the excitation of normal incident CPL. The blue and red lines represent the transmission of LCP light and RCP light, respectively. The transmission of RCP light is above 0.8 in the broad band of 46.5-54.6 GHz, and the maximum transmission of RCP light reaches 0.99 at 48.7 GHz, while the transmission of LCP light is below 0.2. Dissymmetry factor, the key parameter of circular polarizer, further shows the transmitted difference between LCP and RCP light in Fig. 2(b). The maximum dissymmetry factor reaches -1.89 at 54 GHz, which means good performance in polarization selective transmission is obtained in the proposed structure. The high transmission of RCP light results from the spectral overlapping of tensorial electric and magnetic resonances in both layers. The electric field components of orthogonal electric and magnetic dipole resonances are in the same direction, and the contributions of electric, magnetic resonances and the incident electric field in both layers lead to a wideband and nearly unit transmission. Meanwhile, the symmetry breaking in rotationally twisted strips leads to low transmission for LCP light. This is because the electric field components of electric and magnetic resonances are weak, especially in the second layer.

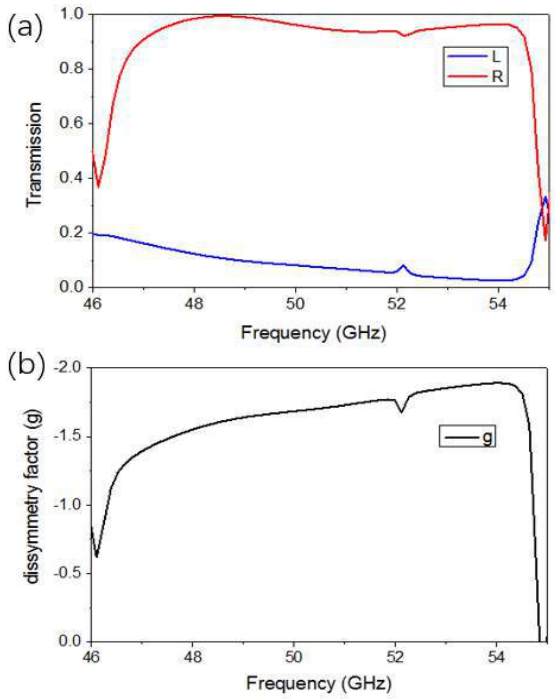

Fig. 2. (a) Transmission spectra of proposed structure simulated by CST. Red and blue lines represent transmission spectra of RCP and LCP light, respectively. (b) Dissymmetry factor spectra of the proposed circular polarizer.

Figure 3 further clarify the origin of the difference in polarization transmission. The black dashed frames in crosscuts along -z direction represent the strips in the proposed structures. Typical electric dipole mode characteristics with opposite polarization charges accumulated at the edges outside resonators and magnetic fields confined at the center of resonators, which mimicked the radiation pattern of electric dipole in the far-field. While the magnetic dipole mode characteristics with polarization charges formed a circle inside strips and the magnetic fields focused inside the resonators. The confined electric fields at the center and the accumulated polarization charges at the edges outside the two-layer strips in Fig. 3(a), (b) represent the magnetic and electric dipole modes in x-z and y-z

planes under the excitation of RCP light. Moreover, the local magnetic fields enhancement at the center of resonators in Fig. 3(e), (f) further demonstrate the simultaneous excitations of electric and magnetic dipole resonances in both x-z and y-z planes of two layers, which is in consistent with the design methodology as shown in Fig. 1(a). Fig. 3(c), (d), (g) and (h) also show the electric and magnetic dipole resonances exist simultaneously in the x-z and y-z planes under the excitation of LCP light. But differently, electric and magnetic resonances of LCP wave is much weaker than the resonances of RCP, especially in the second layer. This is why the transmission of RCP wave is near unit but the transmission of LCP is near zero.

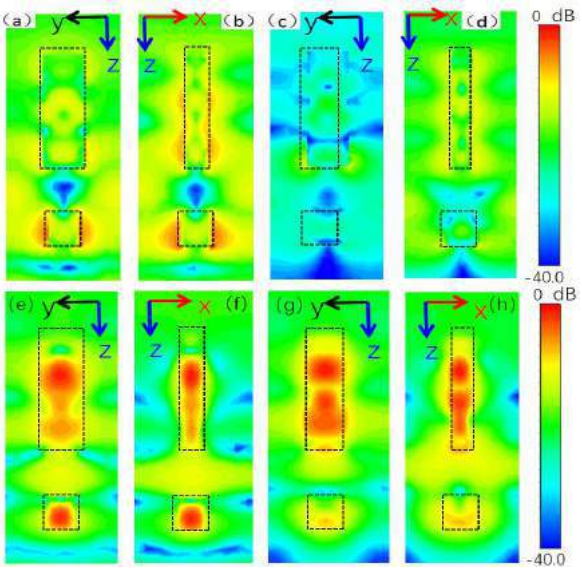

Fig. 3. Field distribution of a unit cell at 54 GHz. (a), (b) absolute value of electric field driven by RCP light at y-z plane and x-z plane, respectively. (c), (d) absolute value of electric field driven by LCP light at y-z plane and x-z plane respectively. (e), (f) absolute value of magnetic field driven by RCP light at y-z plane and x-z plane respectively. (g), (h) absolute value of magnetic field driven by LCP light at y-z plane and x-z plane respectively.

4. Conclusions

In conclusion, a high-efficiency, wideband circular polarizer operating in the microwave band is numerically demonstrated in this paper. The cascaded tensor Huygens surface with asymmetric all-dielectric strips passes nearly all RCP light and blocks most LCP light. The polarization transmission of RCP wave is up to 0.99, which results from the spectral overlapping of the electric and magnetic resonances in both layers. The symmetry breaking of rotationally twisted strips leads to the transmitted difference between LCP and RCP light. The high-efficiency circular polarizer with simple inclusions makes great progress in performance compared to the previously reported structures and paves a way to construct polarization devices by cascading tensor Huygens surfaces with all-dielectric materials.

Abstract

A coplanar waveguide (CPW) fed metamaterial antenna based on mushroom unit cell for dual band applications is proposed. The mushroom unit cell is etched on the host transmission line to engineered left-handed properties. Two resonant modes at 5.2 GHz and 7.3 GHz are obtained for the negative order resonant (NOR) and positive order resonant (POR) modes respectively. The peak realized gain -3.56 dBi and 2.51 dBi are obtained respectively for NOR and POR modes. The antenna has a compact size of 0.4744λo x 0.4934λo at the resonance frequency of 5.2 GHz. The simulated results of the reflection coefficients and surface current distributions are presented. The antenna is suitable for WLAN applications (5.15 GHz-5.25 GHz).

1. Introduction

With the recent development of modern wireless communication system due band antennas are required in this regards [1]. The concept of metamaterials (MTM) among other techniques was developed and applied to antennas design due to its unparalleled advantages. MTMs offers various advantages such as negative electromagnetic constitutive parameters, zero propagation constants, infinite wavelengths and negative group velocities [2]. However, composite left/right-handed transmission line (CRLH-TL) approach provides an intangible method of implementing small resonant antennas. Apart from size reduction, transmission line based MTM offers resonant modes at positive, zero and negative phase constant which can be used for multiband applications [3] . In [4] a CRLH-TL based dual band antenna was obtained which utilizes NOR and POR mode for dual band applications. In [5] a wideband mushroom based antenna was design by merging POR and NOR mode together.

In this paper, a CPW-fed dual band MTM antenna is presented which is loaded with mushroom unit cell. The antenna is compact in size and support dual resonant modes. The NOR mode resonates at 5.2 GHz and the POR mode resonates at 7.3 GHz. The antenna has potential application for WLAN operations (5.15-5.25 GHz).

2. Design and Analysis of the Mushroom based MTM Antenna

The proposed MTM antenna is shown in Figure 1. The antenna is design on Flame retard FR-4 substrate of dielectric permittivity of 4.3, thickness (h) of 1.6 mm and tangential loss of 0.025. The antenna is CPW fed with a MTM unit cell incorporated on the transmission line to engineered composite right/left-handed properties. The transmission line provides the series right-handed intrinsic inductance L_R and the gap (g) etched on the transmission line due to the Mushroom cell provides the series left handed capacitance C_L. The via process connecting the top mushroom patch and the bottom patch is responsible for the shunt left-handed inductance L_L and the right-handed capacitance C_R is obtained due to the coupling between the top and bottom patch. Bloch-Floquet theorem as in [6] can be used to analyzed the unit cell and obtained the dispersion diagram.

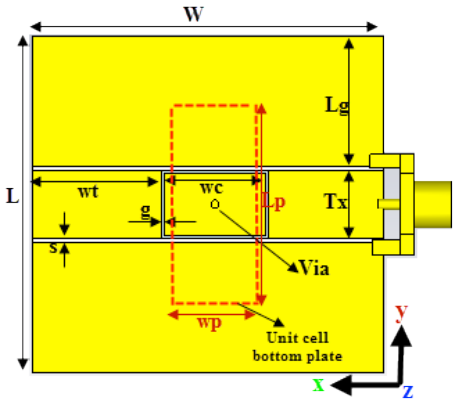

Figure 1: Geometry of the proposed MTM antenna (W = 26 mm, L = 25 mm, Lg = 9.7 mm, wc =7.6 mm, wt = 9.5 mm, h = 1.6 mm, Tx = 5 mm, s = 0.3 mm, g = 0.2 mm, Lp = 16, wp = 6 mm, r = 0.4 mm)

3. Results Discussion

The reflection coefficient of the proposed antenna is shown in Figure 2. The antenna is a dual mode and resonates at 5.2 GHz and 7.3 GHz. The NOR mode at 5.2 GHz is attributed to the left-handed behavior of the composite unit cell while the resonance at 7.3 GHz is due to the right-handed response of the transmission line. The resonance frequency of the NOR can be tuned using the shunt inductance L_L and the POR mode can be tuned through the series intrinsic inductance L_R. Parametric studies on the via which is responsible for the left-handed shunt inductance L_L is investigated in Figure 3. The resonance frequency of the NOR decreases with increase in the inductance of the shorted via from r = 0.4 mm to r = 0.2 mm. The effect of the right-handed series inductance LR on the POR mode is shown in Figure 4. Increase on the length of the signal patch Wt from 25mm to 27 mm decreases the resonance frequency of the POR from 7.28 GHz to 6.50 GHz. The surface current distributions for the resonant modes are shown in Figure 5. High current concentrations can be observed at 5.2 GHz along the shunted via which is a parameter for the NOR. Also, strong current concentrations mainly on the transmission line is indicating that it is the main radiating element as well as parameter for right-handed property. The antennas radiation patterns at both resonant modes for E- and H-plane are shown in Figure 6. A directional pattern is obtained for E-plane and omini-directional pattern for H-plane. The realized gain of -3.5 dBi and 2.51 dBi are obtained for NOR and POR respectively. The radiation efficiencies of 21% and 72% is also obtained for NOR and POR modes respectively. Drops in gain and efficiency of the NOR is due to the un-reflected surface wave cause by the suspended ground plane of the Mushroom cell.

Figure 5: Surface current distributions (a) NOR at 5.2 GHz (b) POR at 7.3 GHz.

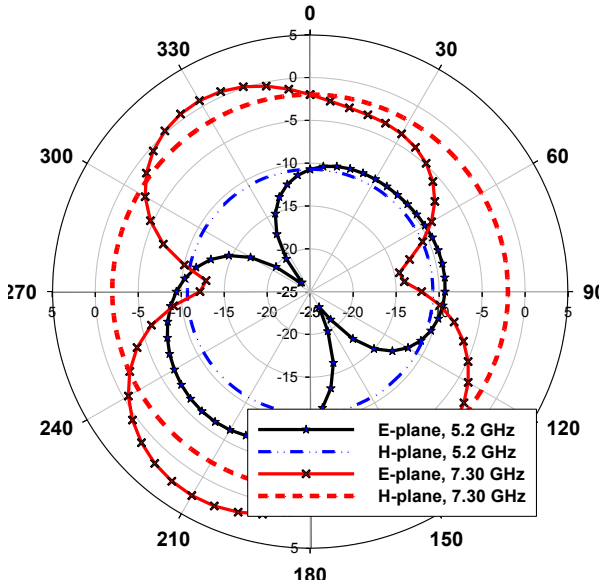

Figure 6: Effect of the series right-handed inductor L_R on the positive order resonance (POR).

4. Conclusions

A CPW fed dual band metamaterial antenna based on mushroom unit cell has been presented. The antenna consists of mushroom unit cell loaded on the host transmission line. The left-handed property was attributed to the composite mushroom cell. The NOR mode was excited by the mushroom cell and the POR was excited by the intrinsic host transmission line. A peak realized gain -3.56 dBi and 2.51 dBi were obtained for NOR and POR modes respectively. The antenna has a compact size of 0.4744λo x 0.4934λo at the resonance frequency of 5.2 GHz. Simulation results presented shows that the designed antenna is suitable for WLAN applications (5.15 GHz-5.25 GHz).

Abstract

A one turn wire spiral structure is proposed as a sensor element in microwave sensors. Based on the changes of the structure's radius and height, the chiral helical structure is significantly sensitive to circularly polarized waves. The linear optical activity shift is observed within the chirality band. This proposed helical structure is an excellent sensor element to be employed in microwave sensors, which will benefit a multitude of sensor applications.

1. Introduction

Microwave sensors are comprised of a microwave generator and a detecting circuit located before and after the sample [1]. These are then connected to interface circuits and to a computer to analyze the sensing responses. This means that no circuits, wires, tubes, or power supply is needed on the actual sensing element, which gives microwave sensors an advantage over conventional sensing elements.

Metamaterials have been researched as a viable sensing element in microwave sensors using split ring resonators (SRRs). Lee [2] shows how SRRs can be used as sensing elements in the microwave regime. These sensing elements work by measuring the shift in resonance of the structure in response to a structural change to the SSR sensing element. In this way, the structural change can be determined by looking at the electrical response of the structure. This method of sensing is met by problems when introduced into an environment where the sensing element can be affected by multiple sources or contaminants. These problems, however, are addressed by using a chiral structure as the sensing element.

The most well-known chiral structure can be observed in three-dimensional (3D) helix structures [3-8]. This was suggested as a negative refractive index material in the microwave to optical regime. The proposed chiral structure is a much simpler variant of the conventional 3D helix. The chiral structure proposed is a one turn wire helix spiral. Instead of reading the change in resonance frequency, this sensor will read the change in optical activity and give a response to external interaction.

The chiral parameters observed in the simulation results are the circularly polarized transmission coefficients, the polarization azimuth rotation angle, θ, indicating the rotation between the phases of two circular polarized waves and the circular dichroism, η, or the elliptical property, which states the amplitude difference between the two transmission coefficients.

2. Chiral Media

2.1. Optical properties

In order to observe the properties of chiral structures, the mathematical model of bi-isotropic chiral media must be derived. Using this mathematical model in conjunction with simulated or measured results, the optical properties of a structure can be extracted and easily analyzed.

Chiral media belongs to a larger range of bi-isotropic media. The equations that characterize bi-isotropic media are as follows:

$$\mathbf{D} = \epsilon_0\epsilon\mathbf{E} + (\chi + i\kappa)\sqrt{\mu_0\epsilon_0}\mathbf{H} \quad (1)$$

$$\mathbf{B} = \mu_0\mu\mathbf{H} + (\chi - i\kappa)\sqrt{\mu_0\epsilon_0}\mathbf{E} \quad (2)$$

where ϵ is the relative permittivity of the medium and μ is the relative permeability of the medium. The difference between isotropic media and bi-isotropic media in these equations lies in the parameters χ and κ. χ describes the reciprocity of the material, while κ describes the chirality of the material. Because in this instance, we will only be looking at a certain type of bi-isotropic media (Pasteur medium) which has no reciprocity and is chiral, χ will be 0. From these equations, considering Maxwell's equations in the frequency domain and considering plane wave propagation, a wave equation can be obtained for the electric field:

$$\mathbf{k}\times(\mathbf{k}\times\mathbf{E}) = -k_0^2(\epsilon\mu - \kappa^2)\mathbf{E} - 2i\kappa k_0(\mathbf{k}\times\mathbf{E}) \quad (3)$$

where $\mathbf{k}$ is the wavevector in the medium and k_0 is the wavevector in a vacuum. This equation can then be simplified by assuming $\mathbf{k} = k\hat{z}$. The equation then becomes:

$$k_\pm = k_0(n \pm \kappa) \quad (4)$$

The wavevector solution k_+ corresponds to the eigenvector of the RCP wave and k_- corresponds to the eigenvector of the LCP wave. If we were to define the index of refraction of RCP/LCP waves from the relation $k_\pm = n_\pm k_0$, it becomes:

$$n_\pm = n \pm \kappa \quad (5)$$

Next, we need to look at two parameters for chiral media defined as optical activity. This is caused by the rotation of the polarization plane of a linearly polarized light passing through a chiral medium. The first parameter is the polarization azimuth rotation angle of elliptically polarized light, defined as:

$$\theta = \frac{1}{2}\delta = \frac{1}{2}[\arg(T_{++}) - \arg(T_{--})] \quad (6)$$

The first subscript in T indicates the initial polarization and the second subscript indicates the transmitted polarization. This means that T_{++} and T_{--} are the transmission coefficients for RCP and LCP waves respectively.

Because the medium we are working with is chiral (therefore asymmetrical) and the circularly polarized waves are turning as they propagate, LCP and RCP light interacts with the medium differently. We characterize this difference using the difference in absorption and distortion between the two polarizations. This parameter is called circular dichroism. Because we can say the impedance is the same for LCP and RCP waves, the circular dichroism is characterized by the ellipticity of the circular polarization [9].

$$\eta = \frac{1}{2}\sin^{-1}\left(\frac{|T_{++}|^2 - |T_{--}|^2}{|T_{++}|^2 + |T_{--}|^2}\right). \quad (7)$$

2.2. Parameter extraction

In order to extract the previously mentioned chiral parameters, the transmission coefficients for both RCP and LCP waves must be obtained. This can be done directly by exciting the structure with a circularly polarized plane wave using circularly polarized antennas. Another, more common way to obtain the transmission coefficients is to measure the linear cross polarized transmission coefficients and converting them to the circularly polarized transmission coefficients.

The linear cross polarized transmission coefficients are denoted as T_{xx}, T_{xy}, T_{yx}, and T_{yy}, where the first subscript indicates the transmitted field polarization and the second subscript indicates the incident field polarization. Equation (8) shows the conversion from linear transmission to circularly polarized transmission [10].

$$\begin{pmatrix} T_{++} & T_{+-} \\ T_{-+} & T_{--} \end{pmatrix} = \frac{1}{2} \times \begin{pmatrix} (T_{xx} + T_{yy}) + i(T_{xx} - T_{yx}) & (T_{xx} - T_{yy}) - i(T_{xy} + T_{yx}) \\ (T_{xx} - T_{yy}) + i(T_{xy} + T_{yx}) & (T_{xx} + T_{yy}) - i(T_{xy} - T_{yx}) \end{pmatrix} \quad (8)$$

Measurement of the linear cross polarized transmission coefficients can be achieved using two horn antennas set up in much the same way a linear measurement would be done. If both antennas are kept co-polarized, the T_{xx} coefficient will be measured. In order to measure, for example, T_{yx}, the receiving antenna should be rotated ninety degrees from the transmitter. This will cross polarize the two antennas. The two other parameters can be measured by rotating the transmitting and receiving antenna by ninety degrees depending on the subscripts [10].

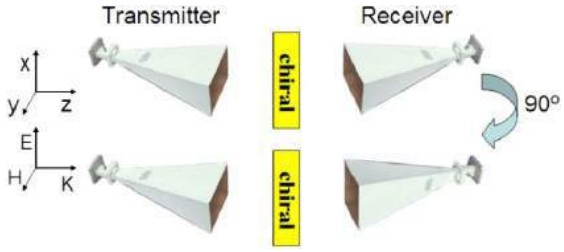

Figure 1: Measurement of chiral media using horn antennas [10].

Since the results shown in this paper will be simulated results, alternative methods will be needed to cross polarize. These will be discussed in the simulation section.

3. Chiral wire helix

The chiral structure will be a wire helix of varying radius and height. The wire is a 22 AWG copper wire. The height will depend on the radius in such a way that the length of the wire will remain constant with changes to the radius. The radius is varied between 2.5cm to 3.4cm by 0.1cm steps. This will create ten data points in the final analysis. The length is kept constant at 25cm throughout the simulation. The propagation direction of the wave is along the length of the spiral.

Equations (9) and (10) show how the height will change according to changes of the radius. Figure (2) shows a visual representation of the spiral if it were uncurled and flattened on a plane. This shows how the structure interacts clearly.

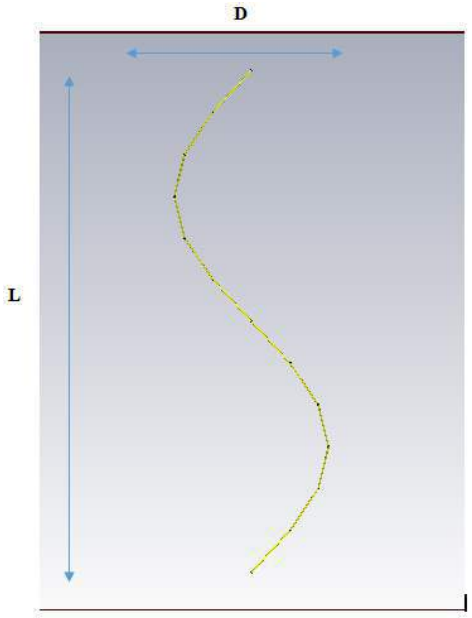

Figure 2: Spiral structure with dimensions labled are L is length and D is diameter.

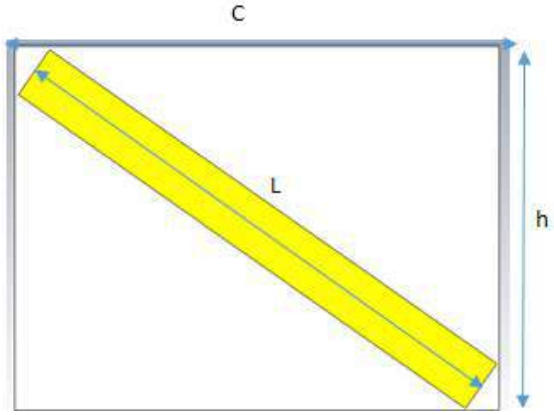

Figure 3: What the spiral would look like if uncurled. This visual representation is useful for understanding how each parameter interacts with the other, where *L* is the length, *C* is the circumference, and *h* is the height.

$$h^2 + (2\pi r)^2 = L^2 \quad (9)$$

$$h = \sqrt{L^2 - (2\pi r)^2} \quad (8)$$

Where *h* is the height, *r* is the radius, and *L* is the length.

4. Simulation

The simulations in this paper are done with CST commercial simulation software. Within this software, a frequency domain solver was used. The boundaries for this simulation were set as open space on all sides and the wave was propagated and received by waveguide ports.

The waveguide ports were set for two modes. In this way, the cross polarized transmission coefficients were simulated by changing the incident and transmitted waves to different modes.

The simulation was carried out with 10 different radii for the spiral.

5. Results and analysis

The optical parameters were extracted from the simulation results. These parameters were then analyzed for recognizable patterns. Figure (4) shows the results of the analysis and parameter extraction. The co/cross-polarization plots are shown, as well as the circular polarization plots. This is to see how patterns emerge as early as these stages. The optical activity was similarly plotted as the transmission plots, but the optical plots were further analyzed to see flawless and concrete patterns.

It can be seen that a clear, linear pattern emerges in the optical parameters of the structure when the radius of the spiral is changed at a linear rate. The peak frequencies for these plots were taken from the first clearly defined peaks that had a linear pattern. This pattern suggests that the radius of a spiral can be easily detected by extracting its optical parameters.

It can be noticed that below a radius of about 2.7cm, the chirality of the structure fails. This is hypothesized to be because the radius is too small to be seen by the wave as a spiral, and begins to see the structure as a straight wire and no longer has any chiral properties.

6. Conclusions

A sensing element in which the main sensing mechanism is the change in optical parameters of a chiral structure is shown to be possible. A clear pattern emerged as a direct effect of outside influence on the structure. Further study is needed on the effects different propagation angles can have as well as what the range of these sensing elements could be.

Abstract

For the first time, the directly magneto-voltaic effect in biomass derived graphene sheets oxide solution was observed. The voltage reaches a maximum was observed and the maximum voltage of 3.0 V would be approached at magnetic field of 0.02 T. The possible mechanism of this process is attributed to the superconducting effect of biomass graphene oxide under a magnetic field.

1. Introduction

Graphene is the single layer of graphite, it was just been discovered within 6 six years. Graphene has higher electron conductivity and thermal conductivity than graphite. Currently the usage of graphene in the manufacturing of super-capacitor is very similar with traditional method. This invention demonstrated ability for using graphene oxide solution as electrolytes for super-capacitor and maintains the stored electron current by magnetic force. Therefore we can control the discharging rate of this totally novel biomass derived graphene oxide based super-capacittery pool. In the future we can determine the storage electron-current amount by the used volume of graphene oxide solution rather than the area of electrodes. In our previously publications, we have demonstrate a feasible pathway for preparing graphene sheets carbon materials from biomass derived biochar [1-5]. In this short communication, we would like to report an unpredicted magneto voltaic occurs in biomass derived graphene sheets oxide solution.

2. Experimental Section

Experimental was carried out by homemade biomass derived graphene sheets oxide solution [1], the concentration was 1 wt% with a transparency light brown color. A homemade wireless charging box was built to provide a homogeneous alternative current magnetic field, from 0 T to 0.05 T. 100mL of the battled biomass derived graphene sheets oxide solution was placed directly in the center area in the magnetic field for wireless charging for 0 to 30 min, under a magnetic field strength of 0 to 0.02 T. Results are shown in the following figures. Fig 1 shows the harging curve of biomass derived graphene sheets oxide solution under various charging time. Fig. 2 show the charging curve of biomass derived ed graphene sheets oxide solution under various magnetic field.

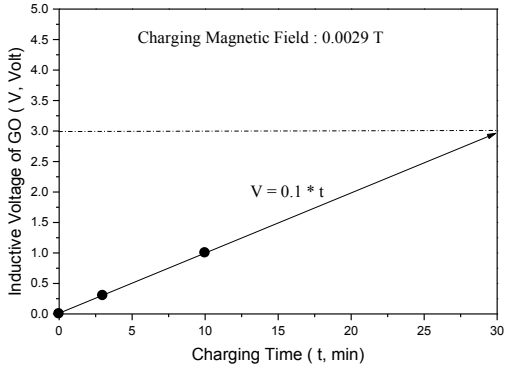

Fig 1 Charging curve of biomass derived graphene sheets oxide solution under various charging time.

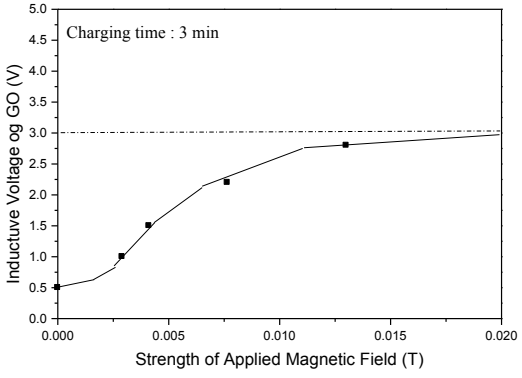

Fig. 2 Charging curve of biomass derived ed graphene sheets oxide solution under various magnetic field.

3. Discussion

For the first time, the directly magneto-voltaic effect in biomass derived graphene sheets oxide solution was observed. The 1% graphene sheets oxide solution is charged by wireless type under low magnetic field (< 0.02 T). The maximum charged voltage is 3.0 V within 30 min, with a charging rate is 0.1 V/min. Figure 1 shows the charging curve for 0 to 30 min under 0.0029 T. The maximum voltage of 1.0 V was measured by a commercial Volta-meter, and the charging rate is 0.1 V/min. Figure 2 shows the voltages of charged biomass derived graphene sheets oxide solution under various magnetic field strength. The voltage reaches a maximum was observed and the maximum voltage of 3.0 V would be approached at magnetic field of 0.02 T. A superconducting storage mechanism of this process is proposed. This invented product is the first demonstration type in the world developed from the idea of the pattern. We predict that the commercial fine product will be produced within future years.

4. Conclusions

For the first time, the directly magneto-voltaic effect in biomass derived graphene sheets oxide solution was observed and s superconducting storage mechanism of this process is proposed.

Abstract

A flexible fluidic antenna embedded in a polydimethylsiloxane (PDMS) structure integrated with a liquid metal Artificial Magnetic Conductor (AMC) plane is presented. The antenna is designed based on the operating principles of a patch antenna to cover its operation in the WLAN ISM 5.8 GHz radio band for wireless communication. The main innovation of this work is the integration of a AMC plane made fully using liquid metal embedded in PDMS to enable a highly flexible antenna, besides potentially adding tunability feature to the structure in the future.

1. Introduction

Flexible antennas to simultaneously support computing and wireless communication functionalities have garnered a great amount of interest in academia and the electronics industry. For wireless transmission requiring of higher data rates, wireless local area network (WLAN) in the 5.725-5.875 GHz band is commonly employed [1]. Antenna design techniques are evolving based on the new and innovative materials available for use. One of such materials which gained attention due to its capability and suitability as the better material for flexible antennas is the liquid metal. This work proposes a flexible and robust antenna with artificial magnetic conductor (AMC) implemented using polydimethylsiloxane (PDMS) as its substrate and eutectic gallium indium alloy (EGaIn) (Ga 75.5% and In 24.5%) as its conductor [2]. The EGaIn liquid metal is injected into microfluidic channels embedded in the multilayered elastomeric substrate. Such structure is advantageous as it provides extra robustness against water and dust, besides enabling better flexibility for the antenna due to the liquid metal's low viscosity [3].

2. Antenna Design

2.1 AMC design

To ensure fabrication simplicity, a simple square AMC unit cell enclosed inside a larger square unit cell sized at 25x25 mm2 is chosen in this work, see figure Figure 1(a). As a result, the proposed AMC realized a bandwidth of 1130 MHz (5.27 GHz to 6.40 GHz) as illustrated in Figure 1(c). Next, 16 elements of the AMC unit cells are arranged into 4x4 array to form the AMC plane and placed behind the radiating element, see Figure 1(b). In this project, the AMC plane is aimed to increase the gain and efficiency [4].

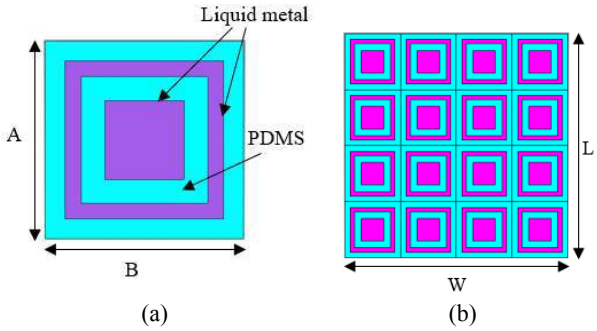

Figure 1(a): Unit cell. The dimension of AMC unit cell (in mm) are, *A*=25, *B*=25, (b): 4x4 array. The dimension of AMC plane 4x4 array (in mm) are, *L*=100, *W*=100

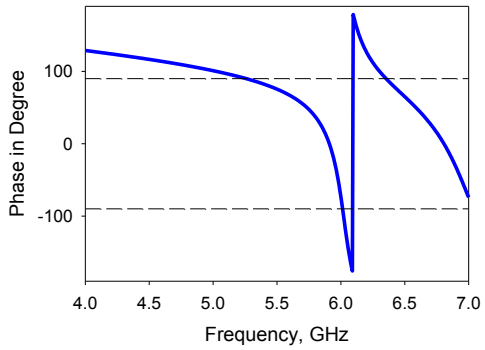

Figure 1(c): Phase response of the proposed AMC.

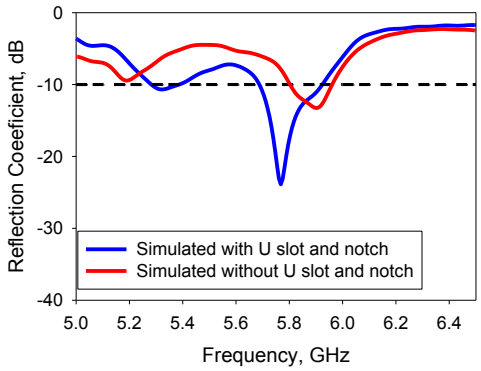

Figure 2(b): Reflection coefficient (S_{11}) of proposed antenna on the AMC plane.

2.2 Radiator Topology

The radiator is designed based on a rectangular patch topology sized at 37 x 43.5 mm2 with a target operating frequency of 5.8 GHz, see Figure 2(a). For the antenna design, a U slot and notches are added onto the patch to increase impedance bandwidth. Consequently, the integration of the AMC layer and the proposed antenna resulted in an operation from 5.68 to 5.92 GHz with 236.4 MHz of bandwidth, see Figure 2(b).

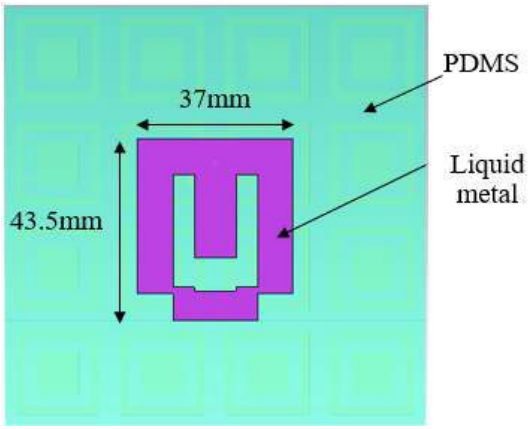

Figure 2(a): Topology of the radiating element

3. Conclusions

As conclusion, the radiator-AMC combination made using PDMS substrate and EGaIn as conductor resulted in satisfactory operation at 5.8 GHz with a gain of 2.570 dB. This result indicates that the antenna operates well and potentially may be used for applications requiring physical flexibility

A Flexible Circularly Polarized Antenna Integrated with AMC for CubeSat Application

A.H. Lokman[1]*, P.J. Soh[1], S. N. Azemi[1], M. F. Jamlos[1], H. Lago[1], and A. A. Al-Hadi[1]

Abstract

This paper proposes the design of circularly polarized antenna operating in the S-band frequency integrated with an Artificial Magnetic Conductor (AMC) plane with a total size of 0.506λ x 0.506λ x 0.0267λ. The AMC provided antenna gain enhancement from 3.52 dB to 5.89 dB at 2.3 GHz. Most importantly, it performed well with circular polarization characteristics centered at 2.3 GHz.

1. Introduction

In recent years, the implementation of CubeSats intensified worldwide due to their cost-effectiveness for various applications. Several antennas have been developed for CubeSat communication aimed at improving gains. These improvements benefited the satellite-to-ground station communication segment, besides other CubeSat applications. The integration of metamaterial-based elements has been proven to improve antenna properties at the desired frequencies by using a number of unit cells [1]. An example of such application is the dual-band crossed asymmetric dipole antenna integrated with a dual-band AMC surface placed beneath it. Such technique resulted in gains of up to 5.1 dBic and 6.2 dBic at 2.4 GHz and 5.2 GHz respectively [2]. Meanwhile, another printed meandered dipole antenna shows gain improvements from 1.8 dB to 5.1 dB by introducing the AMC on its reverse side [3].

2. AMC and Antenna Design

The proposed circularly polarized antenna in this work integrates an AMC plane underneath the antenna and is separated by a 2 mm gap. As depicted in Figure 1(a), four triangular slots were added at each corner of the AMC unit cell for its miniaturization. This unit cell designed on a flexible Kapton film substrate which is 0.635 mm thick to exhibit the behavior of a perfect magnetic conductor (PMC) at 2.4 GHz, as shown in Figure 1(c). This is to enable its application in a deployable format and to save stowage space which is limited on CubeSats. The designed AMC unit cell sized at 33 x 33 mm^2 exhibited a bandwidth of 2.2 % and a zero phase reflection at 2.4 GHz, see Figure 1(c). This unit cell is then arranged in a 2 x 2 array to form the AMC plane with an overall size of 66 x 66 mm^2. Next, a circularly polarized antenna is designed on a thin 0.85 mm Rogers RO4003C substrate to be integrated with this AMC plane. As illustrated in Figure 1(b), the antenna is formed using four elements of dipole antennas placed perpendicular to each other with a phase shifter located at center to generate circular polarization. It is placed over the AMC plane, with an overall size of 66 mm x 66 mm x 3.485 mm. Furthermore, the gain of the antenna has been improved from 3.52 dB up to 5.89 dB at 2.3 GHz by the presence of AMC plane as shown in Figure 1(d).

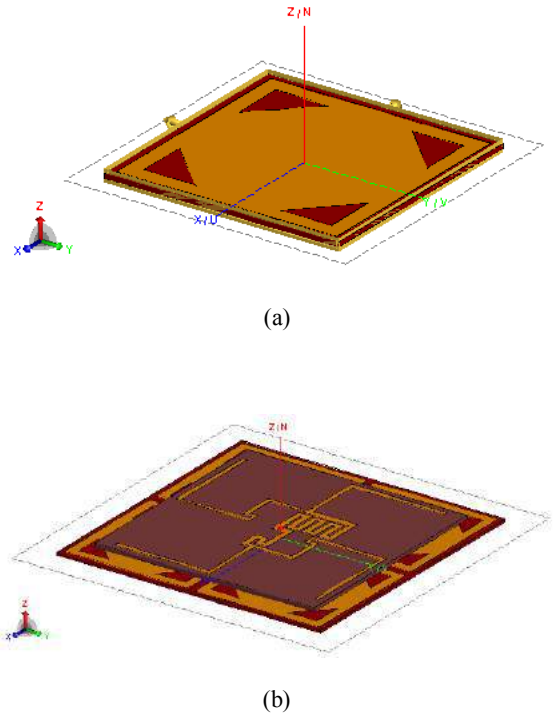

Figure 1: The proposed of (a) AMC unit cell, (b) 2 x 2 AMC plane.

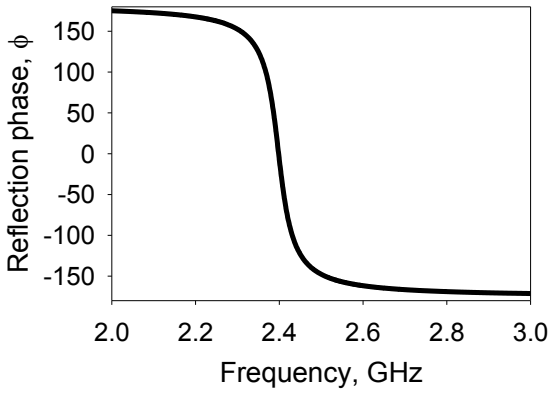
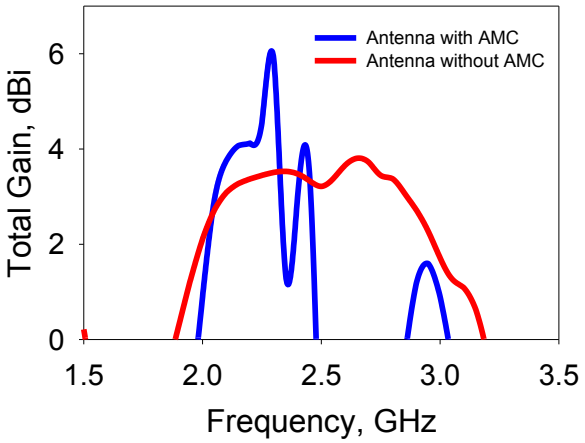


(a)



(b)

Figure 2: (a) Phase response of the AMC unit cell, (b) gain comparison of antenna with and without AMC.

3. Conclusions

An AMC plane capable of enhancing antenna gain for a circularly-polarized antenna is proposed in this work. Careful considerations must be taken to ensure that its integration onto the plane does not affect the circular polarization characteristics. The combined antenna and AMC plane fabricated using thin and flexible materials such as Rogers RO4003C and Kapton film enables it to be potentially applied as a deployable antenna. Its operation centered at 2.3 GHz with a total size of 0.506λ x 0.506λ x 0.0267λ. The gain improvements using this technique is aimed at enhancing the gain to suit satellite communication, especially satellite-to-ground station communication in CubeSats.

Abstract

In this paper, we propose a method to handle the isolation problem of a MIMO antenna for Wi-Fi access point (AP). Firstly, a quasi-Yagi antenna is designed with a transmission-line balun at the feed. Secondly, this conventional quasi-Yagi antenna is adopted for the two closely placed MIMO elements for 2.4GHz-AP equipment, and the coupling between them is checked. The 180^{O}delay-line of one element is long and next to the feed of the other element, which is an obstacle to the isolation improvement. Hence, the conventional balun is replaced by right and left-handed phase shifters, which take up a much smaller area of the feed and result in improved isolation. In addition, the MIMO radiating elements based on the metamaterial phase-shifters show less inclination of the main beam from the intended direction. The MIMO quasi-Yagi antennas without and with the metamaterial phase-shifter balun are designed, and their return- loss, beam-patterns and isolation curves are compared. Also, the full-wave simulation results are given with the measured ones.

1. Introduction

Wireless communication technologies have linked distant points over the globe or inside the office building. For quality communication, it goes without saying that the users have up- to-date handheld wireless devices as well as their software- embedded modules. More importantly, the repeaters are responsible for the connection between the users compliant to the required performances in the environment, and represented by the access point (AP) antennas [1].

Clinging to the ceiling, an AP antenna receives the signal from the transmitter and delivers it to the receiver. It handles the reception of the signals propagating on the horizontal plane. In most cases, the monopole antenna is commonly used [2]. However, there are shortcomings in the use of the monopole antenna in reality, and other types of antenna have been sought to replace it. The first weakness of the monopole structure is that its profile is not low. Though modifications are introduced to the monopole design, they tend to be higher than the body of an AP system[3]. And the second shortcoming is that the monopole radiator mounted on the ground structure results in imbalance between the upper and lower beam-patterns, which causes the H-plane gain to fall significantly. These negative factors make the AP system developers hesitate to use the aforementioned antenna.

To tackle the shortcomings of the customarily used antennas, we can think of the quasi-Yagi antenna [4,5]. The two arms of the driving element are fed by a balun that has a 180^{o}-long delay-line. As the antenna emanates the wave in the longitudinal direction that the driving element and directors sit on the substrate, it works as an end-fire type. The beam covers the user of WiFi connection in the hallway of a building and can be held high or low according to the needs.

When the quasi-Yagi antenna has to be applied to the MIMO AP as [6,7] or as seen in commercial products such as Wi-Fi routers, a few undesirable things will occur. The main beam of each quasi-Yagi element is tilted from its longitudinal direction. This comes from the influence of the degraded isolation between the two quasi-Yagi elements. It results from the fact that the delay line of the conventional balun for one element is situated near the feed of the other. To handle this matter by putting the feeding baluns of the two elements apart, we propose compact baluns comprising short metamaterial phase-shifters. The balun is connected through the right- handed 90^{o}-line and left-handed 90^{o}-line to the right and left arms of the driving element, respectively. Like [8-10], the metamaterial phase shifters can produce a 180^{o}-angular difference as a small structure, which is helpful to obtaining a higher isolation. In line with this, the conventional and novel quasi-Yagi MIMO antennas are designed and their simulated and measured characteristics are compared. Especially, the isolation levels of the two cases reveal the improvement by the proposed technique.

2. MIMO Antenna with the conventional quasi-yagi

This section regards a MIMO antenna having two conventional quasi-Yagi elements. As the preliminary form of the multiple antennas, it is needed to present a single quasi- Yagi radiating device. The geometry originates from the Yagi- Uda array antenna which is the

set of metallic rods in parallel. This 3-dimensional geometry is adapted to the microstrip structure which has the metallic strips printed on the top of the substrate that are analogous to the driving and parasitic elements. The reflecting strip does not exist unlike the 3D Yagi-Uda antenna, but the balun comprising the two paths of 180°-phase-difference is utilized to excite the antenna.

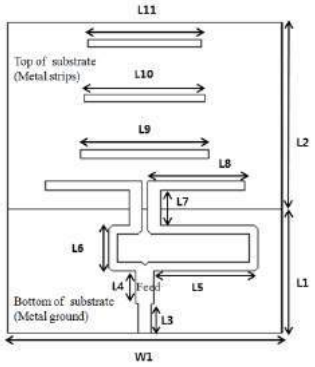

Figure 1: The geometry of the conventional quasi-Yagi antenna

The pattern is printed on FR4 as the substrate of 2-mm thickness. The driver in Fig. 1 has the two arms connected to the shorter and longer paths from left to right. The physical dimensions are given as below for the operation at 2.4 GHz.

Table 1: Physical dimensions of the conventional antenna

Parameter	Length[mm]	parameter	Length[mm]
W1	75	L6	10.5
L1	35	L7	9.5
L2	51	L8	26.5
L3	8	L9	35
L4	9	L10	33
L5	10.5	L11	31

This is applied to the MIMO antenna version of AP device

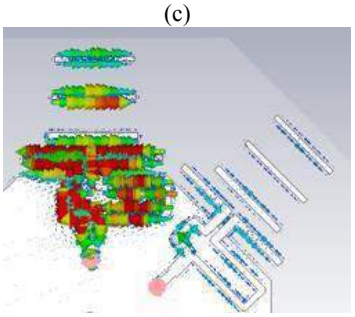
(c)



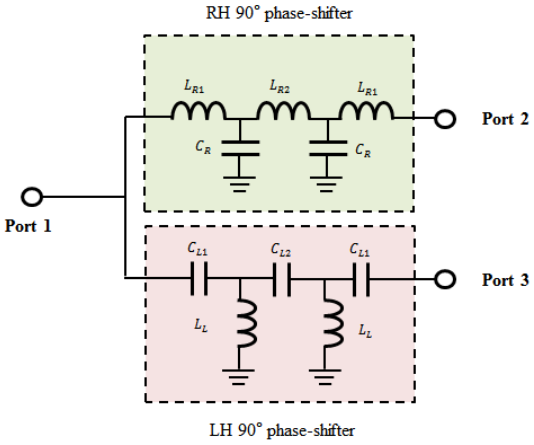
(d)

Figure 2: Electrical and EM phenomena of the MIMO of the conventional quasi- Yagi antenna (a) Geometry (b) Return loss and isolation (c) 3D beam-pattern
(d) Surface current density showing coupling between the two antennas

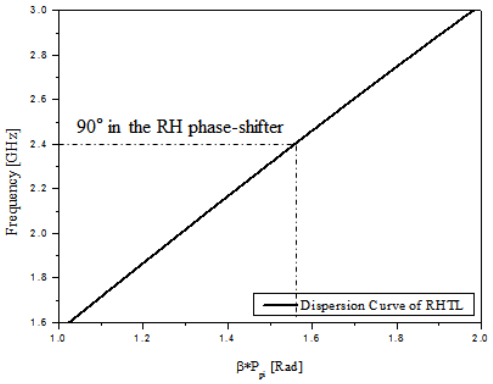
The ports for the quasi-Yagi antennas are 28 mm away as in Fig. 2(a). The EM simulation gives us S_{11} below -10 dB as shown in Fig. 2(b), meaning good input impedance match for antenna 1. The same applies to the port 2 as antenna 2. The isolation is the inverse of the coupling between antennas 1 and 2 symbolized as S_{21} and it is 17.5 dB in Fig. 2(b). At first sight, it seems to have nothing wrong. But, the unnecessary interaction of one antenna to another causes the problem of asymmetry in radiation characteristics. Fig. 2(c) shows this undesirable effect that the main beam of antenna 1 is off the vertical axis due to the surface current induced by the coupling from antenna 1 in Fig. 2(d).

3. Novel MIMO quasi-yagi antenna

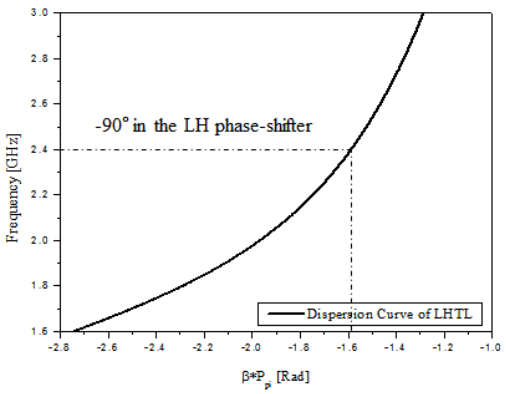
The former MIMO antenna changes to a new one which has the compact balun with metamaterial phase-shifters.



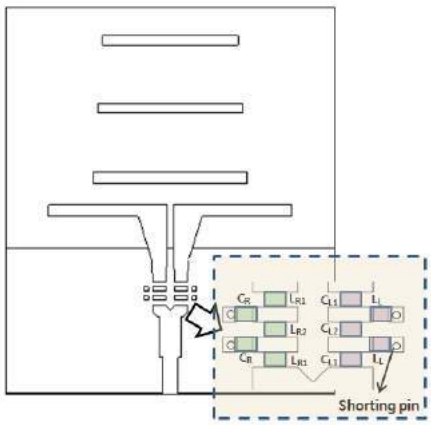
(a)



(b)



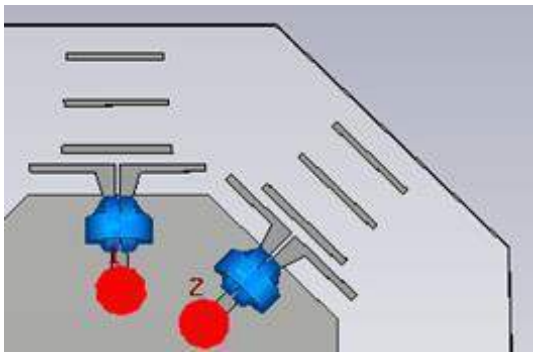
(c)



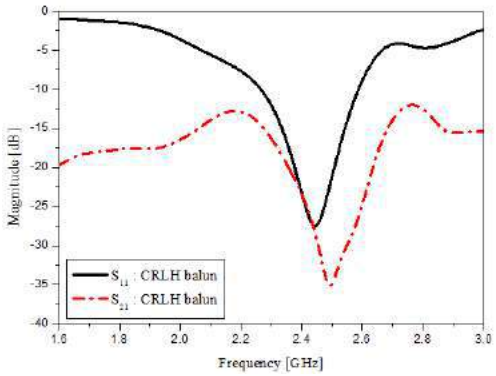
(d)

Figure 3: Small-sized balun of metamaterial phase-shifters and adoption to the quasi-Yagi antenna (a) Equivalent circuit of the balun of metamaterial phase- shifters (b) Dispersion diagram of the RH 90^{O}-phase-shifter (c) Dispersion diagram of the LH 90^{O}-phase-shifter (d) Geometry of the single quasi-Yagi antenna with the metamaterial balun

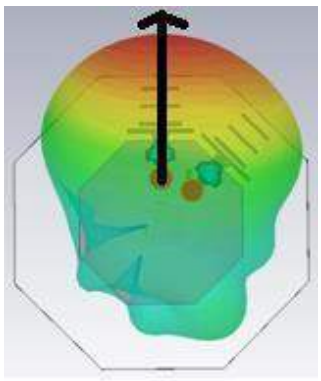
Fig. 3(a) presents the equivalent circuit of the balun made of the RH 90^{o}-phase-shifter and LH 90^{o}-phase-shifter branches. The values of lumped elements for positive and negative 90^{o} are decided as 2.2 nH, 4.8 nH, 2 pF, 30 pF, 12 pF and 30 nH for L_{R1}, L_{R2}, C_R, C_{L1}, C_{L2} and L_L. The phases of the RH and LH phase-shifting lines amount to 90^{o} and -90^{o} at the operating frequency of 2.4 GHz in Fig. 3(b) and (c), respectively. This renders the 180^{o}-differnce required for the balun. This metamaterial component can be adopted in a small area of the quasi-Yagi antenna as in Fig. 3(d). Now, we apply this structure to the MIMO AP antenna.



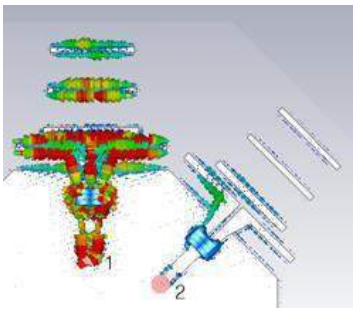
(a)



(b)



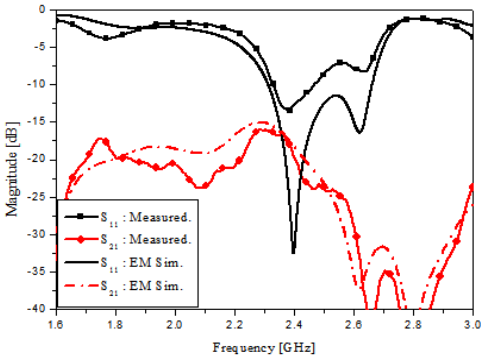
(c)



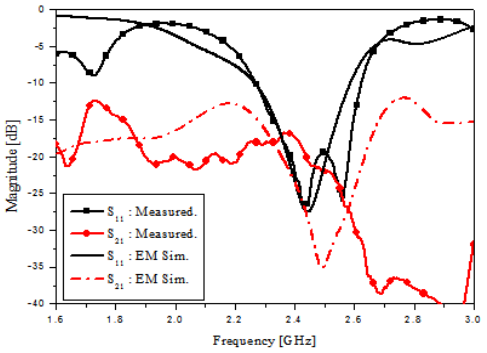
(d)

Fig. 4 : Electrical and EM phenomena of the MIMO of the suggested quasi- Yagi antenna (a) Geometry (b) Return loss and isolation (c) 3D beam-pattern
(d) Surface current density showing the weakened coupling between the two antennas

Fig. 4(a) shows the size-reduced feeds for the two radiating elements copied from Fig. 3(d). This enables the structure to lower S_{21} at 2.4 GHz as the coupling between the adjacently located feeds in Fig. 4(b), meaning improvement in isolation. Also, the main beam returns to the vertical direction in Fig. 4(c). This is explained by much weaker surface current on antenna 2 induced by antenna 1 as shown in Fig. 4(d). The conventional and suggested antennas are fabricated and measured as follows



(a)



(b)

Fig. 5: Measured return loss and isolation levels of the conventional and suggested MIMO antennas (a) Conventional case (b) Proposed case

The two types of the antennas are fabricated by the PCB manufacturing process. The conventional MIMO structure is tested in terms of S_{11} and S_{21}. Fig. 5(a) shows the degraded return loss and isolation. Contrarily, the input impedance of the metamaterial balun-embedded quasi-Yagi antenna is in good shape in Fig. 5(b). With regard to the isolation, the measurement curve is shifted upward from the simulation curve. The discrepancy is expected to be mended by replacing the used L and C elements by those close to the calculated components.

4. Conclusions

The quasi-Yagi antenna has been adapted to the MIMO AP device. When the MIMO elements are fed through the delay- line type of balun, the current on the longer path of the feed of antenna 1 interacts with the feed of antenna 2, which causes problems in antenna isolation. In order to solve them, a compact balun is suggested and has been implemented by the metamaterial phase-shifters. This balun is very small and used to excite the elements of the MIMO antennas. This antenna system

is developed to perform in an improved manner from the view-point of isolation and far-field radiation.

Abstract-We demonstrate an infrared broadband metasurface absorber that is suitable for increasing the response speed of a microbolometer by reducing its thermal mass. A large fraction of periodic patterned holes in a thin lossy metal layer can be used as a non-resonant metasurface that can be integrated with a Salisbury screen absorber to construct an absorbing membrane for a microbolometer that can significantly reduce the thermal mass while maintaining high infrared broadband absorption in the long wavelength infrared (LWIR) band.

The response speed of an infrared microbolometer may be slow because of the very high thermal resistance required for sensitivity. In other words, the absorbing membrane of microbolometer pixels, which is composed of a resistive absorber layer, bolometric layer, and mechanical support layer, is suspended over the metal mirror layer using high thermal resistance arms to provide thermal isolation. One way to reduce the thermal mass is by using a thinner absorbing membrane. For mechanical support, however, microbolometers require a finite thickness support layer; this limits how much the thermal mass of the microbolometer can be reduced. Another way to reduce the thermal mass is by making patterned holes in the absorbing membrane, but this reduces the fill factor of the absorbing layer. Recently, patterning periodic subwavelength-sized holes in a metal layer or metal elements on a substrate have been shown to produce unique spectral responses through the abrupt changes in the phase and amplitude of the incident light at the surface of the metal layer for various electromagnetic wave bands[1-3]. These two-dimensional structures are known as metasurfaces. They can be treated as thin layers with an equivalent effective surface impedance and have been used as part of narrowband[4] or tunable absorbers[5]. These metasurface absorbers have near-unity absorption, even though the fill factor of the absorbing area of metasurface is small. However, the spectral responses of these metasurface absorbers show wavelength-selective narrowband absorption because the effective surface impedance of metasurfaces having the nature of a resonator that is extremely dispersive around the resonance wavelength

In this study, we demonstrated that infrared broadband metasurface absorbers can reduce the thermal mass of microbolometer pixels by incorporating a metasurface with a non-dispersive effective surface impedance into a Salisbury screen absorber. The retrieved non-dispersive effective surface impedance matched to the free space can be achieved by finding the optimised dc surface resistance of a thin lossy metal for a certain patterned hole size by using the proposed dc approximation method. Experiments with the fabricated metasurface absorbers showed outstanding broadband absorption in the LWIR band, even when the fill factor of the absorbing area was reduced to 27.75%. Therefore, this concept for the metasurface absorber can be used in current state-of-the-art uncooled infrared thermal detectors.

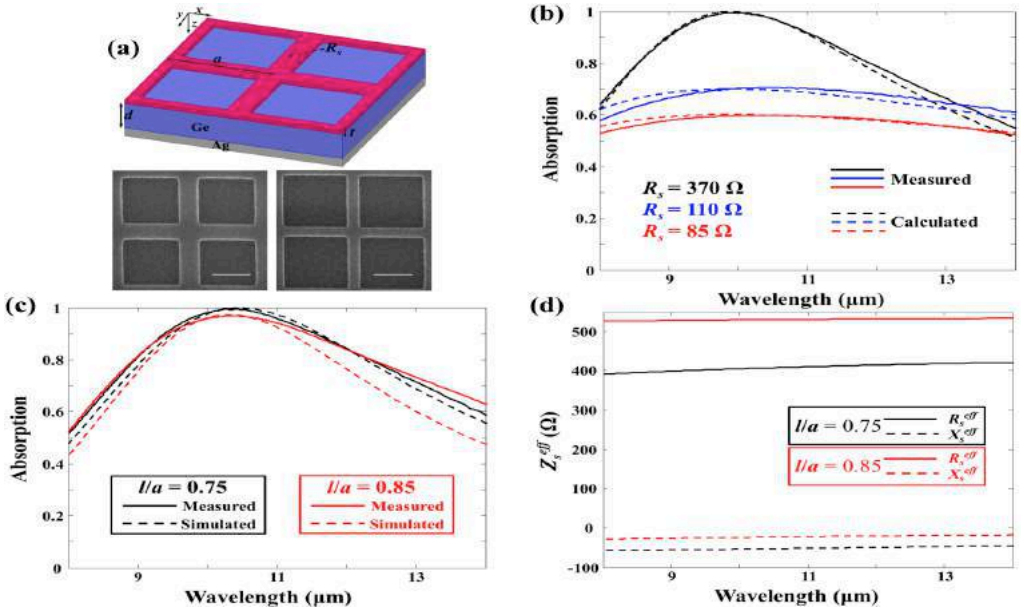

Fig. 1. (a) Schematic and SEM images of the fabricated metasurface absorbers. Scale bar is 500 nm. (b) Measured (solid curves) and calculated (dashed curves) absorption spectral responses of Salisbury screen absorbers with three different surface resistances: R_s = 85 (red curves), 110 (blue curves), and 370 Ω (black curves). Abstract

A microwave metamaterial based on resonator structures is proposed in this study for sensor applications. The metamaterial structure consists of a resonator which is surrounded by a partial ground frame and excited by a microstrip feeding transmission line. The metamaterial has a geometric size of 30 mm × 30 mm, which is imprinted on Rogers RO3010 (tm) substrate with the relative permittivity of 10.2 and the dielectric loss tangent of 0.0035. In the metamaterial structure, the resonator, partial ground frame, and the transmission line are all on a microstrip, thus it is easy to measure the metamaterial by using the common laboratory facility instead of using the waveguide. Numbers of unit cells are needed for traditional metamaterial design, whereas the proposed metamaterial structure has only one cell which can achieve the metamaterial properties. The aim of the study is to apply the presented metamaterial in sensor applications and the results exhibit that the metamaterial is quite appropriate for the microwave sensor applications.

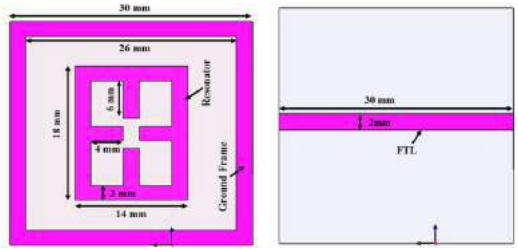
1. Introduction

Metamaterials were first introduced by Veselago in 1968. From the introduction, metamaterials became an interesting field of research for industry and researchers who are devoted to finding metamaterial characteristics such as negative permeability and negative permittivity. Since then, a lot of resonator based metamaterials have been suggested by researchers for different operating frequencies [1]. These metamaterials are designed, analyzed, validated and manufactured for practical experiments [2-11]. A split ring resonator (SRR) and capacitance loaded strip (CLS) unit cell inspired metamaterial antenna has been reported for UWB microwave imaging applications [2]. A metamaterial based fuel sensor has been mentioned in [3] which operates in the ISM (Industrial Scientific and Medical Standard) band. Referenced in [4], a split ring resonator based metamaterial has been discussed for terahertz sensing applications. A metamaterial using broadside-coupled triangular split-ring-resonator for terahertz sensing applications has been rendered in [5]. An electric field coupled resonator antenna has been addressed the comparison among the traditional split ring resonator based devices and the electric-field-coupled (ELC) and complementary electric-field-coupled (CELC) resonators based devices [6]. Referenced in [7], a metamaterial based microwave sensor has been focused where the transmission lines (TL) act as a building block for microwave sensors. In [8], the dielectric characterization of a metamaterial based on the complementary, split ring resonators (CSRR) has been described. Having the shape of CSRR, the sensor operates at a 0.8-1.3 GHz band. The performance characteristics and the comparisons of different metamaterial sensors have been reviewed and summarized [9]. A high sensitive metamaterial sensor has been rendered in [10] for the dielectric characterization of microfluidics. A thin film metamaterial sensor has been reported using rectangular asymmetric double split resonators [11].

In this study, a metamaterial based on resonator has been proposed. The metamaterial is based on a single unit cell which exhibits all the metamaterial characteristics. In the proposed configuration, the resonator and the ground frame are sketched on one part of the substrate. The feeding transmission line (FTL) is sketched on the other part of the substrate. This configuration has quite a lot of amenities which are discussed in this study. The resonator based metamaterials are not new and unique. Some of the examples are discussed in the literature review. The reason to choose the proposed resonator for the metamaterial is its simplicity in design and ease to fabricate. The proposed structure is based on the microstrip technology. The effective metamaterial characteristics for both the simulated and experimented results are fetched and analyzed. Both the results are very much close to each other. The proposed metamaterial can be used in various applications such as antennas, filters, sensors, imaging systems, etc. In this study, the proposed metamaterial is used in sensor applications in the GHz operating band. This study is organized in some sections. In the first section, the design, simulations, fabrication, and measurement technique of the metamaterial is discussed. The second section describes the metamaterial characteristics of the proposed prototype. In section three, the surface current distribution and the field distributions are described. Finally, the sensor application of the proposed metamaterial is discussed in section four.

2. Design, Simulation, Fabrication, and Measurement

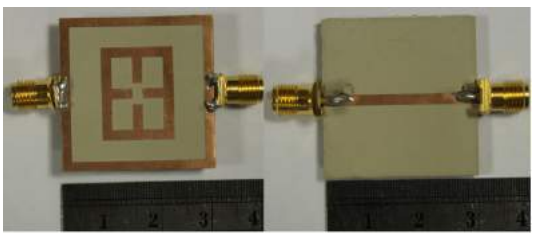
The metamaterial characteristics are unavailable in conventional materials in nature. In this study, a resonator, ground frame along with an FTL are used to make a metamaterial device which depicts all the metamaterial properties. The proposed structure is designed on Rogers RO3010 (tm) substrate with a thickness of 1.28 mm. The substrate has 10.2 relative permittivity with a loss tangent of 0.0035. The resonator and the ground frame are sketched on the same portion of the substrate. The feeding transmission line (FTL) is sketched on the opposite portion of the substrate. The metamaterial structure is simulated and analyzed by using the High-Frequency Structural Simulator (HFSS). The excitation is supplied to the resonator through the FTL. For the proposed structure, the electric, magnetic, boundary condition is used so that the electromagnetic wave propagates through FTL. Figure 1 shows the layout of the proposed metamaterial.



(a) (b)

Figure 1: Geometric layout of the Metamaterial structure. (a) top view and (b) bottom view.

The proposed metamaterial structure is fabricated on the printed circuit board for practical observation. The metamaterial is fabricated using a circuit plotter LPKF, S63. The fabricated prototype of the proposed resonator based metamaterial is illustrated in Figure 2. The measurement was performed in the microwave laboratory at the Department of Electrical, Electronic and Systems Engineering (JKEES), UKM, Malaysia. For the measurement of the proposed antenna, N5227A PNA Microwave Network Analyzer (10MHz- 67GHz) was used. The simulated and measured data are plotted by using data analysis software Origin Pro.



(a) (b)

Figure 2: Picture of the fabricated metamaterial prototype. (a) Top view and (b) bottom view.

Figure 3 shows the reflection and transmission coefficients of the metamaterial. The resonances are found at 2.30 GHz and 7.10 GHz where the reflections are minimum and the transmissions are maximum. The transmission resonance frequency is found at 6.30 GHz. Though there is a little disagreement between the reflection and transmission coefficients between the simulated and measured results, the two results are uniform over the operating band. The disagreement between the simulated and measured results occurs because of the fabrication tolerance, the soldering inaccuracies, and the external reflections.

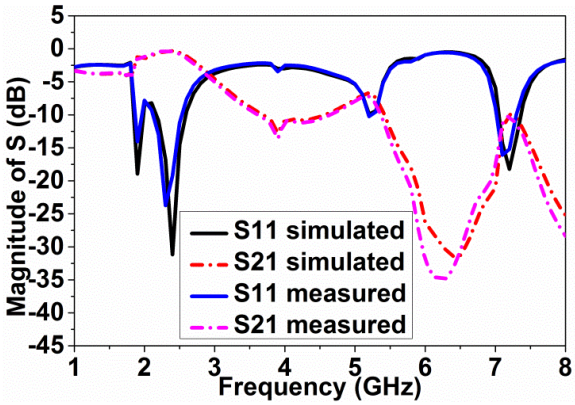


Figure 3: Simulated and measured magnitude of the S-parameter.

3. Metamaterial Characterization

To characterize the metamaterial, the effective metamaterial characteristics are extracted by the Nicolson-Ross-Weir (NRW) method. The method uses the S-parameters of the metamaterial to extract the characteristics. The NRW method is a simple and familiar method to characterize the unknown materials which are utilized for characterizing metamaterials. The refractive index depends on the effective permeability and effective permittivity, but not on reflection and transmission parameters in NRW method. The NRW method is mathematically represented by following equations [12].

$$V_1 = S_{21} + S_{11} \quad (1)$$

$$V_2 = S_{21} - S_{11} \quad (2)$$

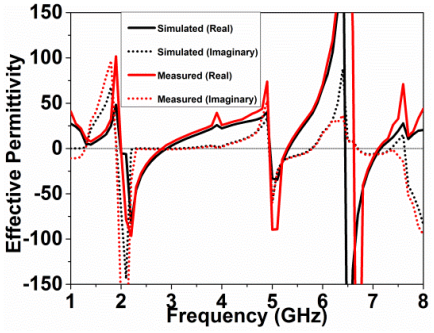
$$\mu_r \approx \frac{2}{jk_0 d}\frac{1-V_2}{1+V_2} \quad (3)$$

$$\varepsilon_r \approx \frac{2}{jk_0 d}\frac{1-V_1}{1+V_1} \quad (4)$$

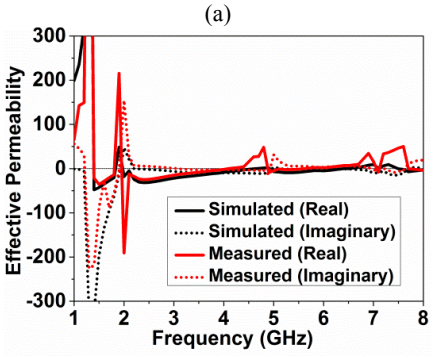
$$\eta = \sqrt{\mu_r \varepsilon_r} \quad (5)$$

Where μr, εr, η, d, and k0 corresponds effective permeability, effective permittivity, refractive index, substrate thickness, and propagation constant, respectively. In NRW method, the calculation of the parameters is based

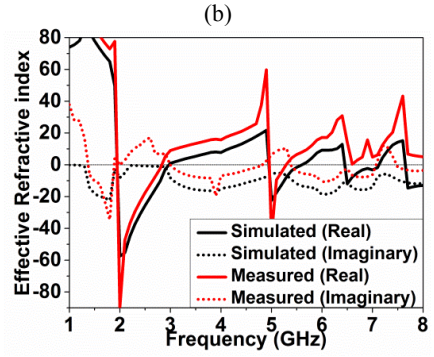
on the S-parameter. The method does not depend on the calculation of the impedance.



(a)



(b)



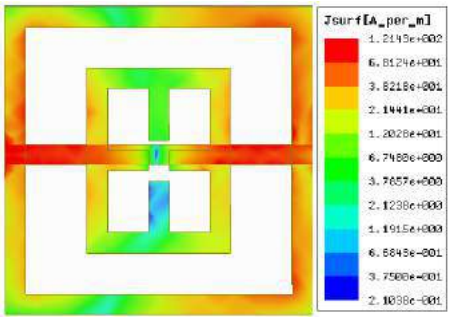
(c)

Figure 4: Simulated and measured effective constitutive parameters of the proposed metamaterial. (a) Effective permittivity, (b) Effective permeability, and (c) Effective refractive index.

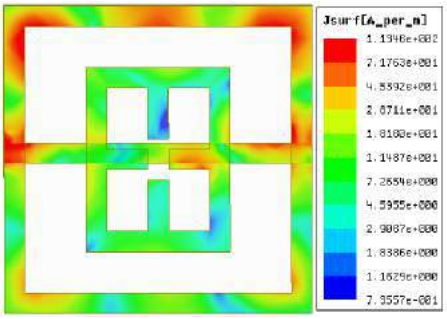
At the peak of the transmission coefficient (S21), the effective permittivity and effective permeability should be negative, which is observed from the Figure 4 (a) and Figure 4 (b). From the Figure 4 (a), the effective permittivity is negative from 2.0 GHz to 2.80 GHz, from 4.90 GHz to 5.20 GHz, and from 6.60 GHz to 7.0 GHz. The simulated and measured data are a little bit dissimilar, but two results are unique throughout the operating frequency. Figure 4 (b) shows the negative permeability from 1.40 GHz to 1.80 GHz, from 2.0 GHz to 3.90 GHz, and from 4.90 GHz to 5.20 GHz. Again, there exists a little discrepancy between simulation and measurement. There exists a variation between the permittivity and permeability due to the polarization effect. This effect happens because of the construction of the metamaterial structure. The permittivity and permeability changes because of the change in design. This is for the unequal distribution of electromagnetic waves on the material which affects the properties of the material by the polarization. The refractive index is also affected by the polarization through the same technique. The refractive index will be negative when the permittivity and the permeability become negative. Figure 4 (c) shows the negative refractive index from 2.0 GHz to 2.80 GHz and from 4.90 GHz to 5.20 GHz. Thus, the proposed metamaterial structure shows double negative characteristics as the permittivity, permeability, and the refractive index is negative in the operating bandwidth.

4. Surface Current Distribution and Field Distribution

Surface current distribution is an important parameter to describe the resonance type of the metamaterial. Figure 5 displays the surface current distribution of the proposed resonator based metamaterial.



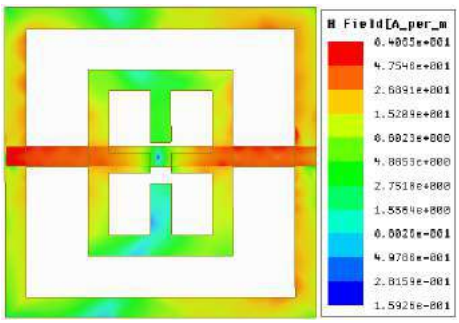
(a)



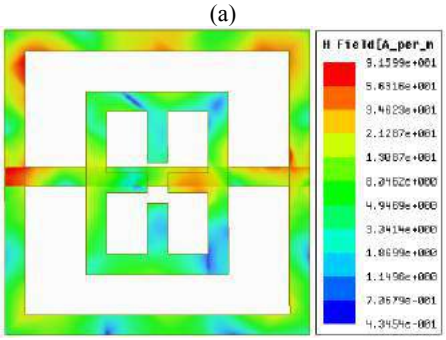
(b)

Figure 5: Distribution of currents of the metamaterial at the resonance frequency. (a) At 2.30 GHz (b) At 7.10 GHz.

From the figure, it is observed that the current density is mainly concentrated on the resonator and the FTL. Two opposite directional magnetic dipoles are formed on the ground frame due to symmetrical rotation of the surface currents on the resonator. Figure 6 shows the induced magnetic field of the metamaterial structure.



(a)

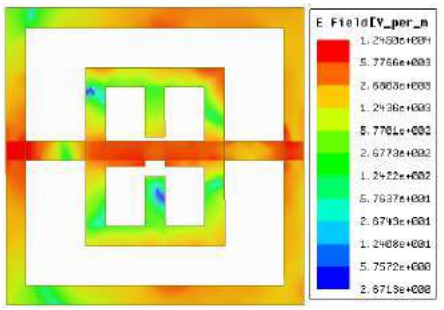


(b)

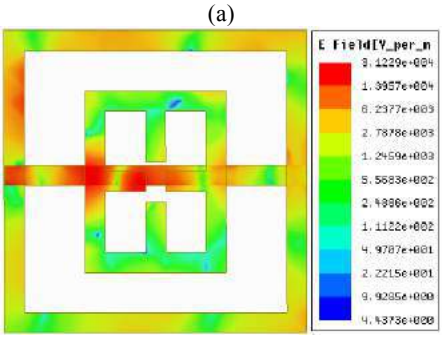
Figure 6: Distribution of magnetic field of the metamaterial at the resonance frequency. (a) At 2.30 GHz (b) At 7.10 GHz.

From the figure, it is investigated that at the resonance frequency, the FTL is coupled to the ground frame and the resonator with its electric field. At this point, the metamaterial structure shows the inductive and capacitive behavior due to the ground frame and the space between the ground frame and the resonator. The induced magnetic field is opposite to the external magnetic field and hence diamagnetism is generated. Due to the diamagnetism property, the negative permeability is extracted by the metamaterial structure. The magnetic field is vertical to the ground frame and the resonator. Thus, the negative permeability rises through the magnetic field, ground frame, and the resonator. As the metamaterial structure shows negative permittivity as well, the metamaterial gives a negative refractive index which is shown in Figure 4. Due to the collateral combination of the electric field of the structure to the ground frame, resonator, and the FTL, the negative permittivity rises. The presence of the ground frame around the resonator produces additional inductance and capacitance to the metamaterial structure and hence it becomes a crucial factor to create resonance. Moreover, the ground frame also serves as the ground plane, which provides the negative permittivity and negative permeability through the inductive-capacitive properties of the proposed structure.

The electric field distribution of the proposed resonator based metamaterial is shown in Figure 7. According to the figure, the electric field distributions are quite consistent with the surface current distribution and the magnetic field distributions. The electric field is distributed on the resonator, ground frame, and the FTL. The intensity of the electric field is enhanced at the higher frequency.



(a)

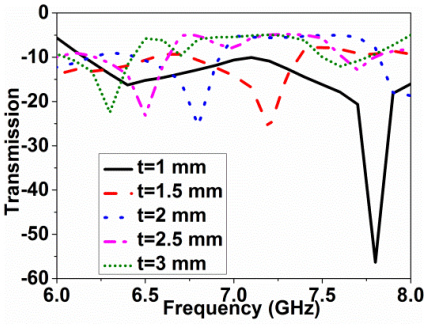


(b)

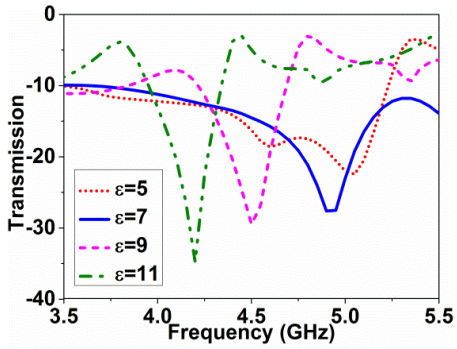
Figure 7: Electric field distribution of the proposed metamaterial at the resonance frequency. (a) At 2.30 GHz (b) At 7.10 GHz.

5. Metamaterial Sensor Application

The proposed resonator based metamaterial structure is used for the double-sided sensing system. The both front and back side of the proposed metamaterial is used in the sensing application. The unknown material which is to be detected is taken as the overlayer. By changing the thickness and the dielectric constant of the unknown material, the frequency response of the metamaterial sensing device is experimented.



(a)



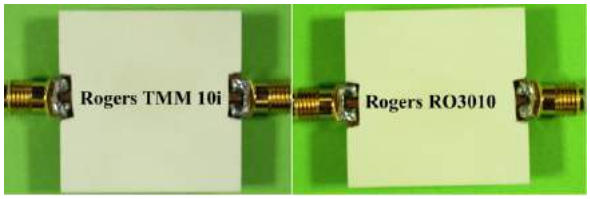
(a)

Figure 8: Change of transmission resonance. (a) for changing overlayer thickness (b) for changing overlayer permittivity.

Firstly, the effect of changing the overlayer thickness is considered to observe the frequency response. For the simulations, an overlayer with dielectric constant 10.0 and 0.0035 loss tangent is considered as it is close to the parameter of the Rogers RO3010 substrate which is used in the proposed metamaterial. Figure 8 (a) shows the simulated results after changing the thickness of the overlayer. From the figure, it is clearly observed that the transmission resonance shifts downward with the increase of the overlayer thickness. The sensing device along with the overlayer can be considered as the RLC resonant circuit in which the resonance frequency is calculated by the effective capacitance and the effective inductance. With the increment of the overlayer thickness, the effective inductance, and capacitance changes. Due to this, the transmission resonance shifts downward as the resonance frequency are directly related to the effective capacitance and the effective inductance. Thus, the proposed metamaterial structure can be effectively used in sensing application in the GHz region.

The frequency response due to changing the overlayer relative permittivity is simulated and analyzed. Figure 8 (b) illustrates the effects of the variation of the overlayer relative permittivity. When the relative permittivity is increasing, the transmission resonance downshifts as well. The higher overlayer permittivity corresponds to a larger downshift of the transmission resonance. Hence, the sensitivity of the metamaterial increases, according to the increment of the overlayer relative permittivity.

For the validation of the simulation, the practical experiments have been performed and the measured results are compared to the simulated results. In the practical observations, the Rogers RO3010 material having a relative permittivity of 10.2 with 0.0035 loss tangent and Rogers TMM 10i material having a relative permittivity of 9.8 with 0.02 loss tangent are used as the overlayers. The thickness of the materials is 1.28 mm and 1.27 mm respectively. The metallic ledge on both portions of the substrates is abolished to have the overlayer having the dielectric materials only. The proposed metamaterial structure with the overlayers is shown in Figure 9.



(a) (b)

Figure 9: Picture of the sensing device. (a) Rogers TMM 10i as overlayer (b) Rogers RO3010 as overlayer.

The measured results of the proposed resonator based metamaterial as a sensor along with the simulated results are displayed in Figure 10.

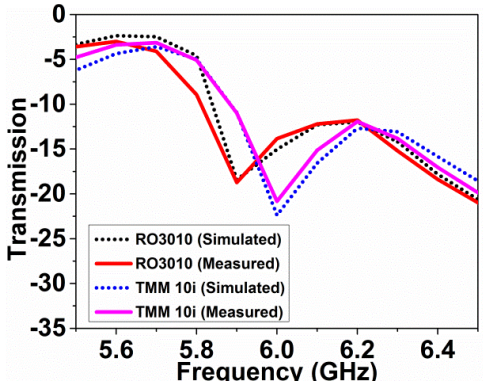


Figure 10: Simulated and measured transmission response with Rogers RO3010 and Rogers TMM 10i overlayer.

From the figure, it is clearly investigated that the resonance frequency shifts downward with the increment of the thickness and the overlayer relative permittivity. As the Rogers RO3010 has a larger thickness and higher relative permittivity than the Rogers TMM 10i material, Rogers RO3010 shifts more downward than the Rogers TMM 10i overlayer with reference to no overlayers which is shown in Figure 3. More specifically, with no overlayer, the transmission resonance is at 6.30 GHz, but using the Rogers TMM 10i and Rogers RO3010 overlayers, the transmission resonance shifts to 6.0 GHz and 5.90 GHz, respectively.

To extend the experiment, double-overlayer structures are considered for perplexing situations. In this scenario, Rogers RO3010+Rogers RO3010 and Rogers TMM 10i+Rogers TMM 10i double-overlayers are used. The simulation and practical investigations are conducted by the similar procedure as described in the previous section. The simulated and measured frequency responses for the double-overlayers are illustrated in Figure 11.

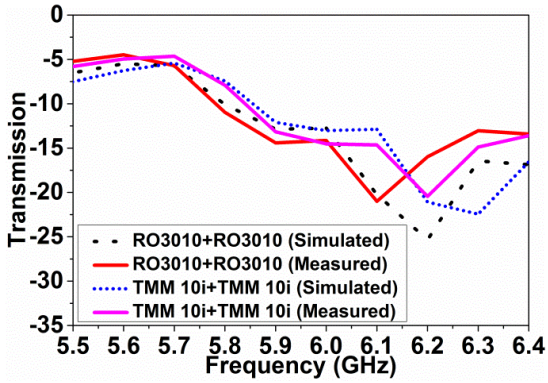

Figure 11: Simulated and measured transmission response with Rogers RO3010+Rogers RO3010 and Rogers TMM 10i+Rogers TMM 10i double-overlayers.

From the figure, it is clear that the resonance frequency shifts downward with the increment of the thickness and the overlayer relative permittivity. With no overlayer, the transmission resonance is at 6.30 GHz, but using the Rogers TMM 10i+Rogers TMM 10i and Rogers RO3010+Rogers RO3010 double-overlayers, the transmission resonance shifts to 6.20 GHz and 6.10 GHz, respectively.

Both in the overlayer and double-overlayer cases, the simulated results vary a little with the measured results. This could be due to the mechanical etching of the metallic layer of the dielectric materials, external reflections during measurements, and soldering inaccuracies. Based on the simulations and measurements performed above, the proposed resonator based metamaterial can detect materials having different values of thickness and relative permittivity. The proposed metamaterial can be used as a sensor in various applications.

6. Conclusions

In this paper, a metamaterial structure on the basis of the resonator is designed, simulated, fabricated, and investigated as a sensor. The resonator is surrounded by a ground frame and is fed by a 50Ω feeding transmission line on the rear side of the substrate. The metamaterial is measured by using common laboratory facilities rather than using of waveguides. Both the results found in the simulation and measurements agree quite well and the proposed metamaterial reveals negative permittivity and negative permeability in the operating band. The proposed metamaterial can be used in various applications including antennas, filters, sensors, imaging systems, etc. In this work, the metamaterial structure is utilized in sensor application where it can detect unknown overlayer materials with good sensitivity. The metamaterial properties with an uncomplicated design, using only one metamaterial unit cell make the structure competent to be used where metamaterial properties are essential.

Abstract

This paper presents the design of a flexible and robust linear to circular polarizer using Polydimethylsiloxane (PDMS) and ShieldIt fabric. The size of the unit cell is 58 x 48 x 3.17 mm^3, which is about 0.3757 x 0.3109 x 0.0205 in terms of wavelength for operation at 1.94 GHz. The simulated structure demonstrated a 3 dB axial ratio bandwidth of 34.53 % ranging from 1.63 GHz to 2.31 GHz.

1. Introduction

Polarization can be classified into three types, a) linear, b) circular and d) elliptical [1]. In satellite communication, RFID, etc., polarization is pivotal as these systems typically use circularly polarized waves for wireless communication. The polarization of transmitter and the receiver has to be identical to polarization losses [2].

Polarizers have been realized using different shapes, thicknesses and topologies using frequency selective structures (FSS). It is a type of planar metamaterial. Most of these structures originated from meander lines, loops, dipoles, or the combination of them [3-7]. The main innovativeness of the proposed work are as follows. The structure attempts maintain a single-layered and low profile topology to maintain simplicity and conformality. Besides that, the polarizer are built using flexible materials, PDMS and ShieldIt Super conductive fabric. This enables the structure to be flexible and robust (waterproof, dust-proof).

2. Unit cell design

A unit cell of the polarizer is modeled and simulated using the frequency domain solver in CST Microwave Studio. Unit cell boundaries, Floquet ports and template based processing are used in the modeling. To extract the CP wave, the ABS(Tx)=ABS(Ty) criterion has to be meet, as presented in Fig. 2. At the same frequency (1.94 GHz) a phase difference of -89.50^0 is observed in Fig. 3, indicating above 99 % of conversion efficiency. Fig. 4 depicts the axial ratio with its 3 dB bandwidth shown inset, with a minimum AR value of 0.08 dB at 1.94 GHz. It can be concluded that the performance of the polarizer is suited for the conversion of linear to circular polarization for a flexible antenna.

3. Conclusions

In this paper, a new flexible, single layered, linear to circular polarizer has been designed for S-Band operation based on PDMS and ShiedIt conducting fabric. The simulated structure demonstrated a 3 dB axial ratio bandwidth of 34.53 % ranging from 1.63 GHz to 2.31 GHz.

Abstract

In this paper, a flexible linear to circular polarizer (LCP) using Felt as substrate and Shieldit fabric its conducting material is designed. The simulated structure demonstrates a 10 dB fractional bandwidth (FBW) of 13.17 %. Meanwhile, its 3dB axial ratio bandwidth ranges from 2.01 GHz to 2.29 GHz. The size of the unit cell is 56 x 67.2 x 3mm^3 which is about 0.4067 x 0.4881 x 0.0218 λ at 2.04 GHz. A phase difference of 81.78^o is observed, which is equal to about 91 % in terms of conversion ratio.

Introduction

Traditionally, antennas are designed and operated in linear polarization [1,2]. However, several other applications such as GPS and satellite communication require the use of circular polarized antennas [3-5]. This is especially relevant when such antennas are required to support location tracking in a wearable format [6,7]. A simple method to enabling circular polarization is to place a linear-to-circular polarization converter in front of a linearly polarized antenna.

In this paper, an innovative linear to circular polarizer is proposed and designed using such flexible materials.

Unit Cell Design

To realize the flexible polarizer, Felt is used as its substrate and ShiledIt Super as its conducting fabric. It is designed using CST Microwave Studio's frequency domain solver and excited using Floquet ports. To create pure circular polarization using linear polarized antennas, the criteria in equation (1) needs to be met, and its phase difference between Ty and Tx components must be ± 90^0 as per equation (2), (3)[3]. A phase difference of 81.78^0, which is equivalent to 90.86 % in conversion ratio (CR) is achieved at 2.18 GHz, see Figure 4. Figure 5 represents the 3dB AR BW of 13.17 % with a reflection coefficient of at least -10 dB. This indicates its suitability to function as a linear-to-circular polarizer for applications requiring material flexibility.

$$|T_x| = |T_y| \tag{1}$$

$$\begin{aligned} \mathrm{PD}(\varphi) &= \left(\frac{\angle T_y}{\angle T_x}\right)(\text{degrees}) \\ \mathrm{CR} &= \left(\frac{PD}{90^0}\right)*100 \ \ (\%) \end{aligned} \tag{2}$$

Conclusion

In this paper, an innovative linear to circular polarizer has been designed for operation in the S band using flexible materials such as textile and ShiedlT super conducting fabric based flexible. The single layered structure also ensures design and fabrication simplicity, compactness and about 91 % conversion efficiency.

Abstract

In this paper, a flexible linear to circular polarizer designed on flexible Polydimethylsiloxane (PDMS) and textiles is proposed. PDMS is used as the substrate while the conducting elements are made using a commercial conductive textile, ShieldIt Super. Two structures consisting of loaded and unloaded circular unit elements are proposed. The unloaded circular unit cell design is sized at 46 x 56 x 3 mm^3 to operate at 2.04 GHz, while the loaded version is sized at 68 x 58 x 3 mm^3 for operation at 2.58 GHz. Both structures exhibited 3 dB axial ratio bandwidths of 33.17 % (1.99 GHz to 2.79 GHz) for the unloaded circular and 19.51 % (2.54 GHz to 3.09 GHz) for the loaded circular-shaped element inscribed in a circular patch.

Introduction

The use of circular polarization has become an essential in satellite communication, global positioning system, radar, weather forecasting and RFID. Due to its unique characteristics, propagation using circular polarized antennas minimizes noise interference, enables greater penetration into buildings, reaching difficult areas, reducing multipath and causes smaller changes to signals when propagating in rain and fog [1-5].

In this paper, two unit cell designs are proposed and investigated as follows: a) a circular patch inscribed with unloaded circles (denoted as "unloaded" in Figure 1) and b) a circular patch inscribed with loaded circles (denoted as "loaded" in Figure 2)[6-7].

Unit Cell Design

The polarizer has been designed using the frequency domain solver in CST Microwave Studio and is excited using Floquet ports. To create circular polarization using linear polarization, the phase difference between the phase of Ty and Tx components must be $\pm 90^0$ as in equations (1) and (2) [8-9]. A phase difference of about -94^0 and $+90^0$ is obtained for the unloaded and loaded structure, respectively, see Figure 4. Meanwhile, Figure 5 illustrates its 3 dB axial ratio (AR) bandwidth, indicating a bandwidth of 33.17 % and 19.51 % for the unloaded and loaded structure, respectively.

$$|T_x| = |T_y| \tag{1}$$

$$\mathrm{PD}(\varphi) = \left(\frac{\angle T_y}{\angle T_x} \right) (\text{degrees}) \tag{2}$$

Conclusion

The use of the loaded circular patch unit cell enabled the polarizer to exhibit a wider AR bandwidth compared to the unloaded version. Despite that, both structures exhibited a

satisfactory functionality as a linear-to-circular polarizer at the center frequency of 2.60 GHz and 2.04 GHz for loaded and unloaded circles, respectively.

Abstract

This paper presents an approach to enable a typical GPS receiver to be much less susceptible to intentional disruption such as jamming and change in link environment. In order for the GPS receiver to cope with jamming and to get adaptivity, 4x4 or 8x8 elements beamforming antenna is designed using metamaterials. The design results show the antenna gain much higher than 5dBi and the movable various beam patterns.

1. Introduction

Recently, as the necessity of location information has been expanded in all industries where IT is applied such as defense, construction, traffic and etc., the demand of GPS(Global Positioning System) antenna is steadily increasing. The Frequency blocks of GPS system are classified into five types and are named L1, L2, L3, L4 and L5 blocks. Among them, the L1 and L2 block can be used for civil use, and the L1 block is in general use for the navigation message signal.
As a typical GPS receiver has a fixed and wide angular beam, when the receiver is mounted on a vehicle or aircraft that moves, it does not have the adaptivity in beam. To overcome the weakness, the beam can be steered by controlling the electrical phase. The electrical phase of each element is controlled with metamaterial phase shifters.

2. Design procedures

The design starts with the element which is going to be extended to a 4x4 matrix. Coaxial-fed patch antennas are placed periodically, and denoted as (1,1) through (4,4) from left to right in the descending order from the top row.

Fig. 1. An adaptable GPS antenna to be designed

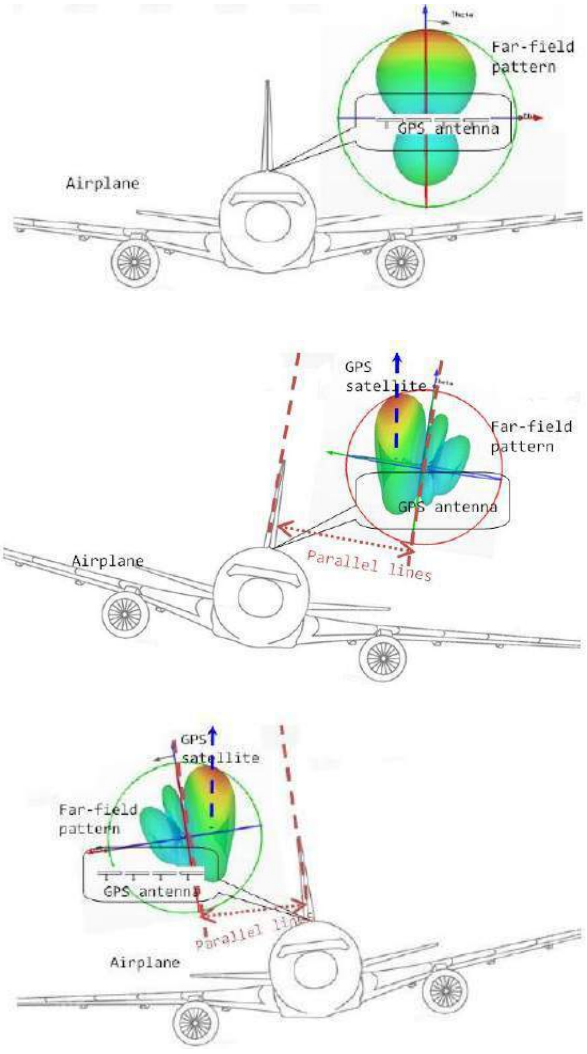

Fig. 2. Adaptivity of the GPS receiver

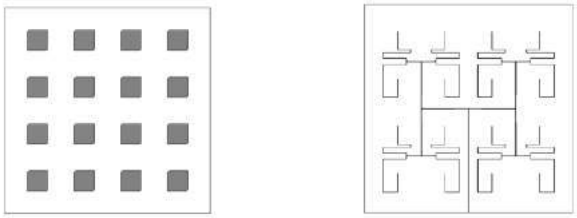
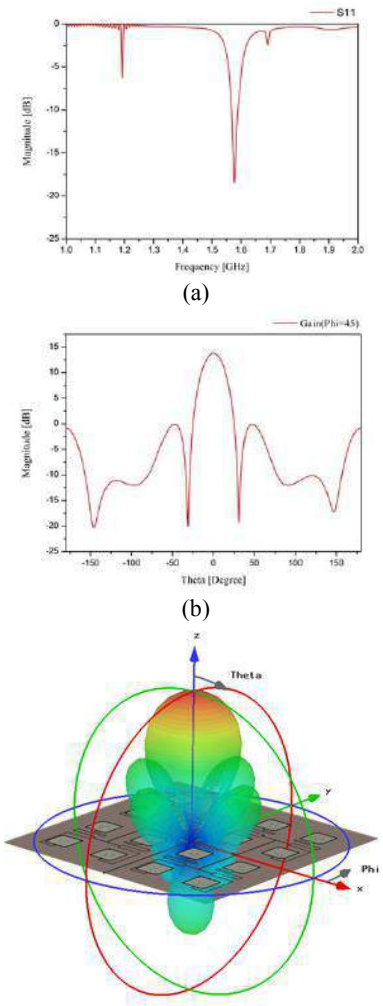
2.1. Basic design array antenna

Figure 3 shows the 4X4 Array antenna and 16 ways power divider. For ease of matching, the radiator and the feeder line are designed to be connected in aperture coupling. Also, in order to reduce the required area and the convenience of the design, the line at the end connected to the antenna was matched with 100 ohms.



(a) (b)

Fig. 3. The designed array antenna and feed network



(a)

(b)

(c)

Fig. 4. Design results of GPS array antenna (a)Return loss (b)Radiation pattern(2D) (c)Radiation pattern(3D)

Simulation results is in the figure 4. The antenna gain is 13.79dBi and efficiency is 50.2%. Also, it shows that the direction of the antenna beam is directed to the vertical direction(+z) because of the in-phase feeding.

2.2. Design metamaterial phase shifter

In order for the array antenna to electrically steer the antenna beam, a different phase difference feed must be applied to each radiating element. In order to realize the metamaterial phase shifter, the combination of the RH transmission characteristic component and the LH transmission characteristic component by combining the lumped element and the shorting pin in the microstrip transmission line. The metamaterial phase shifter has different output phases according to the lumped element combination value.

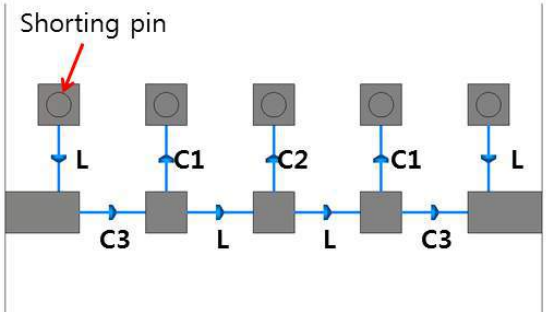


Fig. 5. The proposed metamaterial phase shifter

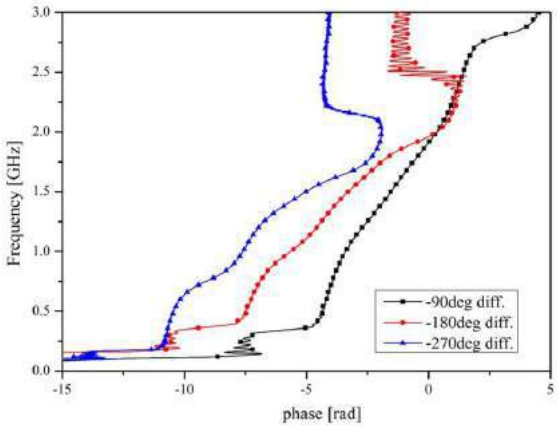

Fig. 6. The phase distribution curve of the proposed CRLH phase shifter

2.3. Combining the array antenna and phase shifter

When azimuth and elevation angle of the main beam are set to 45 degrees, each array elements should have 90 degrees phase differences.

As figure 7 shows, the CRLH phase shifter is combined to the feed network. The results show that the return loss and low mutual coupling are obtained at the L1-band. The antenna gain is 12.54dBi and efficiency is 58.7%. Also when the power was fed so that each adjacent radiator element had a phase difference of 90 degrees, the main beam of the antenna was tilted 43 degrees in the direction of +Theta and +Phi. As well as the null point moved together with the main beam. Thus, by adjusting the appropriate the lumped element value, the beam of the antenna can be steered at various angles and it can increase adaptivity of the antenna.

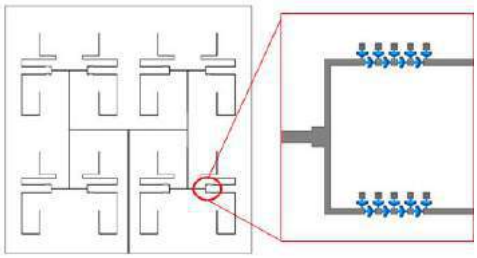

Fig. 7. Combination of array antenna and CRLH phase shifter

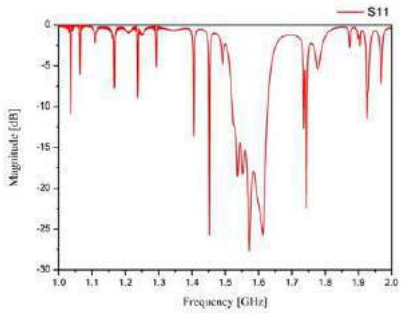
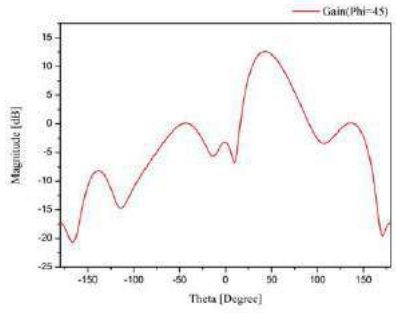
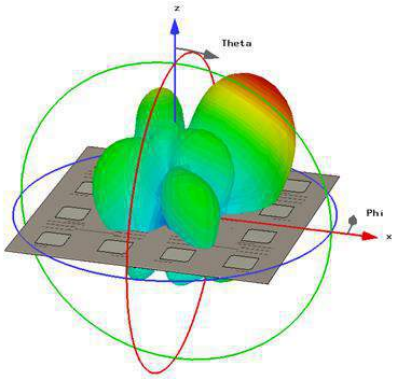


(a)



(b)



(c)

Fig. 8. The simulation results (a)Return loss (b)Radiation pattern(2D) (c)Radiation pattern(3D)

3. Conclusions

In this paper, we have studied beam tilting method for the antenna beam adaptivity and anti-jamming function of GPS receiver used in vehicle or payload, and verified it by simulation. The results show that the main beam of the GPS receiving antenna can be steered by the CRLH phase shifter. The proposed CRLH phase shifter can output various phase according to the lumped element C value. If the CRLH phase shifter is combined with varactor diode, it can steer the antenna beam in realtime.

Abstract

A flexible dual band Artificial Magnetic Conductor (AMC) operating in the two Ultra Wideband (UWB) mandatory channels is proposed. Operations are centered at 4 GHz (channel 1) and 8 GHz (channel 6) based on the IEEE 802.15.4 standard for Wireless Body Area Network (WBAN). Upon validation of its dual-UWB performance, the proposed AMC is subsequently incorporated on a quasi-circular patch antenna to determine its contribution in improving the antenna's reflection coefficient and impedance bandwidth.

1. Introduction

Artificial Magnetic Conductor (AMC) is a metamaterial which exhibits a perfect magnetic conductor's (PMC) characteristics within a certain frequency band [1-10]. AMC is an effective approach to significantly widen the bandwidth [4], [7], [8], for radiation suppression towards a certain direction [1], [6], transmission enhancement [3], impedance matching improvement [8] and gain enhancement [2]. Recently, work in [10] presented AMC-integrated antenna for operation of Ultra Wideband (UWB) mandatory channel 6 centered at 8 GHz with combination of upper Wireless Local Area Netwrok (WLAN) band at 5.5 GHz. On the other hand, a T-slotted rectangular AMC element is proposed in this paper to improve the impedance matching and bandwidth of a dual band UWB antenna in the mandatory channels. The proposed antenna is quasi-circular, comprising of two semicircles with different radii to radiate at 4 GHz and 8 GHz. In comparison, the standalone antenna without the AMC plane is poor in terms of impedance matching due to the use of a closely-located ground plane to the radiator. This can be approximated as a perfect electric conductor (PEC) which introduces a negative image current to that of a source.

2. AMC and Antenna Design

In this work, a rectangular T-slot unit cell is designed and optimized before being duplicated and placed periodically to the complete AMC plane. Fig. 1 illustrate the AMC unit cell operation centered at 4 GHz and 8 GHz with about 222.95 MHz and 561.38 MHz of phase reflection bandwidth, respectively, determined within ±90° from the zero-phase reflection (PMC) point. The planar AMC unit cell is then multiplied to form a 3 x 3 AMC plane layer.

The geometry of the proposed quasi-circular patch antenna and the AMC plane layer is shown in Fig. 2(a) and 2(b) respectively. The full structure consists of the AMC plane which is placed underneath the same 1.5 mm thick felt substrate consisting of a radiating patch made from the *ShieldIt*. Fig. 2(c) shows the cross-section of the integrated AMC-antenna structure.

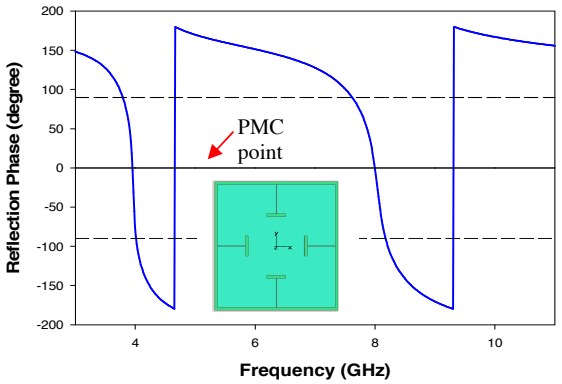

Figure 1: The reflection phase of the AMC unit cell

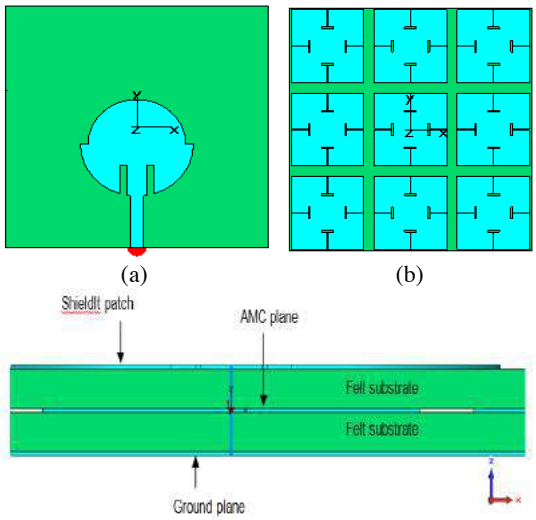

(c)

Figure 2: The quasi-circular patch, (b) 3 x 3 array AMC layer, and (c) overall antenna's cross-section

3. Results and Discussion

As depicted in Fig. 3, the incorporation of the AMC plane into the antenna improved its reflection coefficients. Minimum values of -16.08 dB and -12.22 dB are achieved at 4 GHz and 8 GHz. The performance of the standalone antenna is also provided as a comparison.

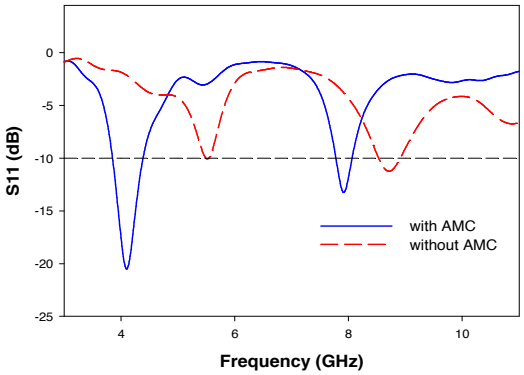

Figure 3: Reflection coefficients of the standalone patch antenna with and without AMC

4. Conclusions

An AMC unit cell based on rectangular patches integrated with T-slots is proposed in this work. Its dual band operation is centered at 4 GHz and 8 GHz with reflection phase bandwidths of 222.95 MHz and 561.38 MHz, respectively. The inclusion of the AMC structure onto a conventional slotted quasi-circular patch antenna successfully lowered its resonances and improved impedance matching at 4 GHz and 8 GHz.

Abstract

A resonator based metamaterial for sensor application is studied in this paper. The resonator is encompassed by a partial ground plane and excited by a microstrip feed-line. As the resonator, partial ground frame, and the feeding transmission line (FTL) are on the same microstrip, the measurement can be executed by using the common laboratory facility instead of using the waveguide. The proposed metamaterial occupies a compact size of 20 mm × 20 mm and is imprinted on a low-cost FR4 substrate. The substrate has a relative permittivity of 4.6 with adielectric loss tangent of 0.02. The resonator and the ground frame are placed on the similar part of the substrate and the feed-line is placed on the other part of the substrate. In metamaterial design, normally arrays of metamaterial unit cells are needed, whereas this study presents only one cell which can achieve the metamaterial properties. The characteristic parameters are fetched and analyzed to find the concurrency between the simulated and measured results. The presented metamaterial is applied in sensor applications where the simulated and measured results reveal considerable agreement.

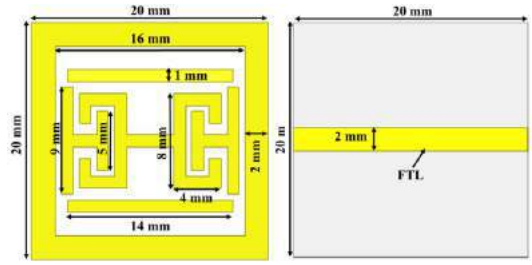
1. Introduction

Metamaterials were first to come into focus by Veselago in 1968. From the introduction, metamaterials became an interesting field of research for industry and researchers who are devoted in metamaterial characteristics such as negative permeability and negative permittivity. Since then, researchers have suggested lots of resonator based metamaterials for different operating frequencies [1]. These metamaterials are designed, analyzed, validated and manufactured for practical observations [2-11]. A split ring resonator (SRR) and capacitance loaded strip (CLS) unit cell inspired metamaterial antenna has been reported in [2] for UWB microwave imaging applications. A metamaterial based fuel sensor has been mentioned in [3] which operates in the ISM (Industrial Scientific and Medical Standard) band. A split ring resonator based metamaterial for terahertz sensing applications has been referenced in [4]. A metamaterial using broadside-coupled triangular split-ring-resonators for terahertz sensing applications has been mentioned in [5]. An electric field coupled resonator antenna has been described in [6] where the comparison among the traditional split ring resonator based devices and the electric-field-coupled (ELC) and complementary electric-field-coupled (CELC) resonators based devices has been addressed. Referenced in [7], a metamaterial based microwave sensor has been focused in which the transmission lines (TL) act as a building block for microwave sensors. In [8], the dielectric characterization of a metamaterial based on the complementary, split ring resonators (CSRR) has been discussed. Having the shape of CSRR, the sensor operates at a 0.8-1.3 GHz band. In [9], the performance characteristics and the comparisons of different metamaterial sensors have been reviewed and summarized. A high sensitive metamaterial sensor has been rendered in [10] for the dielectric characterization of microfluidics. A thin film metamaterial sensor using rectangular asymmetric double split resonators has been reported in [11].

In this study, a metamaterial based on resonator has been introduced. The proposed metamaterial is based on a single unit cell which depicts all the metamaterial characteristics. In the proposed configuration, the resonator and the ground frame are sketched on one part of the substrate. The feeding transmission line (FTL) is sketched on the other part of the substrate. This configuration has quite a lot of amenities which are discussed in this study. The resonator based metamaterials are not new and unique. Some of the examples are discussed in the literature review. The reason to choose the presented resonator for the proposed metamaterial is its simplicity in design and ease to fabricate. The proposed structure is based on the microstrip technology. The effective metamaterial characteristics for both the simulated and experimented results are fetched and analyzed. Both the results are very much close to each other.The proposed metamaterial can be used in various applications such as antennas, filters, sensors, imaging systems, etc. In this study, the proposed metamaterial is used in sensor applications in the GHz operating band. This study is organized in some sections. In the first section, the design, simulations, fabrication, and measurement technique of the metamaterial is discussed. The second section describes the metamaterial characteristics of the proposed prototype. In section three, the surface current distribution and the field distributions are described. Finally, the sensor application of the proposed metamaterial is discussed in section four.

2. Design, Simulation, Fabrication, and Measurement

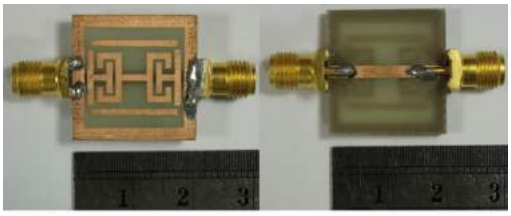
The metamaterial characteristics are unavailable in conventional materials in nature. In this study, a resonator, ground frame along with an FTL are used to make a metamaterial device which depicts all the metamaterial properties. The proposed structure is designed on a low-cost FR4 dielectric substrate with a thickness of 1.6 mm. The substrate has 4.6 relative permittivity with a loss tangent of 0.02. The resonator and the ground frame are sketched on the same portion of the substrate. The feeding transmission line (FTL) is sketched on the opposite portion of the substrate. The metamaterial structure is simulated and analyzed by using the High-Frequency Structural Simulator (HFSS). The excitation is supplied to the resonator through the FTL. For the proposed structure, the electric, magnetic, boundary condition is used so that the electromagnetic wave propagates through FTL. Figure 1 shows the layout of the proposed metamaterial.



(a)(b)

Figure 1: Geometric layout of the Metamaterial structure. (a) top view and (b) bottom view.

The proposed metamaterial structure is fabricated on the printed circuit board for practical observation. The metamaterial is fabricated using a circuit plotter LPKF, S63. The fabricated prototype of the proposed resonator based metamaterial is illustrated in Figure 2. The measurement was performed in the microwave laboratory at the Department of Electrical, Electronic and Systems Engineering (JKEES), UKM, Malaysia. For the measurement of the proposed antenna, N5227A PNA Microwave Network Analyzer (10MHz- 67GHz) was used. The simulated and measured data are plotted by using data analysis software Origin Pro.



(a)(b)

Figure 2:Picture of the fabricatedmetamaterial prototype. (a) Top view and (b) bottom view.

Figure 3 shows the reflection and transmission coefficients of the metamaterial. The resonances are found at 4.90 GHz and 9.30 GHz where the reflections are minimum and the transmissions are maximum. The transmission resonance frequency is found at 7.60 GHz. Though there is a little disagreement between the reflection and transmission coefficients between the simulated and measured results, the two results are uniform over the operating band. The disagreement between the simulated and measured results occurs because of the fabrication tolerance, the soldering inaccuracies, and the external reflections.

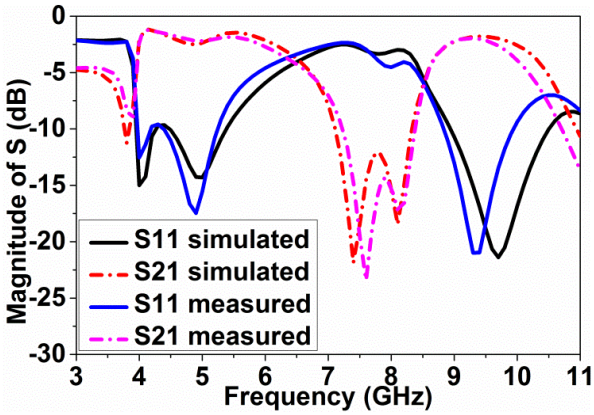


Figure 3:Simulated and measured magnitude of the S-parameter.

3. Metamaterial Characterization

To characterize the metamaterial, the effective metamaterial characteristics are extracted by the Nicolson-Ross-Weir (NRW) method. The method uses the S-parameters of the metamaterial to extract the characteristics. The NRW method is a simple and familiar method to characterize the unknown materials which are utilized for characterizing metamaterials. The refractive index depends on the effective permeability and effective permittivity, but not on reflection and transmission parameters in NRW method. The NRW method is mathematically represented by following equations [12].

$$V_1 = S_{21} + S_{11} \quad (1)$$

$$V_2 = S_{21} - S_{11} \quad (2)$$

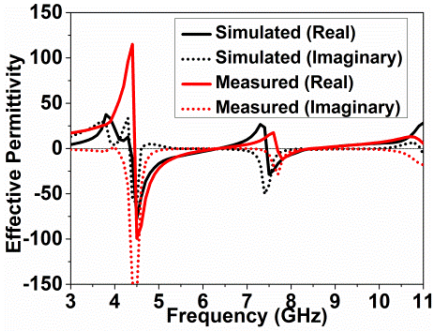
$$\mu_r \approx \frac{2}{jk_0 d}\frac{1-V_2}{1+V_2} \quad (3)$$

$$\varepsilon_r \approx \frac{2}{jk_0 d}\frac{1-V_1}{1+V_1} \quad (4)$$

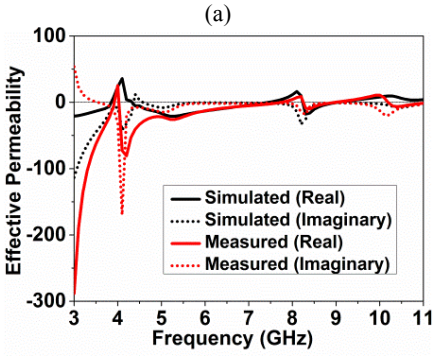
$$\eta = \sqrt{\mu_r \varepsilon_r} \quad (5)$$

Where μr, εr, η, d, and k0 corresponds effective permeability, effective permittivity, refractive index, substrate thickness, and propagation constant, respectively. In NRW method, the calculation of the parameters is based

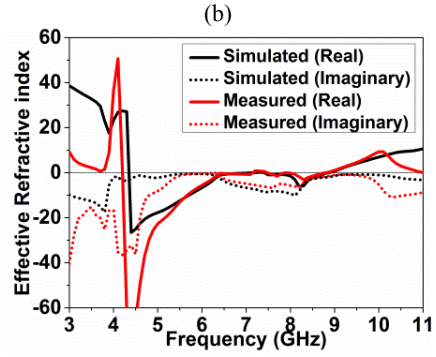
on the S-parameter. The method does not depend on the calculation of the impedance.



(a)



(b)



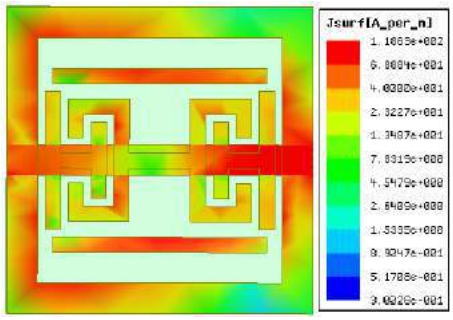
(c)

Figure 4: Simulated and measured effective constitutive parameters of the proposed metamaterial. (a) Effective permittivity, (b) Effective permeability, and (c) Effective refractive index.

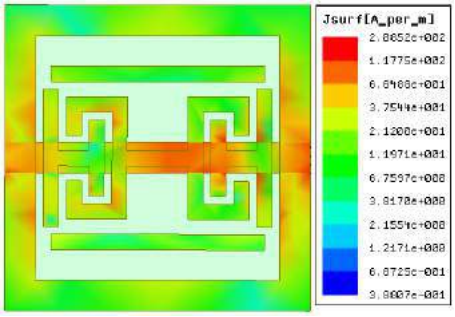
At the peak of the transmission coefficient (S21), the effective permittivity and effective permeability should be negative, which is observed from the Figure 4 (a) and Figure 4 (b). From the Figure 4 (a), the effective permittivity is negative from 4.40 GHz to 6.0 GHz and from 7.65 GHz to 8.30 GHz. The simulated and measured data are a little bit dissimilar, but two results are unique throughout the operating frequency. Figure 4 (b) shows the negative permeability from 4.0 GHz to 7.50 GHz and from 8.20 GHz to 8.80 GHz. Again, there exists a little discrepancy between simulation and measurement. There exists a variation between the permittivity and permeability due to the polarization effect. This effect happens because of the construction of the metamaterial structure. The permittivity and permeability changes because of the change in design. This is for the unequal distribution of electromagnetic waves on the material which affects the properties of the material by the polarization. The refractive index is also affected by the polarization through the same technique. The refractive index will be negative when the permittivity and the permeability become negative. Figure 4 (c) shows the negative refractive index from 4.20 GHz to 6.30 GHz and from 8.0 GHz to 8.60 GHz. Thus, the proposed metamaterial structure shows double negative characteristics as the permittivity, permeability, and the refractive index is negative in the operating bandwidth.

4. Surface Current Distribution and Field Distribution

Surface current distribution is an important parameter to describe the resonance type of the metamaterial. Figure 5 displays the surface current distribution of the proposed resonator based metamaterial.



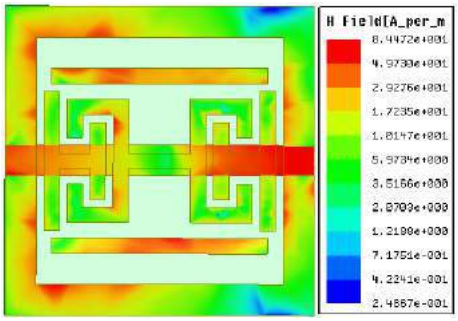
(a)



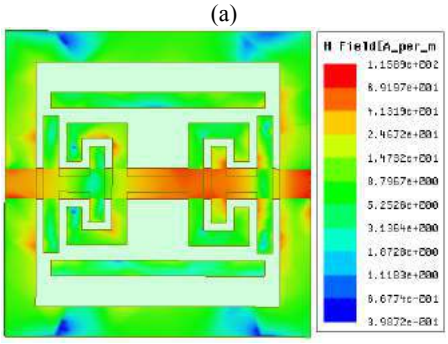
(b)

Figure 5: Distribution of currents of the metamaterial at the resonance frequency. (a) At 4.90 GHz (b) At 9.30 GHz.

From the figure, it is observed that the current density is mainly concentrated on the resonator and the FTL. Two opposite directional magnetic dipoles are formed on the ground frame due to symmetrical rotation of the surface currents on the resonator. Figure 6 shows the induced magnetic field of the metamaterial structure.



(a)

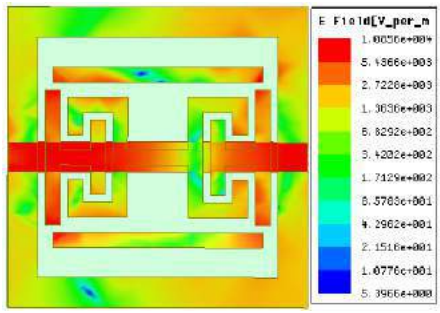


(b)

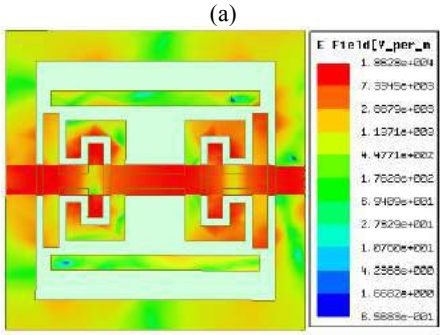
Figure 6: Distribution of magnetic field of the metamaterial at the resonance frequency. (a) At 4.90 GHz (b) At 9.30 GHz.

From the figure, it is investigated that at the resonance frequency, the FTL is coupled to the ground frame and the resonator with its electric field. At this point, the metamaterial structure shows the inductive and capacitive behavior due to the ground frame and the space between the ground frame and the resonator. The induced magnetic field is opposite to the external magnetic field and hence diamagnetism is generated. Due to the diamagnetism property, the negative permeability is extracted by the metamaterial structure. The magnetic field is vertical to the ground frame and the resonator. Thus, the negative permeability rises through the magnetic field, ground frame, and the resonator. As the metamaterial structure shows negative permittivity as well, the metamaterial gives a negative refractive index which is shown in Figure 4. Due to the collateral combination of the electric field of the structure to the ground frame, resonator, and the FTL, the negative permittivity rises. The presence of the ground frame around the resonator produces additional inductance and capacitance to the metamaterial structure and hence it becomes a crucial factor to create resonance. Moreover, the ground frame also serves as the ground plane, which provides the negative permittivity and negative permeability through the inductive-capacitive properties of the proposed structure.

The electric field distribution of the proposed resonator based metamaterial is shown in Figure 7. According to the figure, the electric field distributions are quite consistent with the surface current distribution and the magnetic field distributions. The electric field is distributed on the resonator, ground frame, and the FTL. The intensity of the electric field is enhanced at the higher frequency.



(a)

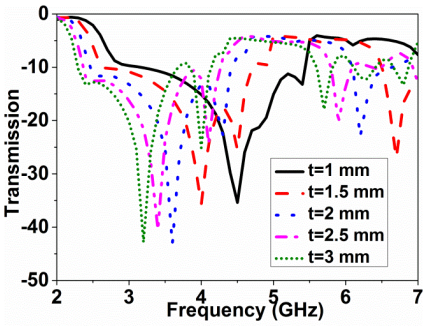


(b)

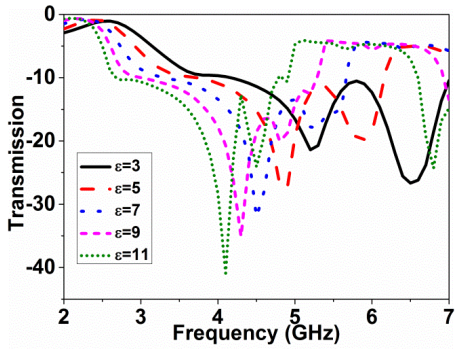
Figure 7: Electric field distribution of the proposed metamaterial at the resonance frequency. (a) At 4.90 GHz (b) At 9.30 GHz.

5. Metamaterial Sensor Application

The proposed resonator based metamaterial structure is used for the double-sided sensing system. The both front and back side of the proposed metamaterial is used in the sensing application. The unknown material which is to be detected is taken as the over-layer. By changing the thickness and the dielectric constant of the unknown material, the frequency response of the metamaterial sensing device is experimented.



(a)



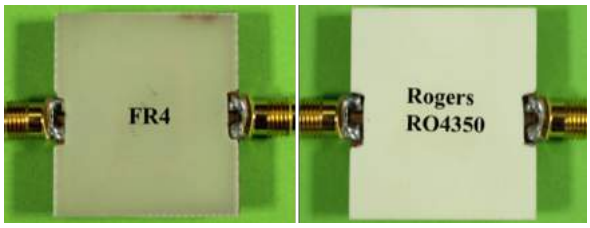
(a)

Figure 8:Change of transmission resonance. (a) for changing overlayerthickness (b) for changing overlayer permittivity.

Firstly, the effect of changing the overlayer thickness is considered to observe the frequency response. For the simulations, an over-layer with dielectric constant 4.4 and 0.025 loss tangent is considered as it is close to the parameter of the FR4 substrate which is used in the proposed metamaterial. Figure 8 (a) shows the simulated results after changing the thickness of the over-layer. From the figure, it is clearly observed that the transmission resonance shifts downward with the increase of the overlayer thickness. The sensing device along with the over-layer can be considered as the RLC resonant circuit in which the resonance frequency is calculated by the effective capacitance and the effective inductance. With the increment of the overlayer thickness, the effective inductance, and capacitance changes. Due to this, the transmission resonance shifts downward as the resonance frequency are directly related to the effective capacitance and the effective inductance. Thus, the proposed metamaterial structure can be effectively used in sensing application in the GHz region.

The frequency response due to changing the overlayer relative permittivity is simulated and analyzed. Figure 8 (b) illustrates the effects of the variation of the overlayer relative permittivity. When the relative permittivity is increasing, the transmission resonance downshifts as well. The higher overlayer permittivity corresponds to a larger downshift of the transmission resonance. Hence, the sensitivity of the metamaterial increases, according to the increment of the overlayer relative permittivity.

For the validation of the simulation, the practical experiments have been performed and the measured results are compared to the simulated results. In the practical observations, the FR4 material having a relative permittivity of 4.6 with 0.02 loss tangent and Rogers RO4350 material having a relative permittivity of 3.66 with 0.004 loss tangent are used as the over-layers. The thickness of the materials is 1.60 mm and 1.53 mm respectively. The metallic ledge on both portions of the substrates is abolished to have the over-layer having the dielectric materials only. The proposed metamaterial structure with the over-layers are shown in Figure 9.



(a) (b)

Figure 9:Picture of the sensing device. (a) FR4 as over-layer (b) Rogers RO4350 as over-layer.

The measured results of the proposed resonator based metamaterial as a sensor along with the simulated results are displayed in Figure 10.

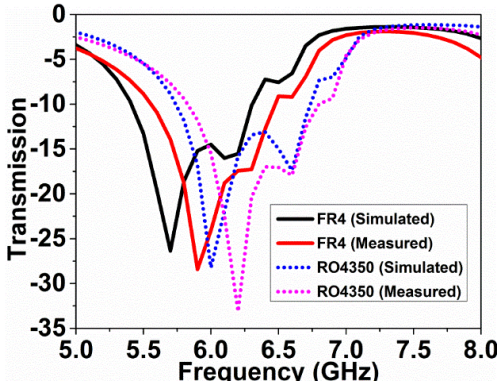


Figure 10:Simulated and measured transmission response with FR4 andRogers RO4350 over-layers.

From the figure, it is clearly investigated that the resonance frequency shifts downward with the increment of the thickness and the overlayer relative permittivity. As the FR4 has a larger thickness and higher relative permittivity than the Rogers RO4350 material, FR4 shifts more downward than the Rogers RO4350 overlayer with reference to no overlayers which is shown in Figure 3. More specifically, with no over-layer, the transmission resonance is at 7.60 GHz, but using the Rogers RO4350 and FR4 over-layers, the transmission resonance shifts to 6.20 GHz and 5.90 GHz, respectively.

To extend the experiment, double-overlayer structures are considered for perplexing situations. In this scenario, FR4+FR4 and Rogers RO4350+Rogers RO4350 double-over-layers are used. The simulation and practical investigations are conducted by the similar procedure as described in the previous section. The simulated and measured frequency responses for the double-over-layers is illustrated in Figure 11.

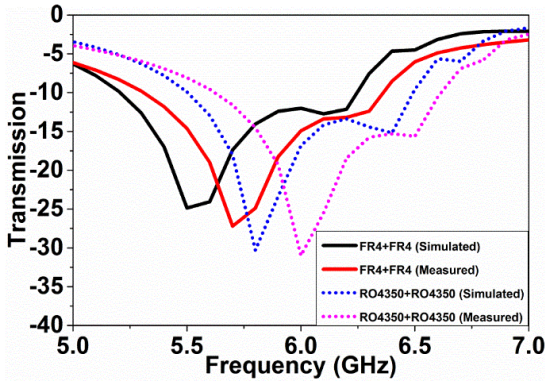

Figure 11:Simulated and measured transmission response with FR4+FR4 andRogers RO4350+Rogers RO4350 double-over-layers.

From the figure, it is clear that the resonance frequency shifts downward with the increment of the thickness and the overlayer relative permittivity. With no over-layer, the transmission resonance is at 7.60 GHz, but using the Rogers RO4350+Rogers RO4350 and FR4+FR4 double-over-layers, the transmission resonance shifts to 6.0 GHz and 5.70 GHz, respectively.

Both in the over-layer and double-over-layer cases, the simulated results vary a little with the measured results. This could be due to the mechanical etching of the metallic layer of the dielectric materials, external reflections during measurements, and soldering inaccuracies. Based on the simulations and measurements performed above, the proposed resonator based metamaterial can detect materials having different values of thickness and relative permittivity. The proposed metamaterial can be used as a sensor in various applications.

6. Conclusions

A resonator based metamaterial structure is designed, simulated, prototyped, and investigated as a sensor in this paper. The resonator is surrounded by a ground frame and is excited by a 50Ω feeding transmission line on the back side of the substrate. The metamaterial is measured by using common laboratory facilities instead of using waveguides. Both the results found in the simulation and measurement agree quite well and the metamaterial shows negative permittivity and negative permeability in the operating band. The proposed metamaterial can be used in various applications such as antennas, filters, sensors, imaging systems, etc. In this study, the metamaterial structure is used in sensor application where it can detect unknown over-layer materials with good sensitivity. The metamaterial properties with an uncomplicated design, using only one metamaterial unit cell make the structure competent to be used where metamaterial characteristics are needed.

Abstract

The aim of this paper is to investigate the inter-relation between lateral displacement and desired axial distance in an integrated planar loop with mu near zero (MNZ) spiral resonators on establishing sustained energy efficiency for low power wireless energy transfer application. The proposed study is done by utilizing RO 4350 from Rogers with dielectric constant of 3.66. Variation ratio of up to 0.37 is observed for operating distance between 20mm to 25mm within quotient value of lateral displacement and distance. It can be discerned that there is potential to achieve robustness towards misalignment with MNZ metamaterials.

1. Introduction

Besides the operating distance between inductive loops, alignment between the transmitter and receiver is also a crucial feature in wireless power transfer as link transfer efficiency is reduced significantly under lateral misalignment condition [1]. Stable power transfer efficiency (PTE) within distance of up to 30 mm is reported in [2] by employing 3 by 3 array of negative permeability metamaterial. This paper provides the examination on the influence of axial distance, z towards efficiency upon integration with metamaterial that possess permeability close to zero. The proposed design is etched on RO 4350 substrate with dielectric constant of 3.66 and thickness of 0.254 mm. The double-sided RO 4350 with the 0.035 mm copper deposited on top is used. The overall dimension of the proposed design is 70 X 70 mm.

2. Design and Output

As shown in Figure 1 (a), inner length of metamaterial unit cell, *Ui* is 13.78 mm whereas the width, *wu* is 1.02 mm. The proposed five turns square spiral resonator is completed with lumped element of 200 pF capacitor to facilitate frequency resonance tuning. The extraction of permeability from single unit cell is retrieved by employing robust method [3, 4]. Figure 1(b) indicates that the permeability is near zero around desired operating frequency of 13.56MHz.

A single turn planar loop with inner diameter length, Di of 58.80mm and loop width, w of 0.85mm is designed on the bottom layer of the substrate as depicted in Figure 1(c). Simulations for axial distances ranging from 20mm till 25mm are performed with the aid from full wave finite element simulator. PTE is derived from s-parameters as $|S_{21}|^2$. Figure 2 reveals that consistency of peak transfer efficiency above 65% is feasible for operating distance between 20mm to 25mm within quotient value up to 0.4. The variation ratios of peak transfer efficiency are tabulated in Table 1. It is observed that optimal axial distance to compensate for lateral displacement, ay for this proposed design is at 20mm with lowest peak transfer efficiency variation ratio of 0.19.

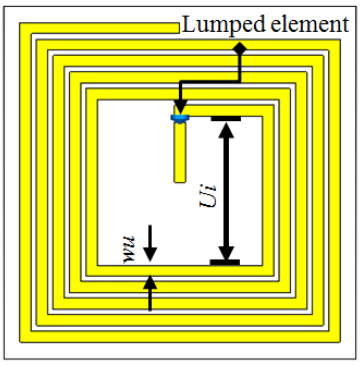

Figure 1(a): Unit cell

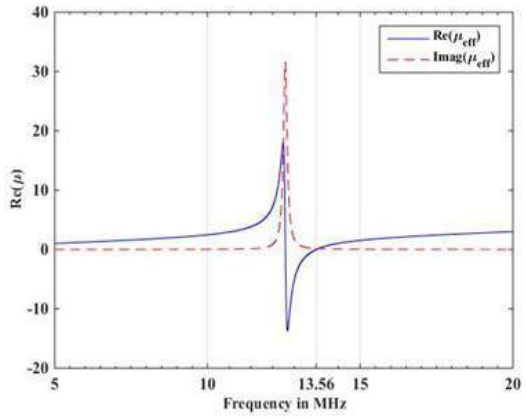

Figure 1(b): Permeability extraction from a unit cell

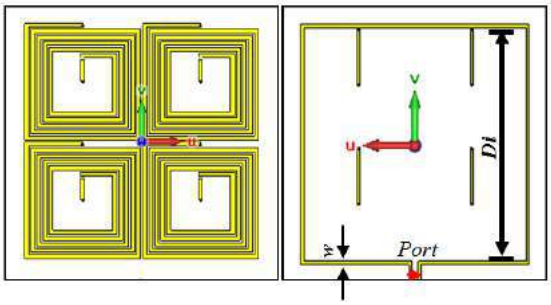

Figure 1(c): Front and bottom layer of proposed design

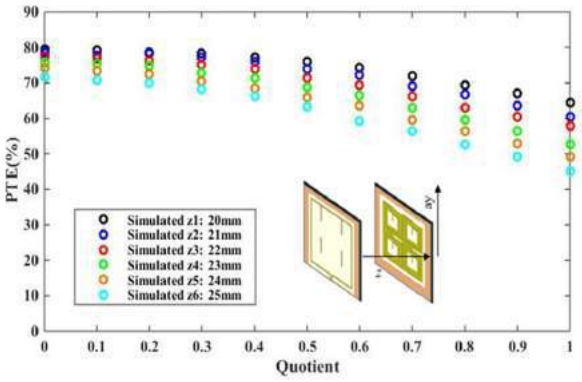

Figure 2: Peak power transfer efficiencies

Table 1: Variation ratio of peak transfer efficiency.

Axial distance (mm)	20	21	22	23	24	25
Variation ratio	0.19	0.23	0.25	0.31	0.34	0.37

3. Conclusions

A single turn planar loop incorporating permeability near zero metamaterial is proposed and analyzed. The capability of permeability near zero metamaterial in enhancing coupling allows a uniform magnetic field and sustained energy efficiency for wireless energy transfer application under lateral displacements condition. This analysis can be further extended to longer axial distances.

Abstract

A high gain circular split-ring resonator (CSRR) based triple band antenna with Frequency Selective Surface (FSS) is presented in this paper. The proposed FSS structure is used to enhance the gain of the antenna. Significant improvement in gain has been noticed after implementing the proposed FSS layer. The antenna achieved realized gain of 3.5 dBi without the FSS where the same antenna with FSS attained 6.0 dBi of realized gain at the resonant frequency. The reflection coefficient has good agreement of the antenna with the FSS structure. The antenna also exhibited directive radiation pattern after using FSS. The proposed unit cell is structured with S-shaped meandered line on FR4 substrate. The dimension of proposed FSS structure's unit cell is 10 mm×10mm. The design and simulation of the proposed antenna and the FSS structure is performed in CST Microwave Studio.

1. Introduction

At presents antenna with high gain, wide bandwidth, directive radiation and low cost are some the prime interests of the researchers in wireless communication. Several versatile methods are being used to enhance the performance of antenna parameters like tapered shaped slot[1],modified ground plane[2], using coupled resonator[3] and many more. Use of frequency selective surfaces (FSS) is one of the most effective technique to enhance the antenna performance. A number of antenna are presented in[4-6] using FSS to enhance the antenna characteristics. In [7], FSS structure is used to aid the bandwidth backing reflector functions. FSS based corner reflector is used to enhance the performance of a dual band monopole antenna in [8]. In this paper, a S-shaped meandered line FSS structure is presented for gain enhancement along with performance verification using a circular split-ring patch antenna.

2. Unit cell and Antenna configuration

The unit cell and the array of the proposed FSS structure is shown in figure 1. The unit cell consists of S-shaped meandered line. The dimension of unit cell is 10 mm×10 mm. The length of each line is 5 mm and width is .5 mm. The array of unit cell used to form a frequency selective surface. The size of array is 3×4 with 41.5 mm length and 31 mm width. The gap between each unit cell is 5.5 mm.

(b)

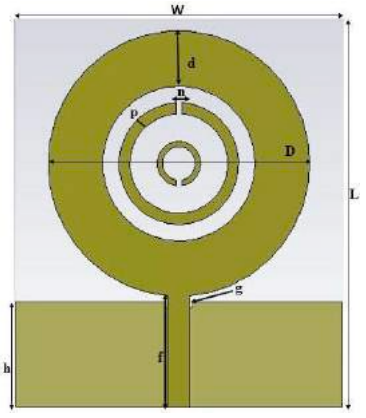
Figure 1. (a) Unit cell (b) FSS structure

The layout of proposed triple band CSRR antenna is depicted in figure 2(a). The parametric values of propose antenna is illustrated in table 1.

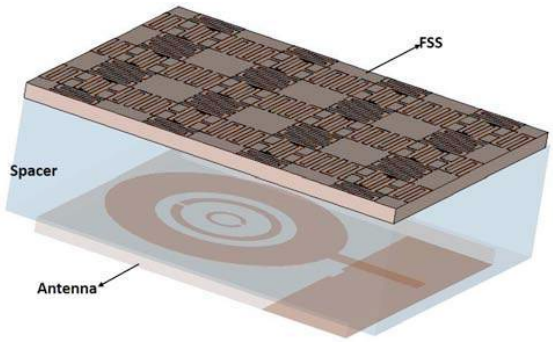
Table 1: Design parameters of propose antenna.

Parameter	Value [mm]	Parameter	Value [mm]
L	35	p	1
W	30	D	24
d	5	g	0.25
n	0.5	h	9.63
f	10.04		

The perspective view of the proposed FSS structure with the antenna is represented in figure 2(b). The antenna and the FSS are combined in a single unit using a spacer vacuum box. The vacuum space between these two layers is 11.85 mm. The appropriate selection of surface-state and accuracy of spacer enhance the antenna performance specially the gain.



(a)



(b)

Figure 2. (a) Antenna without FSS (b) Antenna with Proposed FSS structure.

3. Antenna Performance Analysis

Significant improvement in gain of the antenna is observed after using proposed FSS structure shown in figure 3. Without FSS the realized gain is around 4 dBi, where using FSS the realized gain is reached up to more than 6 dBi. This gain enhancement proofs the effectiveness of FSS structure.

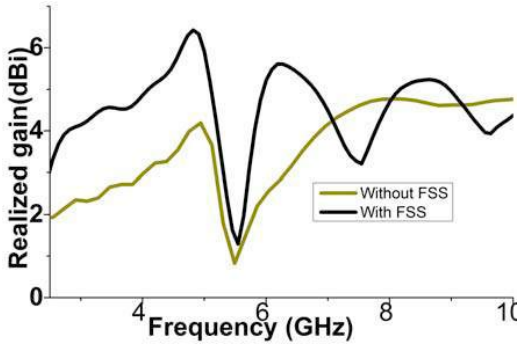


Figure 3. Gain enhancement of proposed antenna using FSS Structure

The reflection co-efficient of proposed antenna is shown in figure 4(a), which shows triple band of -10dB impedance bandwidth from 2.6 GHz to 3.6 GHz, 5.6 GHz to 6.7 GHz and the final band is from 7.9 GHz to 14.3 GHz. The multiband characteristics ensure the use of proposed prototype for multifunctional devices. The proposed CSRR antenna have three working resonance at 3.3, 6, 8.5 and 12.83 GHz.

(c) (d)

Figure 5. Surface current of CSRR antenna (a) 3.3 GHz (b) 6 GHz (c) 8.5 GHz (d) 12.83 GHz

The surface current distribution of proposed antenna is shown in figure 5(a-d) at four resonant frequency. The most current conducting area of the proposed prototype is around fed line and lower part of patch. At higher frequencies, there exist few nulls on the patch due to the higher order current mode. The radiation pattern of proposed antenna is presented in figure 6. The antenna is directive to the z direction and at higher frequency the directivity is moves to the phi direction due to the change of current conducting area on the surface.

4. Conclusion

A triple band frequency selective surface based spit ring

resonator antenna is presented having dimensions 30 mm× 35 mm. FSS structure is implemented with CSRR antenna to enhance the gain. The antenna gain is significantly improved from 3.5 dBi to 6.0 dBi. The antenna also exhibited directive radiation pattern after using FSS. The design and simulation of the proposed antenna and the FSS structure is performed in CST Microwave Studio. The antenna provides triple band over UWB band and be potential candidate for multiband applications.

Abstract

A dual band sub-loaded artificial magnetic conductor (AMC) structure is presented for dual band WLAN application. Detailed evolution of our design has been discussed. It has been shown that the upper AMC band can be tuned by varying the stub length of the structure. The array of the proposed AMC unit cell is then used as a reflector for a monopole antenna. It has been shown that the gain of the antenna is improved up to 6.3 dBi, whereas fractional impedance bandwidth has increased from 14.68 % to 33.87%.

***Index Terms*—Gain, FBR, SAR.**

1. Introduction

Exponential growth of communication systems in real life has necessitate the enhancements of planar antenna performance besides their readily available features such as low profile, light weight, and compliance to rapid prototyping methods which make them easily conformal to the host surface. However, such antennas suffer from several disadvantages such as narrow operational bandwidths, low gains and excitation of surface waves which eventually reduces its radiation efficiencies. Many techniques have been proposed in the literature to overcome these drawbacks such as introducing slots in the patch[1], utilizing thick substrates [2], and employing non-symmetrical CPW feeding[3]. Recently, metasurfaces have also been utilized to increase the radiation performance of microstrip antennas[4]. Among them, AMC/EGBs have gained much attention due to their ability in suppressing surface waves and exhibiting High Impedance Surfaces (HIS) characteristics within their operational frequency bands [5, 6]. AMCs are periodic arrangement of unit cells used as antenna backing surfaces to enhance gain[7], or to improve impedance bandwidth of these antennas[8]. They are also used to mitigate back radiations effects towards human body for wearable antenna applications [8-10].

The most prominent property of the AMC, also known as HIS, is that it exhibits the characteristics of PMC (Perfect Magnetic Conductor) surface reflecting the incident wave with almost zero reflection phase [7]. It is pertinent to note that the opposite of PMC is Perfect Electric Conductor (PEC) plane which exhibits 180^0 phase reflection. The useful bandwidth of AMC is generally defined as the reflection phase between -90^0 to 90^0 on both sides of the zero-phase reflection. Within this phase reflection band, a non-destructive interference between incident and reflected waves [11] occurs, resulting in the impedance bandwidth and gain increase of the antenna, and consequently reducing the back radiation towards the human body for wearable application as reported in [12] .

The AMC design presented in this work enables the higher band to be tuned from 5.2 to 5.8 GHz frequencies with zero reflection phase by increasing only the stubs length. This frequency band is chosen considering its applicability in the WLAN frequencies. Meanwhile, the risk of electromagnetic (EM) radiation towards the human body, defined in terms of the Specific Absorption Rate (SAR) is also evaluated. This limit is defined by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) to be 1.6 W/kg averaged over a 1g of tissue [13-15] in North America and several other countries. The contribution of the AMC array in reducing backward radiation and EM absorption in the human body when worn is assessed using SAR. [9, 10].

In this work, a dual band AMC unit cell to enhance the gain and impedance bandwidth of a monopole antenna with reduced SAR is proposed. The unit cell, as shown in Fig. 1(a), consists of an annular slot loaded with four perpendicular stubs on a simple rectangular patch. Due to inclusion of the stubs in the annular slot, the proposed unit cell reduced resonant frequency from 5.93 to 4.82 GHz (18.72%) compared to the structure consisting of only an annular slot with a radius (r_1) of 5.5 mm on the patch resonating at 6.14 GHz with the same radial length. Impedance bandwidth and gain of the monopole antenna is increased by using our proposed unit-cell as backplane of the antenna. Moreover, reduced values of SAR have been observed due to reduction of back radiations from the antenna.

This paper is organized as follows: the design procedure of

the stub loaded unit cell will be presented in the next section, followed by the CPW-monopole antenna design backed by a 4 x 4-unit cell AMC plane. To validate the safety of the antenna, a SAR analysis to investigate the back-radiation towards the human body is performed prior to the concluding remarks.

2 Unit cell and antenna design

The unit cell and monopole antenna backed by the AMC plane are designed using Computer Simulation Technology (CST) software, which uses the Finite Integration Technique (FIT) for solving Maxwell's equations.

2.1. AMC design

The unit cell of AMC structure is designed on a FR4 substrate with a relative permittivity (ε_r) of 4.5 and a loss tangent (tan δ) of 0.019. It is 3.2 mm thick and sized at 12 x 12 mm^2. The design is based on a simple rectangular patch structure prior to the introduction of an annular ring slot in the patch to enable dual band behavior. Finally, four perpendicular rectangular stubs in the circular patch is added to reduce the second resonant frequency of the structure as shown in the Fig. 1(b). The decrease in the upper frequency band results from the rectangular stubs behaving as interdigital capacitors in the structure. It can be seen in Fig.1(c) that as the length of the rectangular stub is increased from 1 to 3 mm, the higher band of our structure decreased from 5.67 GHz to 4.62 GHz (18.52 %) with slight perturbation (only 3.21 %) in the lower band. This also indicates the miniaturization of the structure with reduced AMC operational bandwidth in the upper band from 656 MHz to 524 MHz with the variation of the stub length.

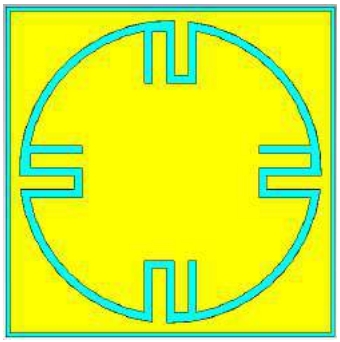

Figure 1:(a) Proposed AMC unit cell

Angular stability is also investigated using a constant stub length of 2 mm. It is observed that for a varying θ angle of the incident TE mode waves, the angular stability of the proposed structure is up to 75^0 for the polarization angle of $\varphi=0^0$.

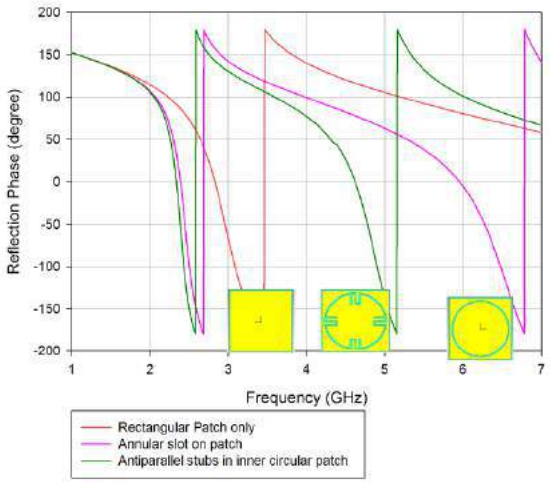

Figure 1:(b) Simulated reflection phase characteristics of the three structures in the design evolution of the proposed unit cell.

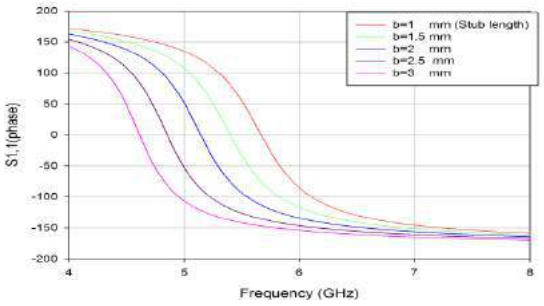

Figure 1:(c) Effect of stub lengths on the upper band of the AMC structure

2.2. AMC backed monopole antenna

A CPW monopole patch antenna is then designed on a 1.6 mm FR4 substrate to validate the functionality of the proposed unit cell design acting as a reflector. Using a 4 x 4-unit cell array to form the AMC plane, a dual band behavior is exhibited to mainly provide operation at 5.2 GHz (upper band) due to the narrow bandwidth in the lower frequency band. The overall size of the AMC backed antenna is 48 x 48 x 9.76 mm^3 including a 4 mm of spacer used to separate the antenna from AMC structure for better impedance matching.

2.3. Results and discussion

The impedance bandwidth of the monopole antenna, as shown in Fig. 2, has been improved from 0.762 GHz (14.68 %) to 1.54 GHz (33.87%) using the proposed AMC structure. Moreover, the gain of the AMC backed antenna increased significantly from 1.07 dBi to 6.3 dBi at 5.2 GHz, which is within the AMC operational bandwidth. This proves that the

proposed structure is behaving as a PMC plane for the monopole antenna. This increased its impedance bandwidth and gain of the antenna.

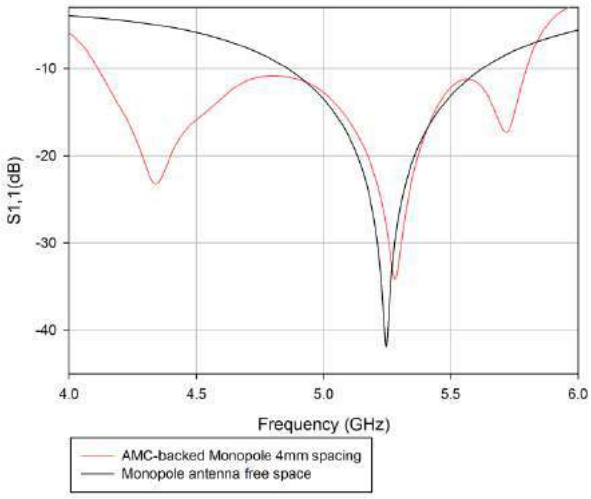

Figure 2: Simulated reflection coefficient of the monopole antenna in free space with and without AMC.

As can be seen in the Fig. 3, the gain of the AMC-backed antenna increased up to 6.3 dBi. The front to back ratio is observed to be more than 12 dB throughout the operational bandwidth of the AMC (4.89-5.45 GHz) with a maximum FBR of 25 dB observed at 4.8 GHz. This indicates its effectiveness in back radiation reduction for wearable antennas.

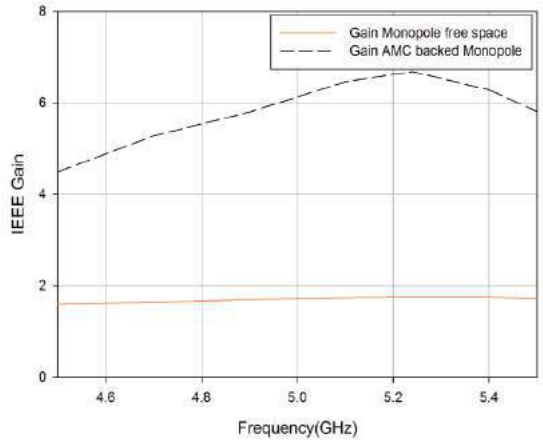

Figure 3:(a) Comparison of the IEEE gain of monopole antenna with AMC-backed Monopole

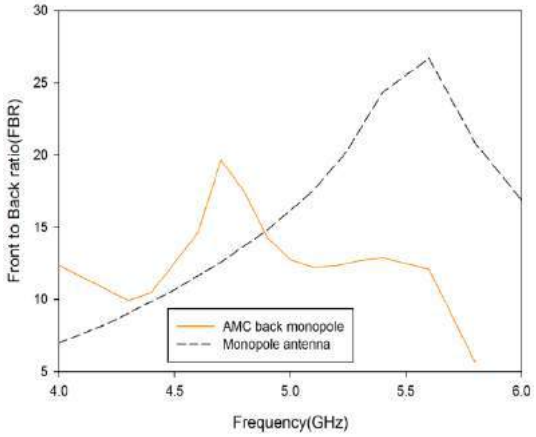

Figure 3:(b) Comparison of the FBR of monopole antenna with AMC-backed Monopole

2.4. Specific Absorption Rate

Due to health concerns resulting from EM radiation towards human body, it is imperative that the SAR of this antenna is evaluated when placed on the human body. For that reason, a series of simulations is performed using a numerical human model consisting of a layer of skin (3 mm thick), fat (7 mm thick), and muscles (60 mm thick). To ensure the $\lambda/4$ margin between the antenna and human tissue model edges, the total volume of the model is taken as 150 x 150 x 80 mm^3. The model and its dielectric properties at 5.2 GHz has been validated in [16, 17]. It has been assigned dielectric values from [18]. The antenna is placed on the body model with and without AMC. The proposed AMC-backed antenna indicated less EM radiation influence on the human body tissues due to the zero-phase reflection provided by the AMC. It can be observed that the maximum SAR is 0.68 kg/W averaged over 1g of tissue, in compliance with the ICNIRP limit of 1.6 kg/W. Generally, the SAR values at the higher frequencies is relatively higher due to the increased conductivity of the human body. Thus it can be expected that the SAR value in the lower ISM band (2.45 GHz) is also relatively lower. The total dimension of the structure also complies with the recommended wearable devices size of 50 x 50 mm^2 [19].

3. Conclusion

A dual band sub-loaded AMC-based structure is proposed and evaluated. It is shown that by varying the stub length of the structure, the higher AMC band can be tuned. The proposed AMC is effective in functioning as a reflector, improving antenna gain up to 6.3 dBi and increasing fractional impedance bandwidth has increased from 14.68 % to 33.87% GHz. It is also validated that the SAR value evaluated in proximity of a simplified human body model is well below the regulatory limits.

Abstract

A wearable planar textile antenna with dual-band AMC plane for GPS and WLAN applications is presented. The antenna design begins with two rectangular slotted octagonal patch to enable miniaturization. This radiator is placed on top of a Kevlar substrate and integrated with an AMC plane beneath it. The AMC unit cells are formed using a corner-truncated square patch with dodecagonal ring for dual-band operation at 1.575 GHz and 2.45 GHz, resulting gain enhancement to 3.05 dB and 3.897 dB, respectively.

1. Introduction

Metamaterial is an artificial structure that is designed to obtain specific characteristics which are not naturally available in nature [1-2]. The unique characteristics of metamaterial have been used extensively in antennas and microwave applications for performance improvement [3].

Artificial magnetic conductor (AMC) has been widely used as a mechanism to enhance antenna performance [1] such as its radiation characteristics on a wideband textile planar antenna [2-5], gain, bandwidth [2-4] and directivity [3, 5]. Many applications also require their antenna to work at two different frequencies simultaneously, resulting in the same requirements for the AMC plane [6]. In this work, a wearable antenna with an AMC plane is designed using textile materials to operate at 1.575 GHz and 2.45 GHz.

This paper is organized as follows. Section 2 presents a description of the materials used in the proposed antenna. Antenna design and results of simulations are presented in Section 3 and finally concluded in Section 4.

2. Textile Materials

Two textiles types were used in this design; ShieldIt Super (as its conductor) and Kevlar (as its substrate). ShieldIt Super is 0.17 mm thick with a conductivity of 1.18 x 105 S/m, whereas Kevlar is a 0.4 mm thick textile with a relative permittivity, (εr) of 1.56 and loss tangent (tan- δ) of 0.0612. The proposed antenna is fed using a 50 Ω SMA connector. CST Microwave Studio software is used for the numerical simulations.

3. Antenna Design

The proposed AMC unit cell is based on a hexagonal patch formed from a square patch and truncated at all corners. A dodecagonal ring slot is then added, as shown in Figure 1. Its resulting reflection phase is plotted in Figure 2, indicating operation at 1.575 GHz and 2.45 GHz. The unit cell is then multiplied to form a 3 x 3 array to form the AMC plane. It is then integrated beneath the optimized antenna as illustrated in Figure 3, resulting in the reflection coefficient seen in Figure 4. This antenna operates at 1.575 GHz and 2.45 GHz.

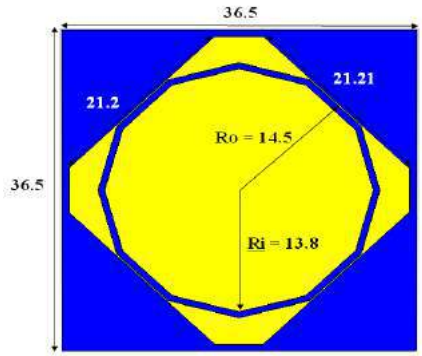

Figure 1: The unit cell of dual-band AMC (all dimension in mm).

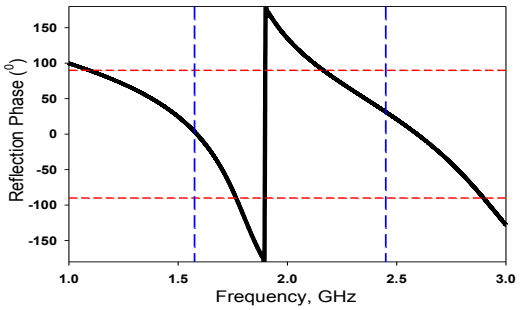

Figure 2: Reflection phase of the proposed unit cell.

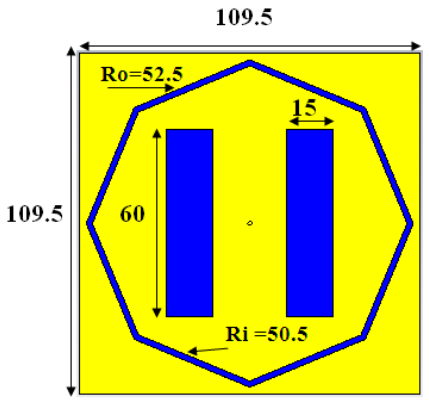

Figure 3: Dual-band textile antenna (all dimensions in mm).

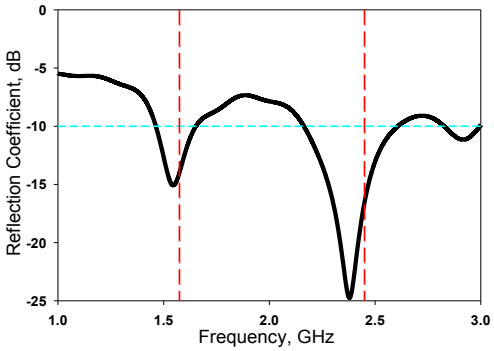

Figure 4: Reflection coefficient of the proposed antenna.

4. Conclusions

A wearable textile antenna with dual-band AMC plane is presented. The radiator is designed using a slotted octagon ring to operate at 1.575 GHz and 2.45 GHz. The AMC plane consisting of 3 x 3 octagon patches slotted with a dodecagon ring operates at 1.575 GHz and 2.45 GHz resulting gain enhancements to 3.05 dB and 3.897 dB in the lower and upper band, respectively.

Abstract

A single rectangular gap-coupled resonator inspired mobile wireless antenna is presented for low specific absorption rate applications. The proposed antenna consists of a microstrip fed rectangular with a slotted partial ground plane. The antenna achieves multiband characteristics, which can operate at PCS 1900, WCDMA, Bluetooth, WLAN 2400, WiMAX 2.5 and WLAN 5 GHz frequency band applications. The antenna is fabricated on copper clad bio-degradable substrate material, made of biomass, organic source material, moulding ceramic powder and polymeric binder. The perceptible novelties of the proposed antenna is appreciable SAR reduction with covering most widely used mobile communication bands.

1. Introduction

With the recent advances in wireless technology system, antenna researchers are facing challenges to design antenna for next generation multifunctional mobile applications. Nowadays, antenna researchers have to concentrate on EM radiation from wireless devices and using environment friendly composite material for ensuring safer use of wireless devices.

In recent years, several planar antennas with different shapes and sizes have been introduced for mobile wireless applications [1-9], like slot antenna [1], metamaterial antenna [2], coupled resonator antenna [3], etc. Alam et al. proposed metamaterial unit cell based antenna for wireless mobile application with the 0.26 λ × 0.26 λ× 0.0084 λ at 1.6 GHz lower frequency band [2]. A coupled resonator concept has been adopted in antenna, which has achieved a significant reduction in antenna dimension with satisfying antenna performances [9]. A metamaterial inspired dual frequency bands antenna has been proposed for mobile applications in [10], which can cover DCS, GSM1800, WCDMA, and Bluetooth frequency bands with dimension of 50×50×1.6 mm3.

Moreover, organic multilayer substrate has been introduced in antenna design, where, conventional fossil petroleum-based material is replaced by bio-based substrate materials [11]. Alam et al. developed a bio-substrate based material for wireless mobile communication [11], which can operate at GSM 1800, UMTS (1.92-2.17 GHz), LTE 40 frequency band with antenna size of 48×48×1.95 mm3.

In this communication, we propose a bio-substrate based coupled resonator antenna for multifunctional mobile applications. In order to satisfy the requirement of the next-generation wireless communication, the EM absorption rate of the proposed antenna has also been analyzed with human head phantom.

2. Antenna Design

The geometrical layout of the proposed coupled resonator inspired antenna is shown in Figure. 1. Commercially available CST microwave studio software has been adopted to design and investigate the antenna performances. The antenna is designed on organic or bio plastic-based substrate with dielectric constant of 15.0. The bio-plastic substrate material made of biomass organic source material, molding ceramic powder and polymeric binder. The antenna consists of a rectangular frame shape radiator and inverted L shape slotted ground plane. The antenna is fed by a 1.5 mm L-shape microstrip line. The input impedance of the microstrip line is 50Ω. All the design parameters are listed in Table 1.

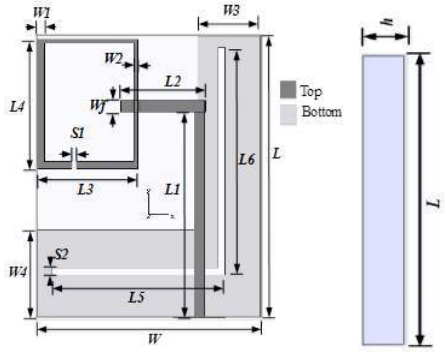

Figure. 1. Schematic design of the proposed antenna

Table 1. The proposed antenna design parameters.

Parameter	Dimension (mm)	Parameter	Dimension (mm)
L	33	S1	0.6
W	32	S2	2.0
h	1.6	L1	28.5
W1	1.0	L2	9.5
W2	0.5	L3	14.5
W3	9.0	L4	16.0
W4	11.5	L5	22.0
Wf	1.5	L6	28.0

3. Antenna Performances

The fabrication of the desired antenna has been performed using a PCB prototyping machine named Protomat S63 from LPKF as depicted in Figure 2. Performance Network Analyzer (PNA Agilent N5227A) has been used to perform the antenna reflection coefficient measurement. The reflection coefficient of the proposed antenna is presented in Figure 3. It is shown from Figure 3 that the measured and simulated reflection coefficients are nearly identical. There is a slight discrepancy between simulation and measurement results, possibly caused by SMA soldering in manual. The antenna shows multi-resonant, which can be used for multi-application of wireless communication. The antenna has achieved two wide impedance bandwidths as, 1.89-4.4 GHz and 4.87-5.84 GHz.

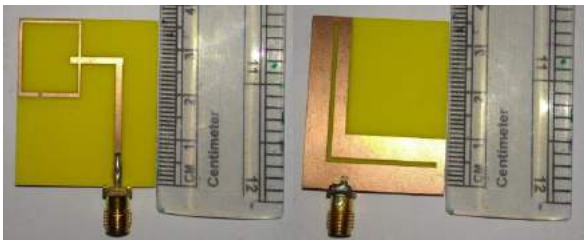

Figure 2: Prototype of the proposed antenna

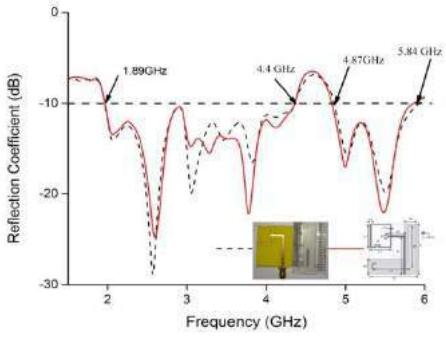

Figure 3: Reflection Coefficients of the proposed antenna

Moreover, the surface current distribution of the proposed antenna at 1.90 and 2.40 GHz are illustrated in Figure 4. From Figure 4, it is seen that at lower frequency the maximum current flows at the rectangular frame patch and for higher order of frequency the main patch has less effect. The far-field radiation pattern of the proposed antenna with human head phantom is shown in Figure 5. The antenna shows directional radiation patterns. The antenna exhibit 4.57 dBi of far-field directivity away from head phantom at 1.90 GHz and 6.81 dBi at 2.4 GHz .

In modern society, the wide use of mobile phone can be resulted inimical radiation from the devices. There are several myths about the biological effect for using a mobile phone. Tissue heating is one of them[12-13]. The principal mechanism of tissue heating is the interaction between radio frequency energy and the human body. The specific absorption rate is defined by the power absorbed per unit of mass of biological tissues, which is the measurement system of tissue heating due to RF energy absorption. At present, two established institutions have developed exposure guidelines: IEEE and ICNIRP. The SAR limit

specified in IEEE C95.1:2005 is 1.6 W/kg in a 1 g averaging mass and 2 W/kg in a 10-g averaging mass of tissue [14]. To comply with the guidelines, the specific absorption rates of the proposed antenna have been investigated. The simulated SAR analysis is presented in Figure 6. And measured result is in Figure 7. It is shown from Figure 6 that the proposed antenna shows 1.21 w/kg and 1.19 w/kg of 1g SAR at 1.9 and 2.4 GHz, respectively. Besides this the measured SAR values of the proposed antenna shows 1.34w/kg and 0.98 w/kg of 1g SAR at 1.9 and 2.4 GHz, respectively. There is a discrepancy is observed between simulation and measurement results due to measurement setup and used measurement liquid. But it is observed from both measured and simulated results that the proposed antenna exposed lower SAR values than standard SAR guidelines.

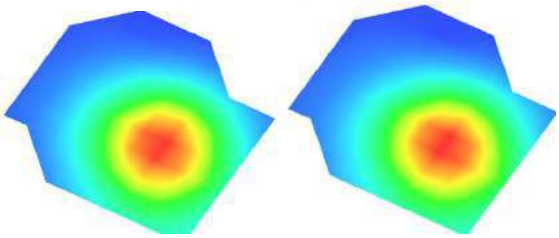
at (a). 1.9 and (c) 2.6 GHz



(a) (b)

Figure 7: Measured specific absorption rate analysis of the proposed antenna at (a). 1.9 and (c) 2.6 GHz

4. Conclusions

A coupled resonator based antenna is proposed for multifunctional wireless applications. The antenna enables to operate in the frequency bands of the upper GSM band, Bluetooth, WLAN 2400, WiMAX 2.5 and WLAN 5 band with satisfactory antenna performances. Moreover, the antenna satisfies the EM absorption guidelines established by IEEE and ICNIRP without degrading other antenna performances.

Abstract

A 3D antenna design followed by metamaterial unit cell is presented in this paper for portable microwave imaging system to scan human head. The proposed antenna is based on bounded H-shaped 10×10 mm^2 unit cell. FR4 lossy material is used as substrate for the box shaped design. 3×3 array of the unit cell is used as ground. Another array of unit cell is used as reflector on the bottom wall of the box. Finally, the antenna achieved operating band at 2.90-3.24 GHz which is within the operating band suggested by researchers for human head imaging. The overall dimension of the antenna is 50×37×14mm^3. The whole design and simulation process is performed under CST Microwave Studio simulation environment. Finally the optimum design has been fabricated and measured. The simulated and measured results are found in good agreement.

1. Introduction

Distribution of electrical property in the body can be observed through microwave images constructed by microwave imaging system in clinical diagnosis. More precisely, microwave imaging is the technique of using electromagnetic wave to observe internal architecture of objects. Microwave imaging system added more values to medical treatment due to fast and safe diagnosis.

Antennas act as main element of a microwave based imaging system. A good performing antenna can lead to an effective and portable medical diagnosis tool and finally have the potential to pave the way of saving lives. In literatures, different types of antenna have been reported for microwave imaging. Some basic properties of antenna are considered as requirements for microwave imaging. For instance, an antenna to be used for biomedical diagnosis in head imaging should have an operating frequency within 1-4 GHz [1], compact size to make the whole system portable etc.

Apart from that, several types of antennas are found in literature that are used in microwave imaging. An study reported about the use of dipole, monopole, bow-tie, Vivaldi, stacked-patch antennas for breast cancer imaging. 3D antennas are also used in human head imaging, congestive heart failure detection, breast cancer detection etc[2],[3],[4],[5],[6].

In this paper a three-dimensional antenna design is revealed for the application of microwave based human head imaging. The antenna design is followed by two arrays of 10×10mm^2 unit cell. Slotted microstrip feed-line is used for excitation purpose. The final 3D structure achieved operating band in lower microwave spectra. Frequency band at 2.90-3.24 GHz is obtained by the antenna.

2. Design of the antenna

The design and simulation of the antenna is performed using CST Microwave Studio. First of all, a unit cell is designed using 1.6mm thick FR4 lossy substrate. During the designing process, operating frequency between 2-4 GHz has been considered as the antenna is opted for human head imaging. Fig. 1 illustrates the design of the unit cell used to design the antenna. The shape of the unit cell is inspired by alphabet 'H'. Finally the shape is modified to the optimum design of the unit cell that obtained desired result.

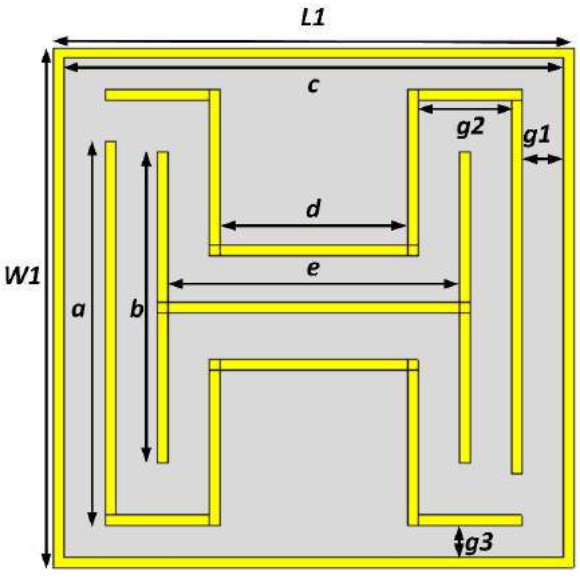

Figure 1: Design configuration of the unit cell

(a) (b)

Figure 4: Change of ground plane; (a) full ground, (b) metamaterial inspired ground

The evolution of the final three-dimensional antenna started from a basic patch antenna, depicted in Fig. 3(a), where 1.6mm FR4 used as substrate and 0.035mm thick copper radiating element. Then the array of the unit cell is placed instead of full ground plane. An array of 3x3 unit cell has been used as a ground plane that enabled the antenna to achieve operating band at lower microwave frequency. Results are shown in Fig. 4.

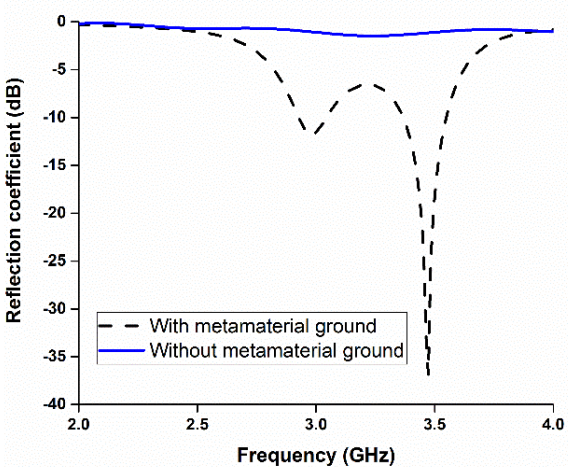

Figure 5: Reflection coefficient of the basic patch antenna

Finally, the antenna is given a rectangular box shaped structure to improve the bandwidth using the sidewalls connected with another array of unit cell on FR4 substrate. The final structure improvised the bandwidth significantly. Meanwhile a parametric study on the length of the feed line is investigated to obtain optimum result.

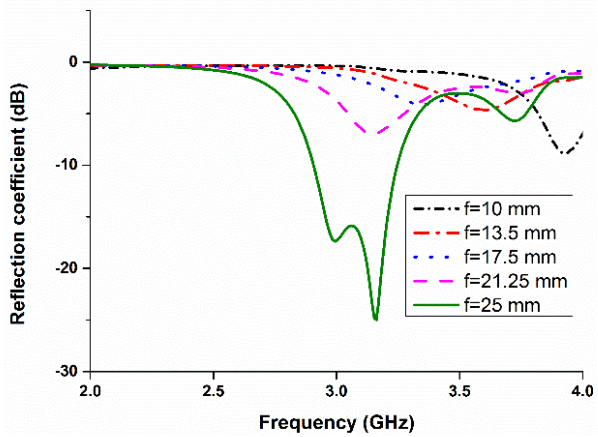

Figure 6: Parametric study on the length of the feedline

The optimum design parameters of the proposed antenna along with the unit cell are represented in Table 1.

Table 1: Design parameters of the proposed unit cell and antenna.

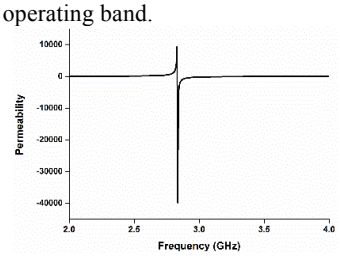
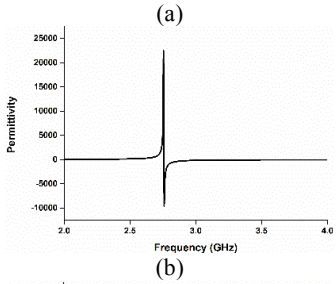
3. Results and discussion

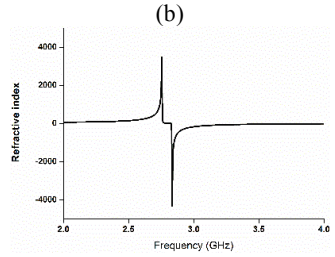
The proposed unit cell that has been used in the antenna has obtained negative permeability, permittivity and refractive index in the operating band.



(a)



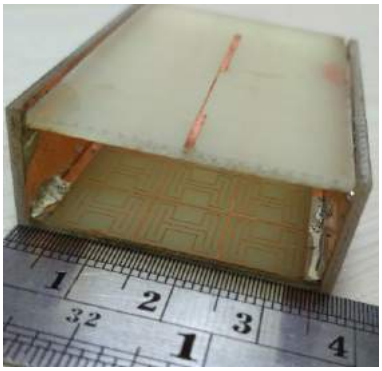
(b)



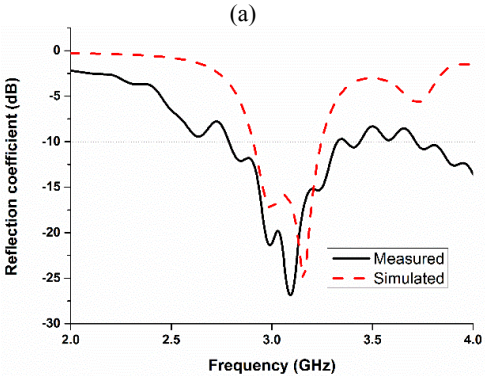
(c)

Figure 7: Calculated (a) permeability, (b) permittivity and (c) refractive index of the proposed unit cell

The final design of the proposed antenna has achieved operating and at 2.90-3.24 GHz in simulation. The fabricated prototype achived opearating band with a larger bandwidth at 3.78-3.34 GHz. The bandwidth increased from 340MHz to 560MHz after fabrication. Possible reason could be fabrication and measurement tolerance. Results are shown below in Fig. 8.



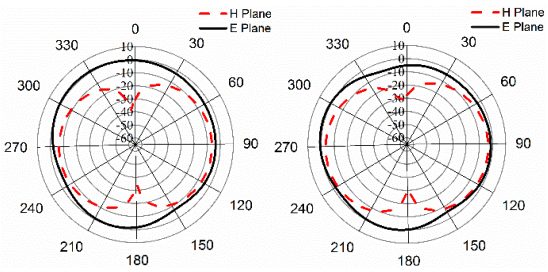
(a)



(b)

Figure 5: (a) Fabricated prototype, (b) Reflection coefficient of the proposed antenna

The proposed antenna achieved bidirectional radiation pattern in H plane and almost omnidirectional radiation pattern in E plane.



(a) (b)

Fig 5: Radiation pattern at (a) 3.00 GHz (b) 3.15 GHz

Radiation efficiency of the proposed antenna has been shown in Fig. 7. From the figure it can also be noticed that,

efficiency of the proposed antenna is more than just the patch antenna with unit cell. Certainly, introduction of the extra layer of the unit cell below the ground plane has increased the efficiency of the proposed design.

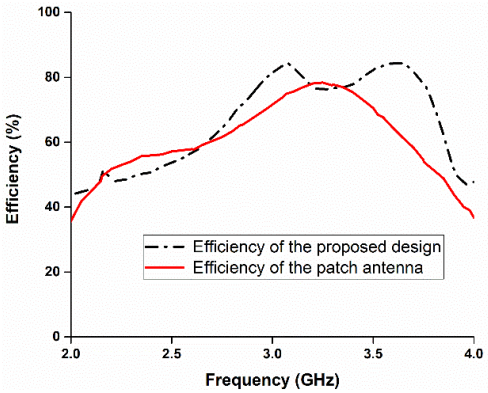


Figure 6: Efficiency of the proposed design and the patch antenna only.

4. Conclusions

A three-dimensional design of a metamaterial inspired antenna has been exposed in this paper. The illustrated unit cell obtained negative permeability, negative permittivity and negative refractive index over the proposed antenna's operating bandwidth. The unit cell is embedded with the antenna's final design. Finally, use of the unit cell and the three dimensional structure aided the antenna to achieve larger bandwidth along with a raise in efficiency level up to 85%. The proposed antenna could be a potential apparatus in for human head imaging using microwave imaging technology because of it's lower band operation.

Abstract

This paper presents a dual-band meta-inspired antenna operating at WLAN 2.4 GHz and WiMAX 2.5 and 5 GHz. The proposed antenna size is 35×35×1.6 mm^3. A left-handed metasurface providing negative refractive index is used as a patch and as a ground of the antenna. The antenna is fed by microstrip feeding methods. The antenna is designed on fiberglass cloth embedded in epoxy resin substrate and simulated on CST Microwave studio software package. The proposed design consists of a modified split ring resonator and a capacitive loaded strip to achieve metamaterial characteristics. The proposed meta antenna archives resonant frequency at 2.53 GHz and 5.58 GHz bandwidth of 360 MHz and 320 MHz, respectively. The gain of the antenna at 2.5 GHz is 4.19 dBi and 5.58 GHz is 4.16 dBi, respectively.

1. Introduction

In recent years, wireless technology requires compactness. For these, researcher has left space to design an antenna. The WLAN and WiMAX system is one of the most widely used technologies to simplify human communication. Using a metasurface mounted on an antenna can catch up with this compactness. The allocated frequency band for WLAN and WiMAX is between 2.5-2.69 GHz and 4.9-5.9 GHz. Left-handed metamaterials can exhibit simultaneously negative values of electric permittivity (ε) and magnetic permeability (μ) over a specified frequency band [1, 2]. Metamaterial based planar antenna design became popular due to enhanced radiation.

Over the years various designs of microstrip transmission line planar antennas have been reported for WiMAX and WLAN wireless communications. Many metamaterial based low profile antennas has been proposed [3, 4], by using metamaterial resonator as a radiating element. T. Alam *et al.* proposed a triangular shaped antenna 48×48×1.57 mm^3 for mobile wireless application [5]. The gain of the antenna at 2.45 GHz is 2.07 dB, and 5 GHz is 4.06 dB with radiation efficiency of 77.15% and 87.6%. Ali *et al.* proposed a 20×40 mm^2 miniaturized slot antenna for WALN in [6]. A nested inverted-F antenna resonating frequency at 2.5 and 5.5 GHz achieved a radiation efficiency of 92% and 88%, respectively [7].

In this paper, a metamaterial inspired antenna is proposed based on modified split ring resonator (MSRR) and capacitive loaded strip (CLS). The geometric layout of the proposed antenna is depicted in Figure 1. The budget FR-4 has been used as a substrate. The proposed antenna consisted with 2×2 CSRR metamaterial unit cell as a top

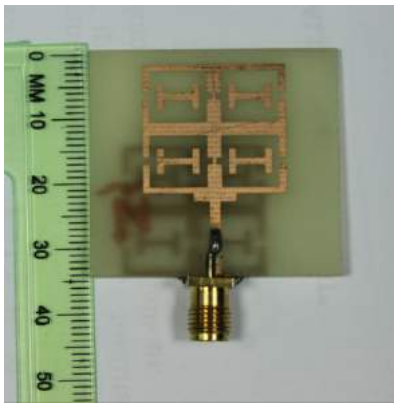
d	1		

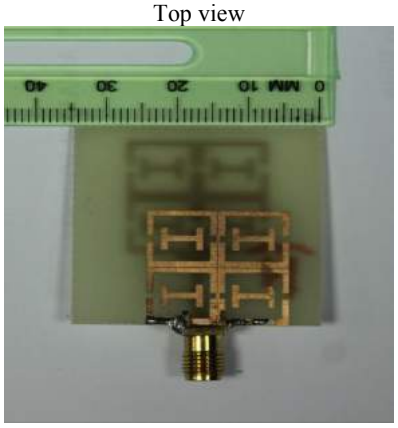
and bottom layer. The size is reduced due to the negative electromagnetic properties of the metasurface. A 50 Ω microstrip transmission line is used to feed the antenna. The antenna achieves -10 dB impedance bandwidth of 350 MHz and 300 MHz.

2. Design and Fabrication

The schematic layout of the proposed meta-inspired microstrip antenna is shown in figure 1, while fabricated prototype is in figure 2. The proposed antenna consists of a 2×2 metamaterial unit cell acting as a radiating component in one side of the substrate also on the opposite side acting as a ground plane. The proposed meta antenna has been designed on FR-4, which is a low-cost material, made from fiberglass cloth embedded in epoxy resin with relative permittivity ε_r=4.3, relative permeability μ_r=1 and loss tangent of δ=0.025. The substrate thickness is 1.6 mm and the dimensions of the antenna is 35×35 mm^2. The conductive copper is 0.035mm thick. The design parameters are represented in Table 1.



Top view



Bottom view

Figure 2. Fabricated prototype of the proposed meta inspired antenna.

3. Metamaterial Characterization

Perfect electric conductor (PEC) and perfect magnetic conductor (PMC) are set as a boundary condition throughout the x and y axis as shown in figure 3. In z-axis, the electromagnetic wave is propagated. The effective parameters of the proposed unit-cell are extracted by using transmission-reflection method [8].

$$z = \pm\sqrt{\frac{(1+S_{11})^2 + S^2_{21}}{(1-S_{11})^2 + S^2_{21}}} \quad (1)$$

$$\eta = \frac{1}{k_0 d}[\{[\ln(e^{ink_0 d})] + 2m\pi\} - i[\ln(e^{ink_0 d})]] \quad (2)$$

$$e^{ink_0 d} = \frac{s_{21}}{1 - s_{11}\dfrac{z-1}{z+1}} \quad (3)$$

$$\varepsilon = \frac{\eta}{z} \quad (4)$$

$$\mu = \eta z \quad (5)$$

Where, S_{11} and S_{21} are the reflection and transmission coefficients, symbol ε is the effective permittivity, μ is the effective permeability, k_0 is the wavenumber, d is the thickness of the substrate, η is the refractive index, m is an integer related to the branch index and z is the relative impedance.

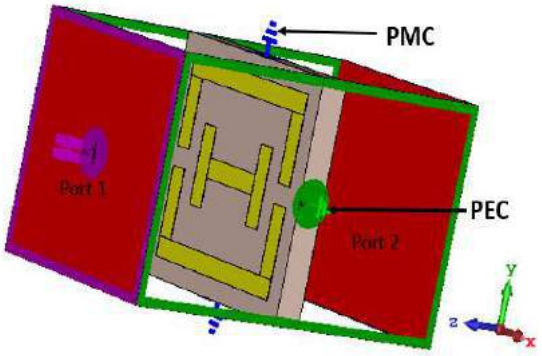


Figure 3. Floquet port arrangement.

4. Antenna Performance

The simulated and measured reflection coefficient (S_{11}) of the proposed meta antenna is depicted in figure 5. It shows a peak below -10 dB from 2.46 GHz to 2.57 GHz bandwidth of 110 MHz and 5.45 GHz to 5.73 GHz bandwidth of 280 MHz predicted by CST. Where the fabricated prototype shows a peak below -10 dB from 2.21 GHz to 2.57 GHz bandwidth of 360 MHz and 5.51 GHz to 5.83 GHz bandwidth of 320 MHz.

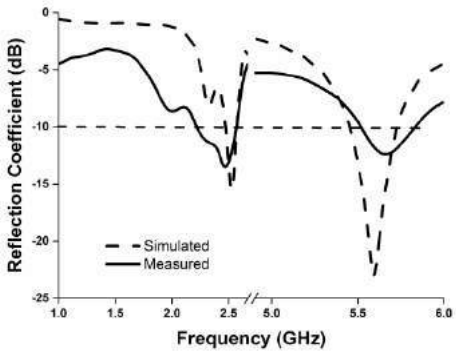

Figure 5. Reflection coefficient of the proposed meta-inspired antenna.

The measured reflection coefficient a bit different from the simulation result. That's because of fabrication tolerance and measurement system loss.

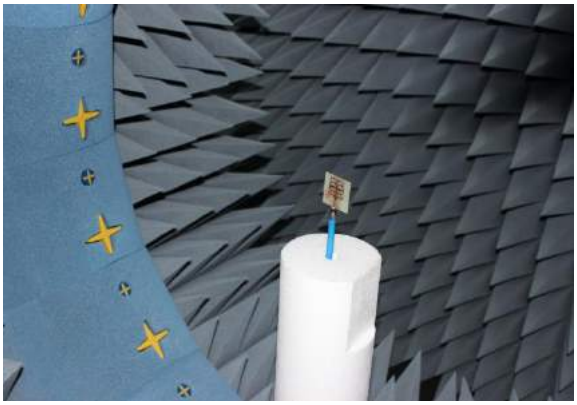

Figure 6. Farfield Characteristics measurement setup.

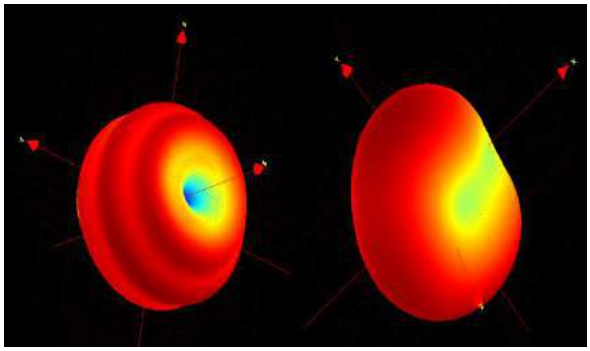
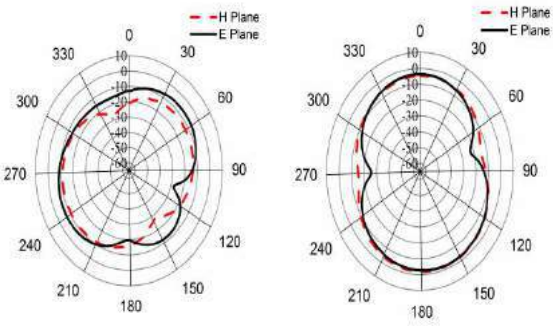
A near field measurement system of Satimo has been used to analyze the farfield performances of the proposed antenna, as shown in Figure 6.



(a) (b)



(c) (d)

Figure 7. Measured 3D radiation pattern at (a) 2.53 GHz (b) 5.58 GHz and H plane and E plane radiation pattern at (a) 2.53 GHz (b) 5.58 GHz

Radiation patterns of the proposed antenna have been shown in figure 7. At 2.53 GHz the antenna achieved almost omnidirectional radiation pattern. Near about bidirectional radiation pattern have been obtained at 5.58 GHz. The value of directive gain obtained by the antenna are GHz is 4.19 dBi at 2.53 GHz and 4.16 dBi at 5.58 GHz.

5. Conclusion

A dual band meta-inspired microstrip patch antenna has been presented for 2.53 GHz and 5.58 GHz. The proposed antenna has various slots and slits on the patch resonator and ground plane to obtain dual band characteristics. The tested results demonstrate that the proposed antenna can be a good candidate of wireless communication. Integrating a negative refractive index (NRI) metamaterial structure to the proposed antenna at the same time enhance the performances along with miniaturization are the distinctive novelty. The proposed antenna can be merged in practical small devices demanding dual band WLAN and WiMAX applications.

Abstract

A simply fabricated double negative metamaterial to reduce specific absorption rate (SAR) of wireless mobile antenna is proposed in this article. Low cost of fabrication and photo paper are the main attraction of this paper. Elliptic based metamaterial (EMTM) is used to reduce the SAR for 1g mass of human tissue. The simulation is performed using head phantom integrated in CST Microwave studio. The SAR has been reduced by 53% and 10.5% at 0.9 GHz and 1.8 GHz for 1g, respectively.

1. Introduction

The hazard of electromagnetic (EM) radiation from mobile phone become a key point of consideration for researchers as its increasing demand and use in our daily life. The fundamental parameter in EM absorption is characterized regarding the specific absorption rate (SAR), or the absorbed power in unit mass of tissue. The electromagnetic radiation radiated by wireless devices are analyzed by measuring the specific absorption rate in a human head phantom, defined as [1]:

$$SAR = \frac{\sigma \left|\vec{E}\right|^2}{\rho} = c\frac{dT}{dt}$$

Where, σ is electrical conductivity, ρ is mass density, *c* is specific absorption rate and *dT/dt* is the changing rate of the body tissue temperature. An exposure limits in terms of SAR are set by standards organizations [2].Recently, researchers work on SAR reduction using metamaterial while focused on low cost and easy implementation procedure. In previous research, many folks use metamaterial to reduce SAR [3-5]. Metamaterial structure used for their unique properties on electromagnetic wave, which cannot be found in nature. It depends on how they structured not in their inclusion.

Hwang *et. al.* [6] presented split ring resonator structure to reduce the SAR value for 1g. By placing thin wires periodically negative permittivity can also be obtained [7]. Sultan *et. al*. proposed an electromagnetic bandgap structure embedded with an antenna to reduce the SAR values in [8]. The metamaterials designed on circuit board make it appropriate for integrated into the mobile phone easily.

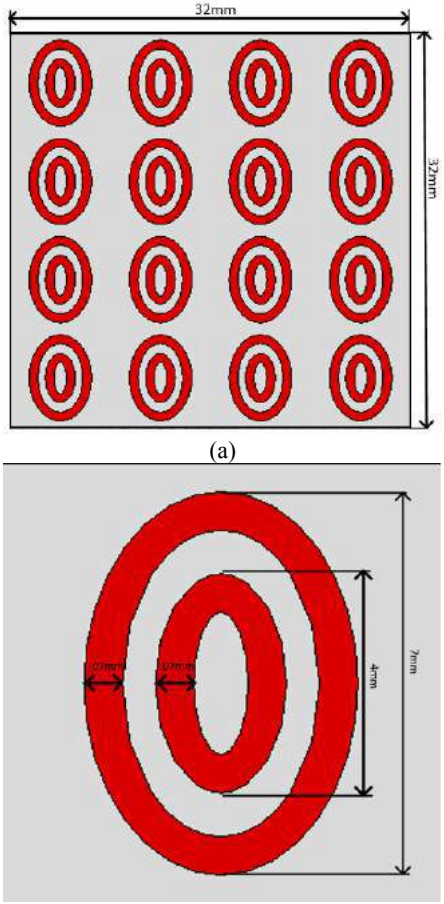

Figure 1. (a) Proposed elliptic based metamaterial and (b) unit-cell design.

2. Metamaterial Deign and Characterization

The proposed EMTM structure is constructed and investigated by using CST Microwave Studio based on finite-difference time-domain method (FDTD). Figure 1, shows the proposed metamaterial. The metamaterial is designed on a photo paper which dielectric constant, ε_r=3.2 and width of the paper is 0.27 mm. The effective characteristics of the presented metamaterial are exemplified in Figure 2. As shown in Figure 2, the effective permittivity of the EMTM is found from 1.98 to 3.98 GHz

and effective permeability from 1.98 to 3.99 GHz. As expected, it shows negative refractive index (NRI) from 1.98 to 3.99 GHz, bandwidth of about 2 GHz. The proposed metamaterial structure doesn't reduce the antenna performance.

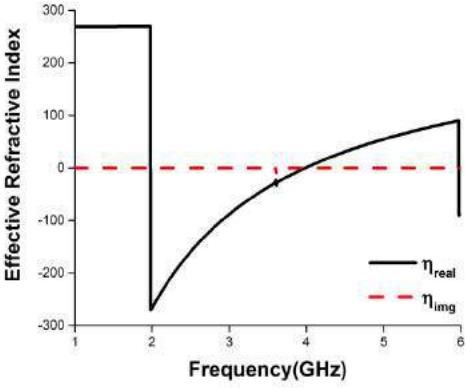
(b)



(c)

Figure 2. Extracted effective parameters (a) effective permittivity (b) effective permeability and (c) index of refraction.

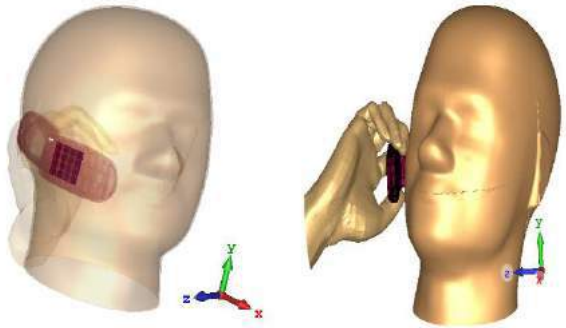


Figure 3. EMTM embedded in hand mobile and SAR simulation head model.

3. Analysis of Specific absorption rate

The SAR values of the presented elliptic metamaterial are observed using CST Microwave Studio 2017. The inbuilt human head phantom of CST has been taken and the reference power has been fixed to 500 mW. The human head model consists of head equivalent fluid with $\varepsilon_r = 40$, $\sigma = 1.4$ and shell with $\varepsilon_r = 5$, tangent delta = 0.05 are set in the SAM head phantom. Moreover, an inbuilt handset model having a circuit board, dial pad, LCD, housing and battery has been combined with the SAM head phantom. The simulation environment has been arranged just as IEEE and Federal Communications Commission standards. The placement of the paper based metamaterial inside the handset model and the full SAR simulation head model are shown in Figure 3.

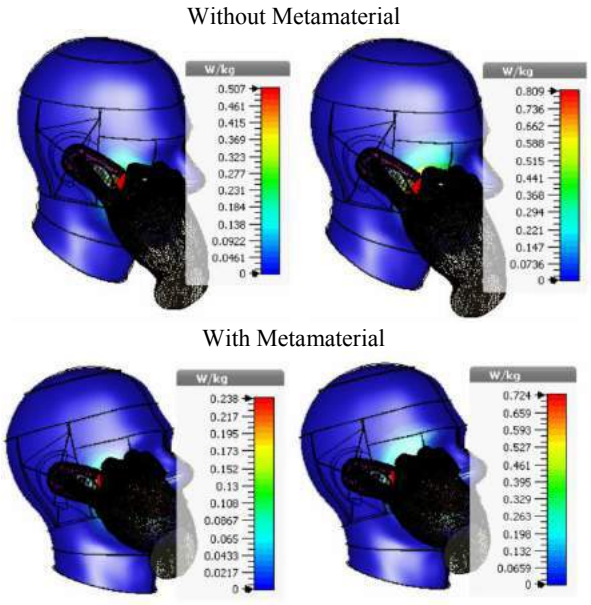

Figure 4. 1g SAR values at .9 GHz and 1.8 GHz.

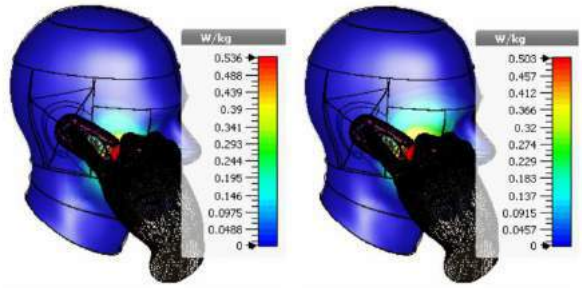
Without Metamaterial



With Metamaterial

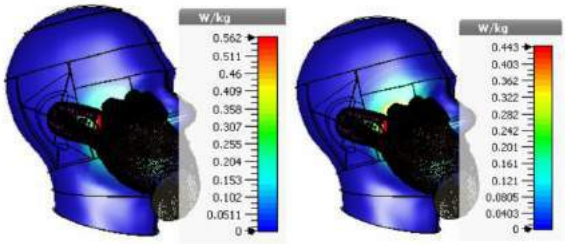


Figure 5. 10g SAR values at .9 GHz and 1.8 GHz.

Initially, the simulation has been done without inserting the proposed paper based metamaterial for 0.9 GHz and 1.8 GHz, presented in figure 4 for 1g and in figure 5 for 10g body tissue. It is shown from figure 4 and 5 that the highest SAR values are shown 0.238 W/Kg and 0.724 W/Kg for 1 g and 0.562 W/Kg and 0.443 W/Kg for 10 g tissue at 0.9 GHz and 1.8 GHz. When inserting the paper based elliptic metamaterial inside the phone model, the highest SAR values are now 0.238 W/kg and 0.724 W/kg for 1g and 0.562 W/kg and 0.443 W/kg for 10 g at 0.9 GHz and 1.8 GHz respectively. A comparison of the SAR values for both 1g and 10g are presented in Table 1.

Table 1: Comparison of SAR values.

Phone Model	Frequency [GHz]	1g SAR [W/Kg]	10g SAR [W/Kg]
With	0.9	0.238	0.562
EMTM	1.8	0.724	0.443
Without	0.9	0.507	0.536
EMTM	1.8	0.809	0.503

The simulated SAR values of the proposed EMTM are lower than the safety guidelines provided by IEEE and FCC. At this point, the presented metamaterial structure plays a vital role in reducing the SAR values.

4. Conclusion

The presented elliptic based metamaterial structure reveals an EM absorption reduction without altering the antenna performances. The newly developed EMTM attachment in the phone model led to a SAR value of 0.238 W/Kg for 1 g and .562 W/Kg for 10 g at 0.9 GHz and 0.724 W/Kg for 1 g and .443 W/Kg for 10 g at 1.8 GHz. Therefore, using a photo paper based elliptic metamaterial (EMTM) can be a remedy from the dangerous effects of electromagnetic wave radiated by the wireless device.

Abstract

A metamaterial inspired dual band rectangular patch antenna design is introduced in this paper for feature phones. The proposed antenna design is based on $10\times10mm^2$ grid shaped unit cell. Four unit cells are interconnected with a thin radiating element to achieve operating bandwidth in lower frequency. The ground plane used a 3×5 array of the proposed grid shaped unit cell, accompanied with a single cell on the upper side of the ground. The electrical dimension of the proposed antenna is $0.46\lambda\times0.017\lambda$ at 0.92GHz lower frequency bands. The proposed antenna can operate at most widely used GSM 900MHz and 1900MHz. The design and simulation process of the unit cell and the proposed antenna is computed using CST Microwave Studio. 1.6mm thick lossy FR4 material is used as substrate for the proposed antenna. Finally, Specific Absorption Rate (SAR) of the antenna has also been calculated to investigate if the SAR values of the proposed antenna remain within public exposure limit.

1. Introduction

The present era of smartphones and smart devices is truly undeniable. Even though the enormous popularity of smartphones, demand for feature phones still prevails. Moreover, places like hilly or rural areas and places which are not still blessed with 3G or 4G communication the GSM network is still being used there. In addition to the facts, even the tech giants are emphasizing on smartphone production, they still have not stopped manufacturing the feature phones considering the demands. Furthermore, an antenna that covers the GSM bands is a mandatory apparatus for wireless communication in smartphones too. In [1] a dual band antenna inspired by metamaterial is presented for GSM and Wimax application. The antenna used 'I' shaped unit cell. However the width of the antenna is comparatively bigger than the proposed antenna. Two dual-band antennas for wireless and GSM applications are reported in [2]. These antenna are based on metamaterial structures. Effect of different material structures on size miniaturization are also reported in this study.

There are more metamaterial patch antennas found in literature for various applications like, miniature satellite communication [3], modern wireless communication [4], 4G mobile communication [5], wireless body centric communications[6] etc.

In this paper, a metamaterial inspired dual band antenna has been proposed for the application of wireless communication in feature phones. The proposed antenna covers GSM 900MHz and GSM 1900MHz. The design of the antenna is engendered from a metamaterial unit cell. Finally, arrays of the unit cell are used to make radiating element of the antenna.

2. Design of the antenna

The design and simulation of the antenna is performed using CST Microwave Studio. First of all, a unit cell is designed using 1.6mm thick FR4 lossy substrate. Then the unit cell is embedded as ground and patch of the proposed antenna. Design configuration of the proposed unit cell and antenna is shown in Fig. 1 and Fig. 2.

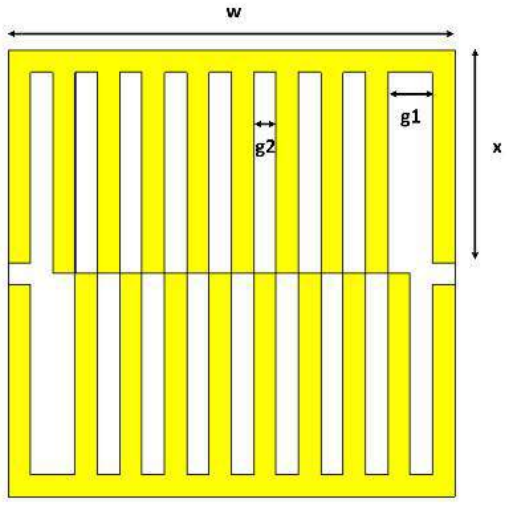

Figure 1: Design configuration of the unit cell

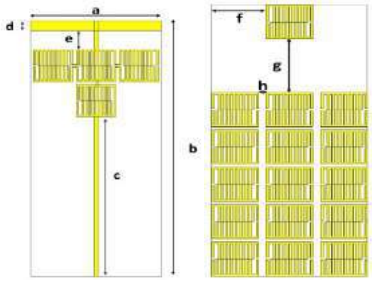

(a) (b)

Figure 2: Configuration of the proposed antenna (a) Front view, (b) Back view.

The patch of the antenna consists of total 4 unit cells where an array of 1x3 unit cell included and they are interconnected. The thickness of the copper radiating patch is considered to be 0.035mm. The ground plane has an array of 5x3 unit cell along with an unit cell placed at the top middle of the ground plane. Design parameters of the proposed antenna are enlisted in Table 1.

Table 1: Design parameters of the proposed unit cell and antenna.

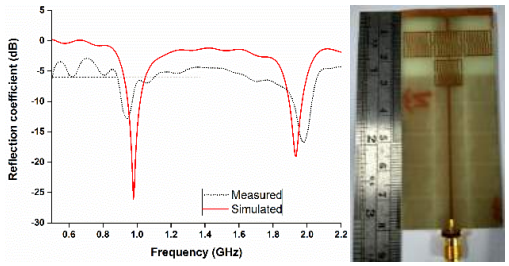
(c)

Figure 4: Calculated (a) permeability, (b) permittivity and (c) refractive index of the proposed unit cell.

It is noticed that, the negative permeability and permittivity has been found at 1.4-2.79 GHz and1.4-2.70 GHz

respectively. The reflection coefficient of the proposed antenna has been presented in Fig. 5. The antenna achieved operating band (<6dB) at 0.92-1.05 GHz and 1.86-2.00 GHz that covers GSM 900 and GSM 1900 bands. The simulated result shifted a bit at the resonances in measured result obtaining a wider bandwidth at 0.88-1.09 GHz and 1.64-2.06 GHz due to fabrication tolerance. However, results of the simulation and fabricated prototype have shown good agreement.



(a) (b)

Figure 6: 3D radiation patterns at (a) 0.98 GHz, (b) 1.93 GHz.

Finally, the proposed antenna has been used in SAR simulation with head model and antenna placed in mobile using CST Microwave Studio. The built-in SAM head phantom is used along with the complete handphone model which includes LCD display, battery, housing case and circuit.

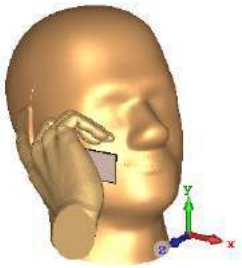

Figure 7: SAR simulation setup of the antenna with head model.

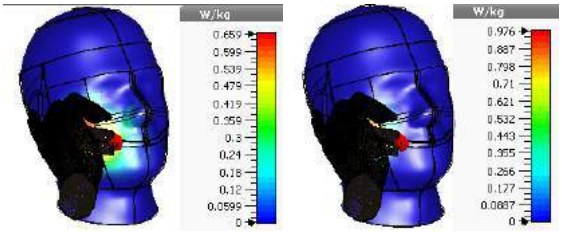

(a) (b)

Figure 8: 1g SAR values of the proposed antenna at (a) 900 MHz and (b) 1900 MHz

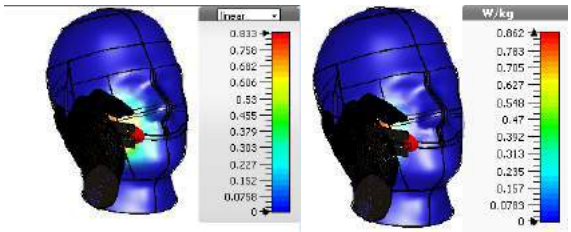

Figure 9: 10g SAR values of the proposed antenna at (a) 900 MHz and (b) 1900 MHz

It can be noticed from the figure 8 and 9 that, 1g SAR value of the proposed antenna are 0.659 and 0.976 W/Kg at 900MHz and 1900 MHz respectively. 10g SAR value at 900MHz is 0.833 W/Kg and at 1900 MHz is 0.862 W/Kg.

4. Conclusions

In this paper, design of a metamaterial inspired patch antenna has been revealed for GSM 900 and GSM 1900 for handheld mobile communication. Metamaterial unit cells have been used to design the patch and ground plane of the antenna. The reflection coefficient has been improvised by using the metamaterial unit cell. The simulation result and measured result of the fabricated prototype have shown good agreement and the designed unit cell aided the antenna to achieve the GSM 900 and GSM 1900 frequency bands.

Moreover, the result of the SAR values are within the public exposure limit of less than 1.6 watts per kilogram, hence making the antenna potential for feature phones.

Abstract

A metamaterial ground planed structured antenna is proposed for multiband wireless mobile applications. The proposed structure consists of microstrip fed polygonal radiator with a meta-structure partial ground plane, which can operate within 1.77 GHz to 4.55 GHz. The antenna covers mostly used mobile application bands, such as GSM 1800, 1900, 2100, WCDMA, Bluetooth, WLAN 2400, WiMAX 2.5. The novel outcomes of this antenna are to achieve wideband with compact size metamaterial structured antenna.

1. Introduction

Nowadays, the mobile antenna design is becoming challenging issue to the antenna researchers due to multifunctional uses of mobile device. Many researches have been performed to design suitable mobile antenna, like as PIFA antenna [1], MIMO antenna [2], metamaterial antenna [3], patch antenna [4] segmented loop antenna [5]. Zhu et al proposed coupled fed triband antenna for mobile wireless applications [2]. In [3], a metamaterial inspired corded shaped antenna has been proposed for mobile applications, which can cover DCS, GSM1800, WCDMA, and Bluetooth frequency bands. Choukiker et. al proposed a fractal antenna for wireless communication which can achieved frequency band of 1.6 to 3.4 GHz with the size of 66 × 27 mm^2 [4]. In [6], a metamaterial unit cell inspired antenna is presented for mobile application with dimension of 48 × 48 × 1.575 mm^3. The antenna covers two bands, one is 1.6–1.97 GHz and another is 2.34–2.72 GHz.
Moreover, mobile antenna must complies the specific absorption rate (SAR) guidelines [7]. The SAR is defined by the power absorbed per unit of mass of biological tissues, which is the measurement system of tissue heating due to RF energy absorption. The SAR limit specified in IEEE C95.1:2005 is 1.6 W/kg in a 1 g averaging mass and 2 W/kg in a 10-g averaging mass of tissue.

In this paper, a compact size antenna is proposed for mobile communication system. Unlike the majority of existing designs, the proposed antenna is both simple in structure and simultaneously has wide impedance with moderate gain and efficiency.

2. Antenna Design and Characterization

The proposed antenna has been designed and characterized using commercially available microwave simulator "CST Microwave Studio" considering substrate material of Rogers 4003, dielectric constant of 3.55 and thickness 0.508 mm. The optimized design is depicted in Figure 1. The antenna consists of a polygonal radiator as main radiator and 3×3 metamaterial array based ground plane. The metamaterial unit cell characteristics has also been analyzed, shown in Figure 2. It is shown from Figure 2 that the negative permittivity of the unit cell shows from 12 GHz to 3.85 GHz and negative permeability shows from 2.635 GHz to 3.62 GHz. The negative refractive index is achieved from 3.08 to 3.70 GHz.

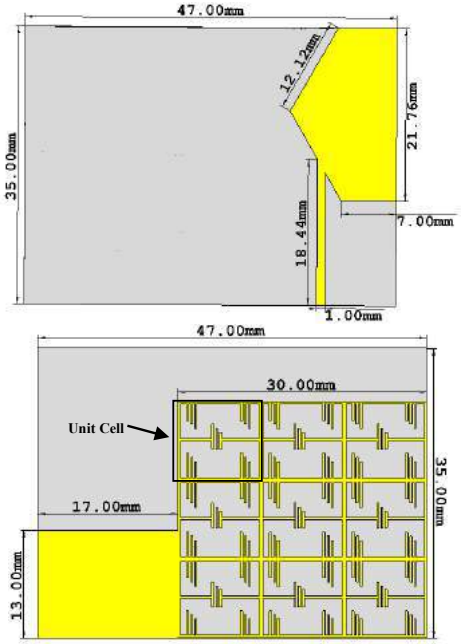

Figure 1: Schematic design of the proposed antenna

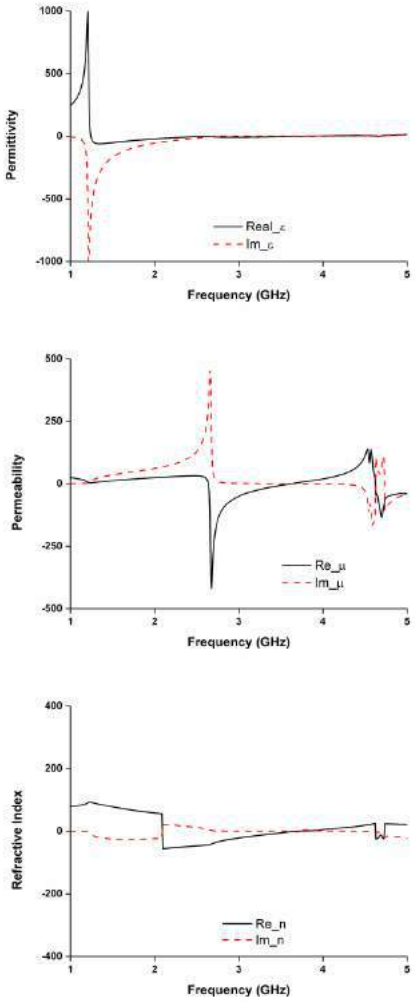

Figure 3: Retrieved metamaterial parameters.

3. Discussion

The optimized antenna shown in Figure 1 has been fabricated to measure the antenna performances, depicted in Figure 3. The measured and simulated reflection coefficient is illustrated in Figure 4. The measured and simulated results matched well though a small disagreement is observed. The possible reason of this mismatch is fabrication and measurement tolerance. The farfield characteristics have also been measured using Satimo nearfield measurement system, illustrated in Figure 5. In Figure 6, 3D farfield radiation is presented. It can be observed from Figure 6 that the antenna shows nearly omni-directional pattern at 1.8 GHz and 2.4 GHz.

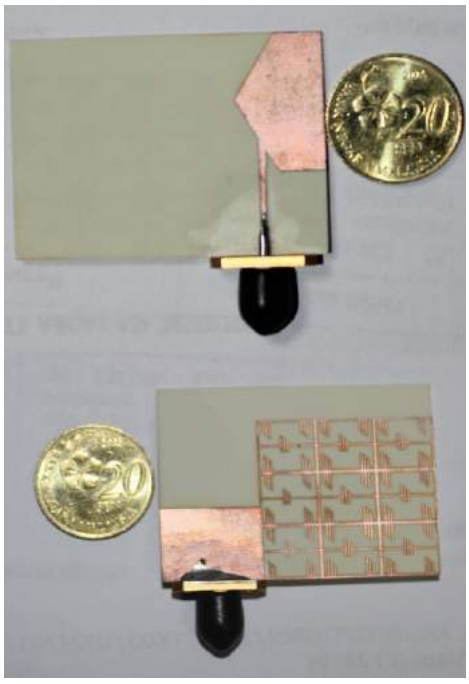

Figure: 3: Fabricated prototype of the proposed antenna

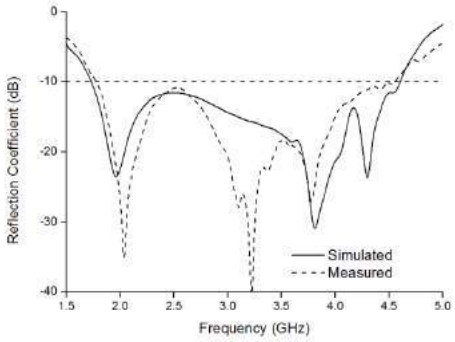

Figure 4: Reflection Coefficients of the proposed antenna

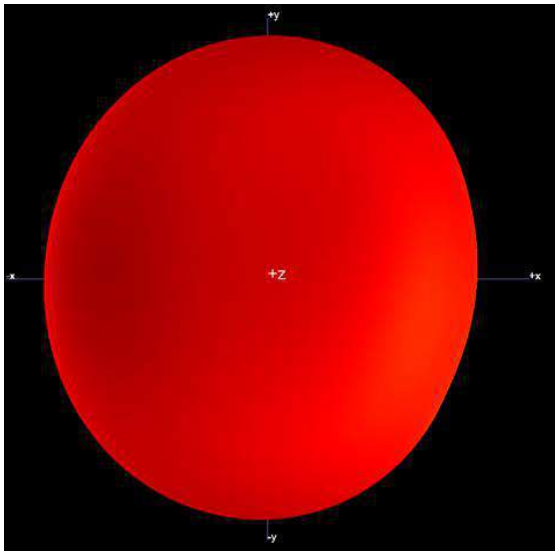
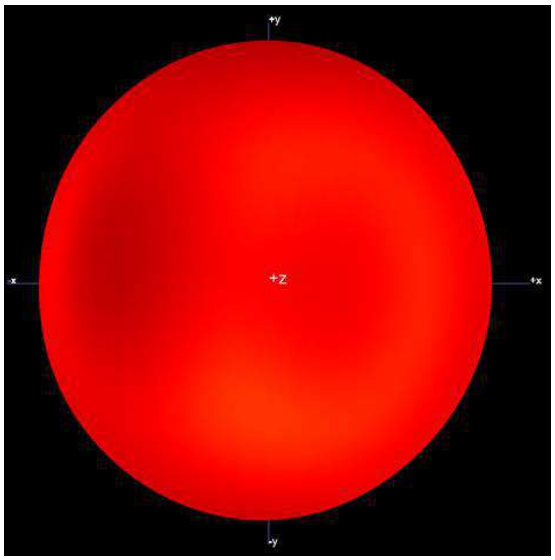
Figure 5: Antenna measurement in Satimo nearfield measurement system.



(a)



(b)

Figure 6: 3D farfield radiation pattern at (a) 1.8 GHz and (b) 2.4 GHz

The radiation efficiency and the realized gain is presented at Figure 7. The antenna shows -1.53 dB and -2.4 dB of radiation efficiency at 1.8 GHz and 2.4 GHz, respectively. Moreover, the antenna achieves 1.373 dB and 0.38 dB of realized gain at 1.8 GHz and 2.4 GHz, respectively.

The Specific absorption rate (SAR) values of the proposed antenna has been performed to ensure the compatibility with mobile communication system. The SAR measurement setup is demonstrated in Figure 8(a). And Figure 8(b) presents the SAR values at 1.8 GHz for different distance. The antenna shows 0.95 W/Kg of 10-g SAR and 1.62W/Kg of 1-g SAR at 1.8 GHz, which complies the SAR guidelines [7].

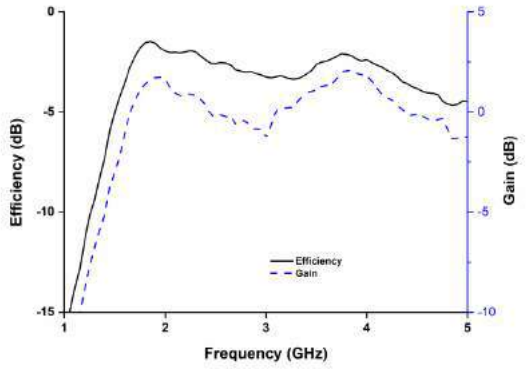


Figure 7: Measured efficiency and realized gain of the proposed antenna

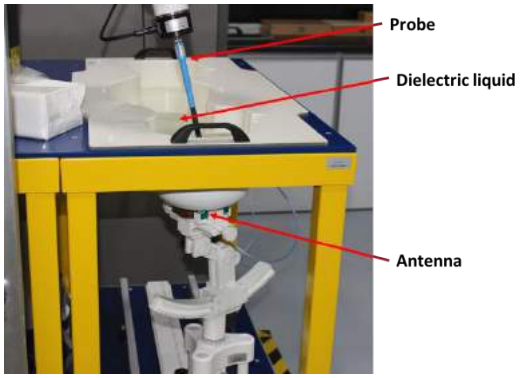
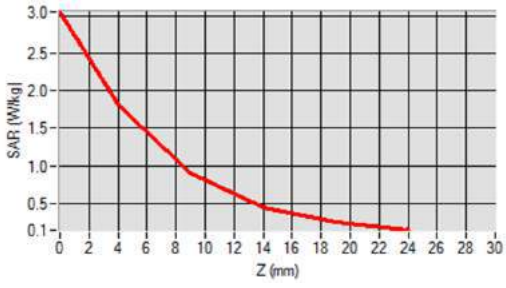


(a)



(b)

Figure 8: SAR measurement of the proposed antenna (a) measurement setup (b) SAR at 1.8 GHz for different distance.

4. Conclusions

A metamaterial ground plane inspired has been presented. The antenna has achieved -10 dB impedance band of 1.77 GHz to 4.55 GHz, which can operate at mostly used mobile bands. Moreover, the antenna complies the SAR guidelines and the antenna can be utilized in wireless devices due to its and relatively small size and simple structure.

Abstract A new metamaterial-based wideband electromagnetic rectangular cloak is being introduced in this study. The metamaterial unit cell shows sharp transmittances in the C- and X-band and displays wideband negative effective permittivity region there. The metamaterial unit cell was then applied in designing a rectangular-shaped electromagnetic cloak. Scattering reduction technique was adopted for the cloaking operation. The cloak operates in the certain portion of C-and X-band that covers more than 4 GHz bandwidth region. The experimental results were provided as well for the metamaterial and the cloak.

1. Introduction

Artificially constructed metamaterial is now contributing in almost all the fields of electromagnetism including invisibility cloak design. Metamaterial provides essential property to synthesize proper electromagnetic cloak. An electromagnetic cloak can hide an object electromagnetically. Cloaking is usually used in the defense sector for hiding aircraft, satellite or missile from the hostile radar system. An object can be hidden electromagnetically if it does not scatter wave in any direction. In other sense, it does not absorb any power. Utilization of metamaterial guides the applied electromagnetic waves around the object instead of scattering and restores the waves to its original path that results transparency to the observer. Since the first successful attempt was done in [1] based on transformation optics (TO) technique, several research groups adopted numerous approaches to build compact metamaterial and an invisibility cloak [2-5]. In TO-method, a volume of no-field region is formed making the volume electromagnetically undetectable. However, the property requirement for the material that is utilized in designing a TO-cloak is difficult. A material with value of effective permittivity or permeability is between zero and greater than one can be utilized for the construction of TO-based cloak. Moreover, multiple layers are needed for designing metamaterial-based TO-cloak [6]. Among the other cloaking methods, scattering reduction method is easier to obtain the cloaking operation. Usually a good cloak reduces the normalized total scattering cross section (NTSCS) of an object close to zero [7]. Actually, a physical cloak diminishes the normalized total scattering cross section to some non-zero value, below one. A metamaterial with epsilon negative property is suitable for designing a cloak to suppress the scattering of an object [4]. Scattering reduction method was realized as well for the TO-cloak [6]. Previously few studies were performed on metamaterial-based cloak. However, most of the cloaks were cylindrical in shape and very few of them were found operating in C-band. Like, Xiaohui Wang et *al*. in [7], proposed a dielectric resonator based metamaterial X-band cloak but it was cylindrical in shape. They demonstrated that their cloak reduced the total scattering width below one in the X-band. A metamaterial-based cloak was developed in [8] for C-band operation but it was square-shaped and operating over 500 MHz region. A metasurface-based single layer cylindrical cloak was claimed by Matekovits *et al*. in [9] but it was operating in the K-band of microwave region. Another single layer cloak was proposed in [10] for C-band application but it was square-shaped and operating over 900 MHz region.

In this study, a rectangular-shaped wideband cloak is proposed that was designed using a bare-H-metamaterial. The cloak operates over more than 4 GHz frequency ranges. For designing the cloak, only one layer of metamaterial shell has been utilized.

2. Design and characteristics investigations of the metamaterial unit cell

The design and the S-parameters investigation of the metamaterial unit cell was done by the finite integration technique based CST Microwave Studio software. In this study, a bare-H-shape structure was formed on a $12\times12mm^2$ FR-4 substrate material by the combination two inner and outer magnetic copper made resonators of thickness 0.035mm. The inner resonator forms the basic bare-H-shape structure adopting a mirror symmetry, which helps to form negative effective permittivity property. Another split square resonator was added to the basic structure as outer resonator. Two gaps in the top and bottom of the outer resonator was kept 0.46mm. Each arm of the split square-shaped resonator is taking part to generate the inductive effect and the two gaps between the metal arms are responsible for generating the capacitive effect. The inductive and capacitive effects constitute the negative effective medium property for the metamaterial. The dielectric constants and thickness of the substrate material was 4.2mm and 1.6mm respectively. Fig.1a and Fig.1b depicts the new bare-H-shaped metamaterial unit cell and its fabricated sample consecutively. The structure and size of the proposed metamaterial unit cell was finalized to obey the proper effective medium ratio. The effective medium ratio for the metamaterial unit cell was $\lambda/a=6$, where λ is the wavelength.

At each side, 1 mm gap was maintained from the resonator to the end of the substrate. The design parameters were expressed in the Table-1.

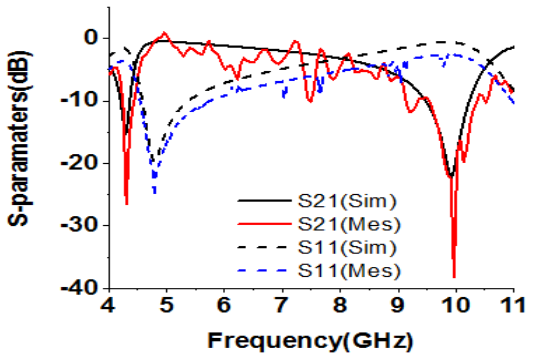
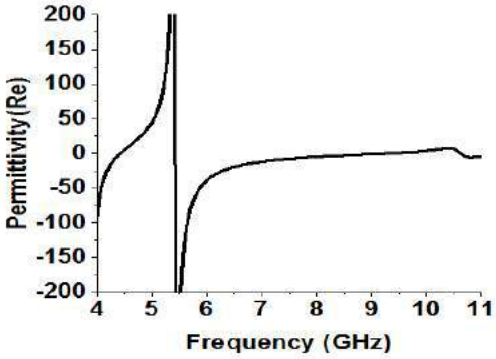
L	12

To calculate the S-parameters of the metamaterial unit cell, electromagnetic wave was propagated through the unit cell using two waveguide ports. Perfect electric-magnetic boundary condition was applied for the simulation. The acquired S-parameters were adopted to evaluate the effective medium property of the material. For the calculation of the effective medium property of the material, Nicolson-Ross-Weir method [11] was utilized.

To perform the measurement of the unit cell, a sample unit cell metamaterial prototype was fabricated using LPKF laser based electronic machine. The fabricated sample was placed between two rectangular C-band waveguides, acting as transmitter and receiver. The waveguides were linked to the vector network analyzer (VNA) N5227A. From the VNA the S-parameters were obtained.



(a)



(b)

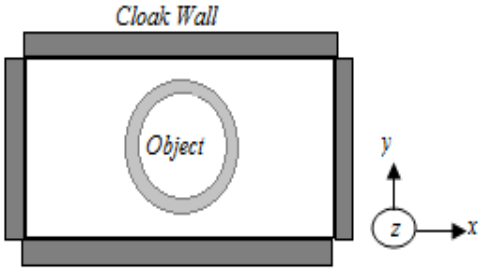
Figure-2. (a) Simulated and measured S-parameters for the unit cell (b) effective permittivity for the metamaterial unit cell

The simulated and measured results of S-parameters are shown in the Fig.2a for the metamaterial unit cell. Form the Fig.2a, the numerical curve shows transmittances at the frequency of 4.29 GHz and 9.93 GHz. The experimental transmittance also follows the numerical curve well. Similarly, the experimental reflection parameter agrees well with the numerical one. The effective permittivity curve is also presented in the Fig.2b where the curve displays negative peak from 4GHz to 4.43 GHz and 5.42GHz to 9.26 GHz in the frequency range. This negative region has significant effect for creating cloaking zone. This type of negative region regions creates opposite dipole moment that is useful for cloak operation.

3. Development and performance investigations of the metamaterial-based cloak

The newly developed metamaterial was applied for the construction of an electromagnetic cloak. The same CST Microwave Studio tool was also adopted for the design and numerical investigation of the metamaterial-based cloak. Scattering suppression technique was chosen to perform the cloaking operation. In this technique, a kind of dielectric shell or coating is surrounded by the object to be cloaked. The shell helps to reduce the scattering from the object and return the electromagnetic waves back to its usual path at a certain frequency. Therefore, the electromagnetic waves bend around the object and thereby make the object hidden to the observer or radar.

To perform such operation, four unequal walls were prepared where two parallel walls were equal. Two side walls were composed of four unit cells and two width walls were built by two unit cells of the proposed metamaterial in this study. As an object, an aluminium made cylinder was chosen that has 4mm inner and 5mm outer radius with equal height of the cloak. The four metamaterial walls were arranged to form a rectangular shape structure. The object was placed at the center of the cloak. The top view of the square-shaped cloak structure is being displayed in the Fig.3a with the object inside it.

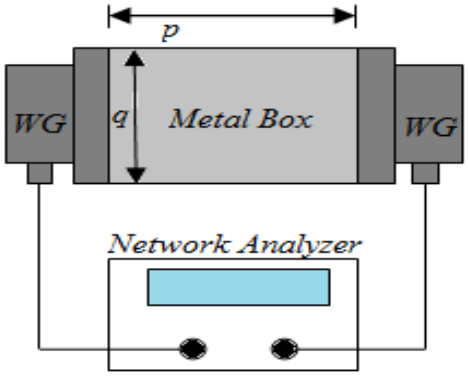


(a)Top view

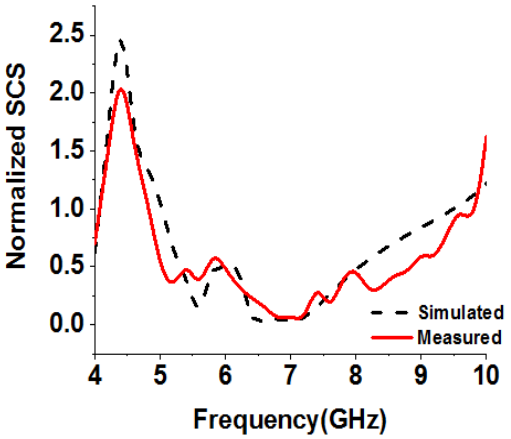
(b)

Figure-3. (a) The rectangular-shaped cloak structure with an object (b) Fabricated cloak prototype with aluminium made cylider inside.

evaluation of the cloak, the normalized scattering cross section (NSCS) is determined. Total scattering cross section is the ratio of scattered and incident energy from the cloaked object. NSCS is the ratio of total scattering cross section (TSCS) of cloaked object normalized by the TSCS of uncloaked object that can be calculated according to the equation mentioned in [7]. Similarly, for the measurement purpose, according to the design, two 24×24 mm^2 walls and two 24×12 mm^2 walls were fabricated and each of the walls consists of unit cells of the metamaterial. The WR159 and WR112 waveguide sets as well as the VNA (vector network analyzer) N5227A were utilized for the measurement. The metamaterial walls were arranged in such a way that had produced a rectangular-shaped cloak. Aluminium made metal cylinder with diameter 8mm in the inner surface was utilized as object having same height of the cloak so that the metal cylinder can be placed easily inside the cloak. Fig. 3b shows the fabricated cloak sample with a metal object inside.



(a)

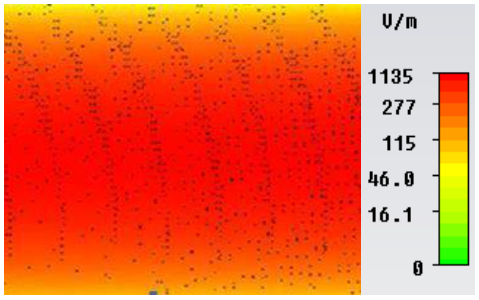


(b)

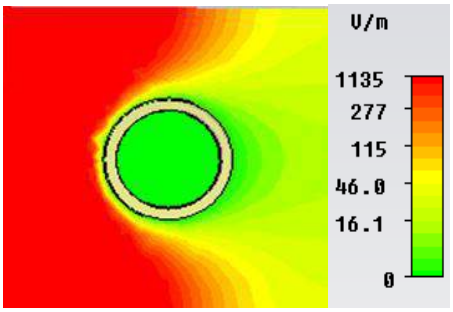
Figure-4. (a) The measurement setup for the cloak (b) simulated and measured results of TSCS of cloaked object normalized to the TSCS of bare object in the *xy*-plane

waveguides were connected to VNA as well. The whole cloak measurement setup is seen in the Fig.4a.

For the evaluation of NSCS, field status of incoming and scattering were measured. By placing the two waveguides face to face into the metal box, the incoming (Ei) field was measured. Afterwards, the metal object was placed between the waveguides inside the metal box and field parameters were measured that actually integrates total filed (Et) including the incoming and scattering field (Es). Deducting the incoming field from the total filed, the scattering field can be obtained. In addition, field measurement was also performed after placing the cloaked object inside the metal box and the scattering field was measured following the same way as mentioned above.



(a)

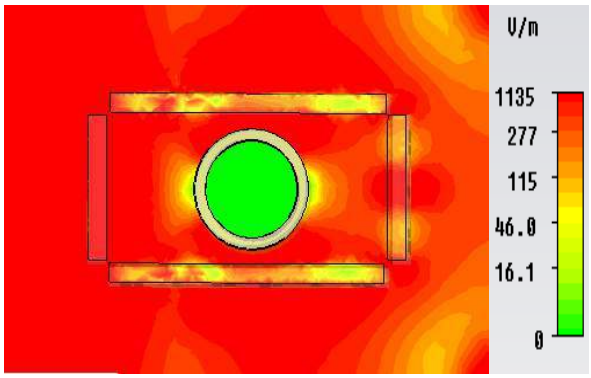


(b)

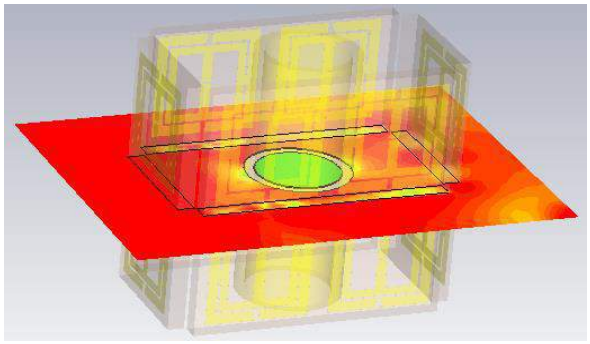
Figure-5. (a) Free space E-field distribution in the *xy*-plane, (b) E-field distribution for the uncloaked object at the lowest cloaked frequency (7 GHz) in the *xy*-plane.

In the Fig.4b, the simulated and measured result of normalized TSCS of cloaked object normalized by the TSCS of uncloaked object is being displayed. According to the numerical result of Fig.4b, it is evident that the simulated normalized scattering width curve shows value less than one, from 5.04 GHz to 9.47 GHz in the frequency range that covers more than 4 GHz bandwidth in the certain region of C- and X-band of microwave spectra. The lowest value is 0.03 and it was achieved at the frequency of 7 GHz. Moreover, the metamaterial unit cell exhibits epsilon negative region at this lowest point with the complex value ε= -11.80. However, the frequency range 5.04 GHz to 9.47 GHz can be considered as the zone where the cloaking operation is taking place. The measured normalized scattering cross section is found complying well with the numerical result although the lowest point was found at the same frequency of 7 GHz with the value 0.08. The measured curve shows less than zero value from 5 GHz to 9.40 GHz that covers more than 4 GHz bandwidth in the certain portion of C-and X-band. Therefore, this region can be considered as the realistic cloak operating area.

In the Fig.5a, the numerical electric field distribution in the *xy*-plane for the open space condition is being shown. The Fig.5b shows the electric field distribution over the metal object in the *xy*-plane. From the Fig.5b it is evident that, electric field is being scattered in the forward direction by the bare metal object. Moreover, no wave front reconstruction is taking place in the forward direction and therefore zero field region is being created in the forward direction i.e. right side of the object.



(a)



(b)

Figure-6. (a)Distribution of E-field for the cloaked object at the cloaked frequency (7 GHz) in the *xy*-plane, (b) transparent view of E-filed distribution at 7GHz.

In the Fig.6a, the electric field map in the *xy*-plane is revealed at cloaked frequency, where the metal object has been cloaked with the metamaterial-shell. It is seen from the Fig.6 that, no forward scattering was taking place there and reconstruction of wave front in the forward direction was achieved. This reconstruction of wave was gained due to the metamaterial-shell around the object and it points towards the competency of scattering diminution of the metamaterial walls. Therefore, any hostile observer or radar will not be

able to track the object. This has happened due to the epsilon negative property of the metamaterial as it prevents the scattering from the object being cloaked. The Fig.6b shows the transparent side view of the cloaked object that demonstrates the cloaking operation by the bare-H-shape metamaterial wall.

4. Conclusion

In this paper, a new metamaterial unit cell was introduced and its characteristics were evaluated. The characteristics of the metamaterial reveal the epsilon-negative property at certain region of the microwave C-band. Moreover, a rectangular-shaped cloak was designed using the metamaterial and a metal cylinder was cloaked perfectly in the wide region of C-band and some portion of X-band where the metamaterial contains the epsilon-negative property. Experimental results for metamaterial and the cloak was provided to the validated the performance of the metamaterial and the cloak. Therefore, the metamaterial and the cloak can be efficiently utilized for the C-band operation.

Metasurfaces and flat optics

Reflection phase measurements by thick-gap Fabry-Pérot interferometry and correction of numerical aperture effect

Tsz Kit Yung* and **Wing Yim Tam**

The Hong Kong University of Science and Technology, Hong Kong

*tkyungaa@connect.ust.hk

Abstract- Metamaterials, artificial materials with sub-wavelength structures capable of exhibiting novel electromagnetic behaviors, have been actively perused as a hot research topic in recent years. The small feature sizes have led to challenges in characterizing the properties of the metamaterials. A new method for measuring the absolute phase change on reflection for small samples in the optical range using converging incident beam is presented as the usual techniques work only for bulk samples and in discrete wavelengths.

To measure the reflection phase of small samples, a Fabry–Pérot interferometer (also name as FP etalon) is used together with a microscopic objective. Figure 1a is an example of the setup. The airgap between the top reference glass and sample can be varied by a micrometer. Using a 5x objective, the detected area can be zoomed down to 100 X 100 μm^2 in the visible range with possible improvement by using higher magnification objective. To model the effect of converging incident beam, a detailed analysis based on a 2-beam interference is presented and correction is applied to the measured interference peak positions.

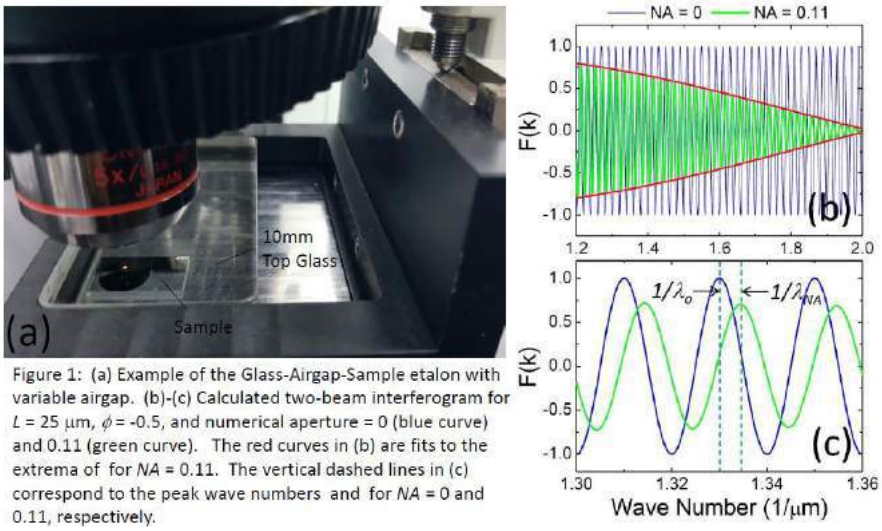

Figure 1: (a) Example of the Glass-Airgap-Sample etalon with variable airgap. (b)-(c) Calculated two-beam interferogram for L = 25 μm, ϕ = -0.5, and numerical aperture = 0 (blue curve) and 0.11 (green curve). The red curves in (b) are fits to the extrema of for NA = 0.11. The vertical dashed lines in (c) correspond to the peak wave numbers and for NA = 0 and 0.11, respectively.

Following the analysis of Kino and Chim[1] the reflected interference intensity $I(k)$ from FP etalon can be written as the weighted sum of the incident beams over all angles. For monochromatic case, the expression is given by Dubois et al[2], which can be generalized to all wavelengths in the visible range by including the dispersion of the objective. The results show that the interference peaks/troughs are shifted by a slowly-varying envelope due to objective 's numerical effect (Shown in Figure 1b and c). To characterize the shift in the interference peak's position, the condition for constructive interference with converging incident beam is derived

from the 1st derivative of reflected intensity. By assuming $L>>\lambda$ with small angular-aperture, the condition for constructive interference can be expressed by equation 1:

$$m = \frac{2L}{\lambda} + \phi + \frac{1}{4} \mp \frac{1}{2} + \frac{1}{2\pi}\arctan\left\{\frac{\cos^2\theta_{\max}\sin\left[4\pi L/\lambda\left(\cos\theta_{\max}-1\right)-\pi\right]}{1+\cos^2\theta_{\max}\cos\left[4\pi L/\lambda\left(\cos\theta_{\max}-1\right)-\pi\right]}\right\} \quad (1)$$

where m is the interference order, L is the airgap between top glass and sample, ϕ is the reflection phase of sample at normal incident normalized by 2π, λ is the wavelength at peak interference under the influence of objective and $\theta_{\max}$ is the half-angular aperture of objective. Due to the arctan term, directly fitting of Eqn. (1) using the measured m and λ, in most of the cases, do not converge. Here, instead of using Eqn. (1), we choose to correct the peak/trough's position such that a simple 2-beam interference model can be used to obtain the correct airgap and absolute reflection phase of the sample expressed as:

$$m = \frac{2L_{fit}}{\lambda_{NA}} + \phi_{fit} \xrightarrow[\lambda_{NA}\to\lambda_0]{correction} m = \frac{2L}{\lambda_0} + \phi \quad (2)$$

and λ_{NA}, λ_0 is the interference peak's position in wavelength with and without influence of objective respectively. L_{fit} and ϕ_{fit} are the as-measured airgap and reflection phase obtained by a direct fitting a simple 2-beam interference model to the data[3].

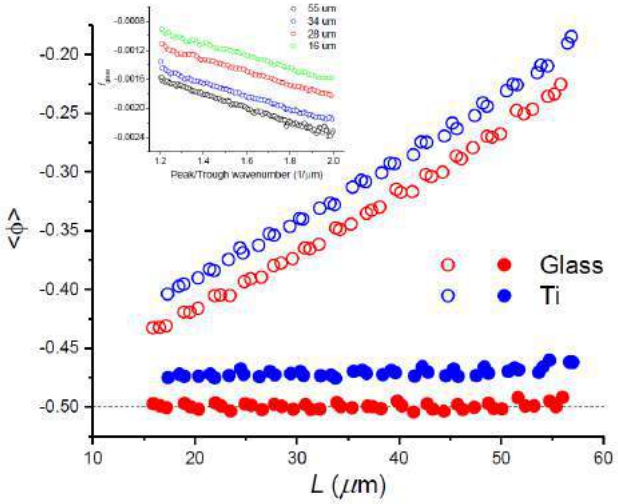

Figure 2: The plot of average reflection phase airgap before (hallow circles) and after the correction by f (solid circles) for glass (red scatters) and 200nm titanium (blue scatters). Inset is the measured value of f plotted at different wavenumbers and airgaps.

The required correction term f can be defined as the relative shift in interference peak/trough's position in wavelength:

$$f = \frac{\lambda_{NA}-\lambda_0}{\lambda_0} \leftrightarrow \frac{1}{\lambda_0} = \frac{1}{\lambda_{NA}}(1+f) \quad (3)$$

By considering its properties under the given experiment conditions, using glass as reference, its value can be fitted from the measured difference of ϕ_{fit} and ϕ as a function of wavelength. The inset in Figure 2 are the measured dispersion of f for glass at different airgaps. As a demonstration, corrections are performed on the measured data from 200nm Titanium on Glass and the obtained average reflection phase before and after correction are also shown in Figure 2.

Abstract-We present the tunable optical response of phase change material, which can be used to metasurfaces with varied functionalities. The concept of reconfigurable metasurface, which have different combination of unit cells with various geometries and phase states are proposed. The research is promising to apply to the area of the metadevice.

. . **Introduction**-Due to thermal stability and rapid transition of phase-change material $Ge_2Sb_2Te_5$ (GST) between amorphous and crystalline states, it has been utilized as the recording medium in optical and electronic rewritable data storage. Metamaterials and metasurfaces, the artificial sub-wavelength structures exhibit the abilities to actively control the optical responses and therefore play potential candidates for a number of feasible applications. Recently, the development have been focused on integration of phase-change material into such artifical photonic structures [1, 2]. However, in most of researches, the use of phase-change material is limited as a switchable dielectric environment (a switch between crystalline and amorphous states).

In this paper, we present the tunable optical resonance of phase-change material $Ge_2Sb_2Te_5$ in the near-infrared regime. Further, we propose the concept of reconfigurable metasurfaces, which have different combination of unit cells with various geometries and phase states.

Result&discussion-The optical transmission spectra of amorphous and crystalline $Ge_2Sb_2Te_5$ nanoantennas with various length L are shown in Fig. 1 (a)-(b). The dielectric constants of the $Ge_2Sb_2Te_5$ in crystalline and amorphous states are adopted and transformed from Ref. 2. The height and width of nanoantenna are 50 nm and 150 nm, respectively. When the polarization of the incident light is parallel to the long axis of the nanoantenna, the resonant dips observed in the transmission spectrum. The resonant wavelengths of the nanoantenna are red-shifted with the increased lengths. We also consider the partially crystalline ability of $Ge_2Sb_2Te_5$ for the multi-level optical resonance shown in Fig. 1 (c).

To further investigate the potential of $Ge_2Sb_2Te_5$ in novel metadevice, we design two kinds of reconfigurable metasurfaces. The dolmen structure is composed of a horizontal nanoantenna and a pair of vertical nanoantennas shown in Fig. 2. With different composition of phase-change rods, the transmission spectrum of the dolmen structure changes dramatically. Another one is the gradient metasurface composed of $Ge_2Sb_2Te_5$-SiO_2-Au resonators for realizing the light steering shown in Fig. 3. The super cell of gradient meta-surface consists of a 130-nm-thick Au mirror, 50-nm-thick SiO_2 spacer and twelve $Ge_2Sb_2Te_5$ nanoantennas with various lengths and phase states. The phase delay of each unit cell depends on the phase state and length of nanoantenna. Fig. 3 (b)

shows the scattered electric field of the gradient of metasurface. The reconstruction of wavefront indicated by a dashed line is shown. The scattered electric field intensity of gradient metasurface versus reflection angles at λ = 1550 nm normal incidence is shown in Fig. 3 (c) as well.

Abstract-We experimentally demonstrated 2-dimensional subwavelength detection of optical phase differences using a metasurface consists of an array of plasmonic nanostructures. The metasurface is fabricated from arrays of coupled gold nanorods where each group of three rods form the circuit to perform the difference operation in one-direction of the *xy*-plane. This metasurface at subwavelength scale can be applied to optical signal processing, ultrafast computing, and biosensing.

Metasurfaces that perform mathematical operations may provide solutions, since they can control the phase, amplitude, and the polarization of light within a thickness smaller than the free space wavelength, forming highly compact optical elements. In this work, we demonstrate plasmonic metasurfaces that perform mathematical operations in two dimensions on an incident light beam, with potential applications in phase-shift key decoding and biosensing.

The plasmonic circuits are fabricated using electron beam lithography. The meta-atom patterns are written on the electron beam resist using the 100 kV electron beam and developed in methyl isobutyl ketone (MIBK): isopropyl alcohol (IPA) solution with the ratio of 1:3. Thereafter, electron beam evaporation was performed to deposit the 2 nm thick germanium adhesion layer and 30 nm gold layer followed by a lift-off process using acetone. Note that the center-to-center distance of the two parallel nanorods used in both circuits to detect differences in the incident light is only 190 nm, which is subwavelength compared with the free space wavelength of 640 nm. The nanorods were designed to be 90 nm long, 40 nm wide, and 30 nm thick.

It is clearly observed that this metasurface performs a two-dimensional mathematical difference operation at the subwavelength scale, which results in it being sensitive to optical phase differences. Phase sensitivity is useful for decoding optical signals carrying data by phase shift keying. The difference operation has potential in nanoscale optical logic operations, since this device behaves like an XOR gate - there is an output if either of the inputs is active, but not both. More generally we have introduced a class of plasmonic devices that can perform a variety of linear mathematical operations with complex coefficients on light fields, determined by the configuration of plasmonic particles. Biosensing for transparent biomaterials is another potential application of this metasurface.

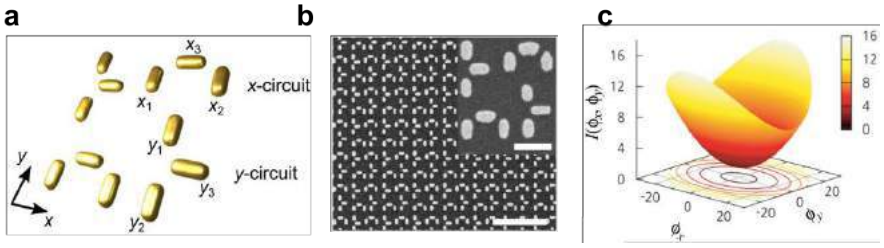

Fig. 1. (a) The unit cell of the metasurface. (b) The SEM image of fabricated metasurface with the magnified image of the unit cell in the inset. Scale bars are 1 μm and 200 nm. (c) Surface plot mapping responses on phase differences in both *x*- and *y*-directions.

Abstract- Meta-surfaces offer an alternative to bulk three-dimensional metamaterials. Because of the two-dimensional nature of the meta-surface structures, they occupy less physical space and can exhibit lower loss. We have pointed a 2.15 GHz wide bandwidth meta-surface for C-band applications. The proposed structure is consisted of ring resonators, where the dimensions of a single unit cell is 11×11 mm^2 and the effective medium ratio 5.27. Commercial available CST Microwave Studio software is utilized to design and numerical analysis. The numerical and the experiment results are around overlapped together. The measured transmittance shows the resonance at 5.17 GHz, and for simulation it was 5.26 GHz. The proposed design is also described by the equivalent inductive-capacitive circuit model and shows left handed characteristics from 6.35 to 7.72 GHz frequency ranges.

Electromagnetic meta-surfaces are artificial material with more compact size comparable with conventional structures and have some infrequent properties, which does not exist in nature materials. In 2000, Smith et *al*. introduced a material that is shown simultaneously negative permittivity and permeability with some exceptional characteristics of microwave frequency [1]. In 2016, Faruque et *al*. suggested a compact square split z-shape meta-atom with left handed features, wide bandwidth for S-, C-, X- and Ku-band applications. The presented meta-atom was investigated at 0^0, 15^0, 30^0, 45^0, 60^0, 75^0 and 90^0 (xy-axis) rotation angle. The designed structure shown resonances at S-, C-, X-, and Ku-band with 5.67 GHz wide bandwidth. The compact meta-atom had an effective medium ratio 9.10 and exhibited left handed characteristics at 8.50 GHz [4]. In 2016, Pan et *al*. proposed a meta-surface to control the absorption and radiative loss and to reduce the radar cross section, where the meta-surface was designed by metallic square patch and square loop structure inserted with resistors, and absorption in the S-band [11]. In 2016, Hasan et *al*. exhibited a compact z-shaped double negative metamaterial for wideband applications. The 10×10 mm^2 structure metamaterial unit cell was applicable for C- and X-band operations and the effective medium ratio was 4.0 [3].

Figure 1(a) shows the schematic geometry of the proposed structure. In figure 1(b), measured transmittance shows the resonance at 5.17 GHz, which is the C-band and the amplitude of the resonance point is 26 dB. In addition, the simulation results of the transmittance (S_{21}) are also shown in the same figure, where the resonance point at 5.26 GHz and the magnitude of the resonance point is 43 dB. From figure 1(c), the designed structure can be called as a left handed meta-surface for any frequency points in the frequency range of 6.35 to 7.72 GHz. However, figure 1(d) represents the effect on resonance frequency by FR-4, Rogers RT 5880, Rogers RT 5870, Rogers RT 6010, Rogers RT 4350, Rogers RT 4003, Mica, and Polyimide, materials used as substrate.

Table 1: Configurations of the proposed meta-surface single unit cell

Parameters	a	b	l	w	l1	w1

Designing flat lenses using a transformation optics approach

Mircea Giloan*, **Robert Gutt**, **and Gavril Saplacan**

Company for Applied Informatics, Cluj-Napoca, Romania,

Abstract— In the context of transformation optics theory we developed a method for designing optical devices able to manipulate the wave vectors in the specific manner required by the functionality of the device. This new approach was applied for designing both diverging and converging flat lenses. As the waves propagate inside the transformation media of the lenses the wave vectors are properly changed in order to impose a converging or diverging propagation of the emergent waves.

The transformation approach is based on the theoretical result which shows that Maxwell's equations have the same form whether we apply a coordinate transformation or introduce specific gradients in the permittivity and permeability of the original space [1]. This approach was successfully used to design a variety of electromagnetic devices including lenses [2]. Recently, a great attention was paid to the design of flat optical devices due to the ability of integration with the planar integrated circuit technology and to the simplicity of fabrication. The concept of optical phase discontinuities was applied to design flat lenses by shaping the wavefront of the emerging wave [3].

In this study we show how the concept of transformation optics can be used to design transformation media able to manipulate the wave vectors in the desired manner, while the alteration of the wave path remains of a secondary importance. In order to manipulate the wave vector inside a flat device having the input and output planes perpendicular to $z-$axis the following class of coordinate transformations was used:

$$\left\{ \begin{array}{l} x^{!} = x \\ y^{!} = y \\ z^{!} = zf(x,y) \end{array} \right\} \tag{1}$$

where $f(x,y)$ is a function of two variables which transforms the z coordinate with respect to x and y coordinates. Following some mathematical computations, detailed in reference [4], we proved that at normal incidence the wave vectors are properly manipulated in order to fulfill the functionality of an aberration-free lens surrounded by the free space when the transformation function has the form:

$$f(x,y) = \frac{1}{\delta - \gamma(\varphi^2 + (x-x_F)^2 + (y-y_F)^2)^{\frac{1}{2}}} \tag{2}$$

where $\gamma = \pm 1/z_D$ (a positive/negative value corresponds to a converging/diverging lens), z_D is the thickness of the lens, $\delta = 1 + \varphi\gamma$, φ is the focal length measured from the output plane of the lens along the $z-$axis, x_F and y_F are the $x-$ and $y-$axis coordinates of the focal point, respectively. The input plane of the designed flat lens coincide with the xy plane of the coordinates system. For the simplified case of a linearly polarized transverse magnetic (TM) plane wave described by the field components $\{E_y, E_z, H_x\}$ and a focal point located on $z-$axis the stretching function f reduces to:

$$f(y) = \frac{1}{\delta - \gamma(\varphi^2 + y^2)^{\frac{1}{2}}} \tag{3}$$

while the permittivity and permeability of the transformed medium are given by the symmetric tensor:

$$\varepsilon = \mu = \begin{bmatrix} h(y) & 0 & 0 \\ 0 & h(y) & -zh^{!}(y) \\ 0 & -zh^{!}(y) & \dfrac{(zh^{!}(y))^2 + 1}{h(y)} \end{bmatrix} \tag{4}$$

where $h(y) = 1/f(y) = \delta - \gamma(\varphi^2 + y^2)^{\frac{1}{2}}$ and $h^{!}(y)$ denotes the derivative of function h. The constitutive parameters tensor given by equation (4) is expressed in terms of the $y^{!}$ coordinate of

the transformed space with the prime dropped for aesthetic reasons. The transformation function given by equation (3) has two singularity points $y_S = \pm\sqrt{z_D(z_D + 2\varphi)}$ where z_D is the thickness and φ is the focal length of the lens.

Figure 1 shows the results of numerical simulations performed using a two-dimensional Finite-Difference Time-Domain (FDTD) algorithm [4]. The thickness and the focal length of the lens were the same ($\varphi = z_D$). Hence, the singularity points of function f are $y_S = \pm z_D\sqrt{3}$. The geometrical dimensions of the lens used in simulations were related to the wavelength of the incident wave as follows: lens thickness $z_D = 5\lambda$ and lens aperture $2y_D = 16\lambda$, where $y_D = (8/5)z_D$ satisfies the inequality $y_D < y_S$ required for positive values of constitutive parameters. The lens was illuminated at normal incidence by a plane wave source of wavelength λ with field components $\{E_y, H_x\}$ of magnitude equal to unity located at $z_S = -z_D$. The simulation area span on $z-$axis from z_S to z_P, where $z_P = 5z_D$. The simulation area was terminated with periodic boundary conditions on $y-$axis and uniaxial perfectly matched layer (UPML) absorbing boundaries on $z-$axis. The simulations have been performed using an orthogonal computational grid with a step resolution $\Delta = \lambda/50$ for each axes and a time step reaching the Courant limit $\Delta t = \Delta/c\sqrt{2}$, where c is the speed of light in free space. Computer simulations show reliable focusing capabilities of the converging flat lens designed in the context of the developed method.

Abstract-A novel and simple approach to trap helical light within a subwavelength metafilm cavity is proposed with a theory and numerical calculations. A silver metasurface giving phase-gradient, dielectric thin-film, and a half-infinite silver mirror are stacked in order to form a metafilm cavity. Compared to conventional metal-insulator-metal (MIM) cavity, the proposed scheme is based on generalized Snell's law using geometric phase of the metasurface and strong interference of multiple scatterings. The proposed metafilm cavity is more compact than MIM cavity and the performance is especially depending on a magnitude of light spin. This approach to trap helical light would be very fruitful for compact optical sensor designs and various nano-cavity applications.*n*

In the field of nanophotonics, explosive attention has been paid on the concept of metasurface for the past few years. Metasurface is an artificial surface to control scattering properties of light in an anomalous way. In 2011, Yu *etal.* proposed the concept of generalized Snell's law of reflection and refraction with discontinuous phase-gradient [1]. Since then, many researches have been published using various metasurfaces to implement ultra-thin flat optical devices [2]. Among those, the concept of geometric phase, also known as optical Pancharatnam-Berry phase, has been widely studied for polarization dependent anisotropic scatterings of light by using metallic nanoslits and nanorods [2-4]. Studies on metasurfaces employing geometric phase concept have mainly focused on holographic purposes, implementing specifically engineered optical wavefront in free space or on a metallic plane.

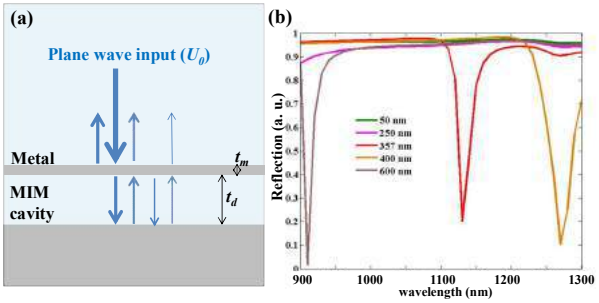

Figure 1. (a) A conventional MIM cavity for Fabry-Perot resonance. t_m is fixed to 30 nm. (b) Calculated reflection spectra using when t_d are 50 nm, 250 nm, 357 nm, 400 nm, and 600 nm, respectively.

However, trapping light within a nanocavity has not been connected with holographic metasurface approach and generalized Snell's law despite the significance of nanocavity and light trapping [5]. Here, we propose a novel scheme to trap helical light using geometric phase of metasurface, generalized Snell's law, and strong interference. As shown in Fig. 1, a simple MIM cavity can also have Fabry-Perot resonance (FPR). To make an FPR in a conventional MIM cavity, at least half-wavelength of optical length is needed for the lowest order resonance. However, the proposed method, named metafilm cavity depicted in Fig. 2(a) and 2(b), is able to make FPR with more compact thickness owing to artificially designed optical paths inside the cavity through generalized Snell's law.

$$\sin\theta = \frac{1}{nk_0}\frac{d\Phi}{dy} = \frac{1}{nk_0}\frac{2\pi}{p_y},\ \theta \approx 48^{\circ}. \tag{1}$$

Discrete subwavelength rotations of silver nanoslits by 45 degrees give phase-gradient and anomalous refraction for cross-polarized right circular polarization (RCP) light as shown in Fig. 2(b). Co-polarized left circular polarization (LCP) light is not affected by phase-gradient in y-direction while reflected or transmitted. As a result, the total 0^{th} order reflection can be approximated as a sum of co-polarized LCP partial waves ($U_{1,LL}$, $U_{2,LL}$, and $U_{3,LL}$). Fig. 2(c) clearly shows that the dips of 0^{th} order reflectance caused by FPR can be obtained with shorter cavity-length rather than those of conventional MIM cavities. We expect that our result would be highly applicable to various flat metafilm absorbers and nanocavity applications in the future.

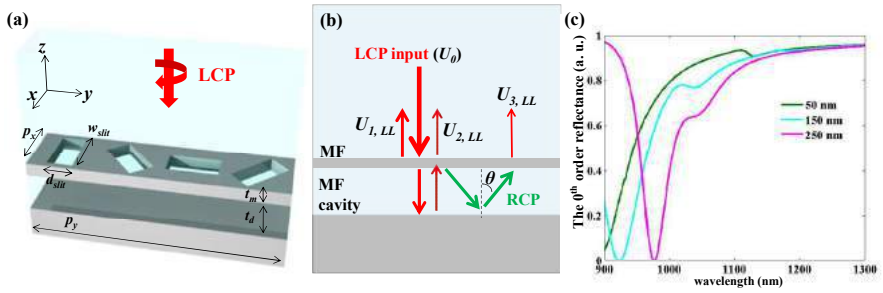

Figure 2. (a) The unit cell scheme of the metafilm cavity. w_{slit}, d_{slit}, t_m, p_x, and p_y are 200 nm, 60 nm, 150 nm, 240 nm, 960 nm. Rotating angle difference between two adjacent silver nanoslits is fixed to 45 degrees. The refractive index of dielectric layers is set to 1.4. (b) A scheme for dominant multiple light scattering processes. Red and green arrows denote lights with left and right handedness, respectively. Total reflectance of LCP light is nearly a sum of $U_{1,LL}$, $U_{2,LL}$, and $U_{3,LL}$. High-efficiency electro-optic transmission modulation with multiply stacked Si *p-n* junction subwavelength gratings

Ki Young Lee[1], Jae Woong Yoon[1*], and Seok Ho Song[1,*]
[1]Department of Physics, Hanyang University, Seoul 133-791, Korea
[*]corresponding author: jaeong.yoon@gmail.com and shsong@hanyang.ac.kr

Abstract- We propose a free-space electro-optic transmission modulator based on multiple *p-n*-junction semiconductor subwavelength gratings. The proposed device operates with a high-Q guided-mode resonance undergoing electro-optic resonance shift due to direct electrical control. Using rigorous electrical and optical modeling methods, we theoretically demonstrate a modulation depth of 84%, on-state efficiency 85%, and on-off extinction ratio of 19 dB at 1,550 nm wavelength under electrical control signals within a favorably low bias voltage range from –4 V to +1 V. This functionality operates in the transmission mode and sustainable in the high-speed operation regime up to a 10-GHz-scale modulation bandwidth in principle. The theoretical performance prediction is remarkably advantageous over plasmonic tunable metasurfaces in the power-efficiency and absolute modulation-depth aspects

Leaky-mode resonances in nanopatterned thin-film metasurfaces are of interest owing to their great potential for creating integration-compatible, multifunctional devices harnessing desired spectral, polarization, intensity, and phase properties [1,2]. Adding active tunability to these device classes by means of direct electrical controls, free-carrier-induced electro-optic (EO) effects in heavily doped semiconductors and transparent conducting oxides (TCO) at epsilon-near-zero (ENZ) conditions provide an efficient tuning mechanism. In particular, ENZ nanofilms incorporated in metal-oxide-semiconductor (MOS) capacitor arrays have showed remarkable intensity and phase modulation properties driven by field-effect free-carrier accumulation and depletion [3]. In this approach, highly dissipative, deep-subwavelength plasmonic resonances are necessary to induce significant optical interaction with sub-10-nm-thick EO-active layers.

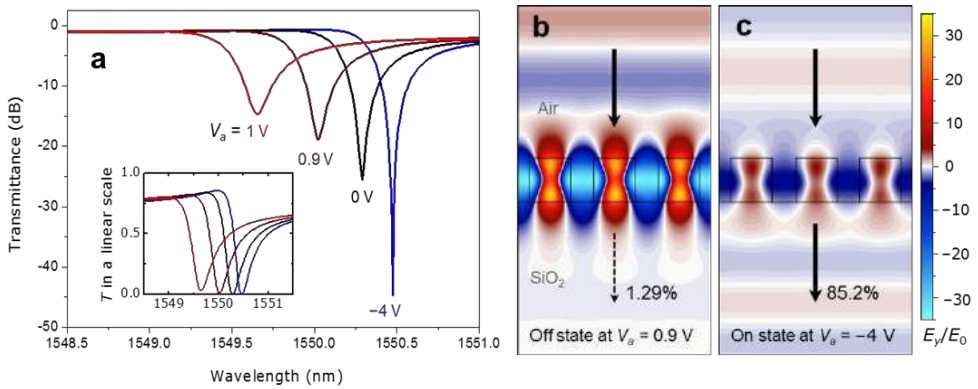

Figure 1. Trasnmission modulation properties. **a** Bias-voltage dependent trasmittance spectrum. **b** Total electric field patterns for off-state and **c** on-state operation regimes.

Pursuing high-performance tunable leaky-mode resonance devices operating in the transmission mode in this paper, we propose an approach based on high-Q GMRs. The proposed device class consists of moderately doped, low-loss semiconductor *p-n* junctions in a resonant subwavelength grating structure. This structure is designed such that a high-Q GMR is supported in the optical domain while in the electrical domain bias voltage across multiple *p-n* junctions effectively control density of conduction electrons and holes, resulting in the associated tuning of the Drude-part optical dielectric constant [4]. we select an interleaved Si *p-n* junction nanograting architecture as one promising example.

We apply the obtained bias-voltage-induced mobile-carrier effect to an example GMR element optimized for the transmission-mode optical modulation in the telecommunications C-band around 1,550 nm. Figure 1 (a) shows the V_a–dependent transmission spectra in dB (a linear scale in the inset) under transverse-electric (TE) polarized planewave incidence at surface-normal angle ($\theta = 0$). Following the standard convention, the TE polarization refers to electric field oscillating in the axis of grating lines (*y*-axis). We use the finite-element method in this calculation involving $\varepsilon_{Si}(z)$ profiles. The transmission spectra show an asymmetric Fano-resonance profile as a result of the configuration interference between resonant and non-resonant pathways. The resonant pathway is created by coupling of the incident wave with a leaky TE_0 mode and its radiation decay toward the transmitted zero-order planewave channel through dominant first-order diffraction processes. This resonance feature possesses remarkably high resonance Q factor ~ 3.69×10^3. Consequently, the design yields a very high field enhancement factor ~ 1.2×10^3 in the 550-nm-thick EO-active Si-*p*-*n*-junction at the resonance center wavelength.

Subtle interaction between the highly enhanced resonant optical fields and bias-voltage-induced mobile-carrier effect results in a resonance-center (λ_c) shift as shown in Fig. 1 (a). Using well-established electrical and optical modeling methods, we theoretically demonstrate a robust transmission modulator with on/off power ratio of 18.9 dB, on-state efficiency of 85.2%, and modulation bandwidth of 54.3 GHz at an operation wavelength of 1550 nm as shown in Fig. 1(b) and (c). These performance characteristics are driven by favorably small bias voltage values in a range of –4 V ~ +1 V and possibly maintained in the high-speed operation regime up to 50 GHz when appropriate in-plane miniaturization schemes are incorporated.

Notably, the obtained properties are supported by the low-loss free-carrier-induced EO effect occurring in the whole device region with 500-nm-thick Si layers as opposed to the transparent-conducting-oxide-based plasmonic metasurface approaches involving a sub-10-nm-thick EO-active region and strong ohmic absorption. Therefore, experimental realization of our proposed device class is of great interest to develop compact, low driving power, and high-speed optical modulators for applications in telecommunications, optical information processing, LIDARs, small-signal detection systems, high-power laser machining, and many others.

Abstract- Conventional metallic metasurfaces are difficult to achieve tunable devices once a structure is fabricated. We propose a method to realize metasurfaces with active focal tuning by graphene-metal hybrid structures. Tunable metasurface lenses in both mid-infrared and terahertz frequencies are proposed.

Unlike conventional optical components, which require enough thickness of the media to achieve wavefront shaping, metasurfaces introduce abrupt and controllable changes of optical properties in two-dimensional (2D) space [1]. However, the modulation of each unit cell is hard to change once a metasurface is manufactured, lacking the flexibility for achieving tunable modulators. Graphene is a 2D form of carbon in which the atoms are arranged in a honeycomb lattice. In addition, the Fermi level of the cone-shaped electronic band structure of graphene is modulatable by an external gate voltage [2], which makes graphene a promising material for tunable optical devices. In this work, based on Berry geometrical phase theory [3], we theoretically demonstrate mid-infrared (mid-IR) and terahertz (THz) tunable graphene-metal metasurface lenses to achieve focusing and active focal control by tuning the graphene chemical potential uniformly.

We first give the design of a cylindrical lens for mid-IR frequencies [4]. The schematic structure of the tunable metasurface lens is depicted in Fig.1 (a). It is composed of an array of rectangular apertures etched on a thin Au film. The metallic film is deposited on a monolayer graphene, which is used to change the scattering electromagnetic fields of the apertures. A glass substrate and a transparent conducting film are below the metal layer. A gate voltage V_g is applied to tune the chemical potential of the graphene layer. The incident light is right-handed circularly polarized (RCP). The inducing transmitted field can be divided into a right-handed circularly polarized light and a left-handed circularly polarized (LCP) light with an abrupt phase change of 2φ. Thus a desired phase change of the LCP light can be obtained by the rotation of the aperture. By this principle, a lens with a focal length of f can be designed by [5]:

$$\varphi(x) = \frac{\pi}{\lambda}\left(\sqrt{x^2 + f^2} - f\right) \tag{1}$$

In order to design a tunable metasurface lens, the phase change should be different for each unit on the metasurface when the graphene chemical potential varies uniformly. We find that the phase of the LCP scattering light can be tuned by changing the chemical potential of the graphene layer and the length of the aperture (not depicted here), thus a tunable metasurface lens is expected to be achieved. We choose 17 apertures along the x-direction. The designed result is shown in Fig.1(c). FDTD simulations are then conducted to verify the focal effect and the tunability of the lens. The electric field intensity distributions of the transmitted LCP light are shown in Fig.1(d).

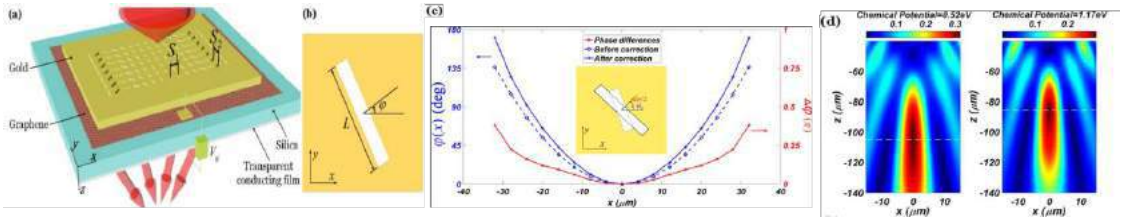

Fig.1 (a) The structure of the cylindarical lens for mid-IR. (b) A unit cell of the metasurface. (c) Rotation angles (blue solid line) corresponding to the 17 slits of the designed lens at different positions. (d) Electric field intensity distributions of the transmitted LCP light corresponding to the chemical potentials of 0.52eV and 1.17eV, respectively. The focal length changes from 105 to 85μm when the incident wavelength is λ=6.6μm.

This method can also be applied to design tunable Thz lenses. We design a tunable metasurface sperical lens in Thz frequencies (λ=400μm). The schematic structure of the metasurface is depicted in Fig.2 (a). When the lens is illuminated by RCP light, the electric field intensity distributions of LCP light are shown in Fig.2(b). The focal length changes from 4.67mm to 5.24mm.

The SNOM observation of surface plasmon modes from different chiral plasmonic structures

Feng Lin*

School of Physics, State Key Laboratory for Mesoscopic Physics, Peking University, Beijing 100871, China

*corresponding author: linf@pku.edu.cn

Abstract-Au nanostructures can be fabricated to intentionally guide the propagation of surface plasmon polaritons (SPPs), which leads to the varying of propagating directions for the SPP beams, and thus generates the orbital angular momentum (AM) of SPPs. Here, we investigated the coupling of such plasmonic orbital AM with optical spin AM, and found that the chiral characteristics of Au nanostructures impose great effects on the electromagnetic modes of SPPs under this spin-orbit interactions.

The optical spin-orbit interaction is that a coupling of the intrinsic angular momentum (photon spin) and the extrinsic momentum (orbital angular momentum) [1-2]. The effect is usually observed when the light passes through an anisotropic and inhomogeneous medium. For instances, the optical spin Hall effect, beam displacement and momentum shift due to the optical spin, was observed at the medium interface. In plasmonic structures, the surface plasmon polaritons travel along the path that can be defined to within a subwavelength scale by the geometric patterns of the structures, which generate a significant optical orbital angular momentum. In our work, on the Au thin film deposited on glass substrates, we fabricate the subwavelength holes by focused ion beam, which form the ring shape. Using the scanning near-field optical microscope, the different propagation modes of surface plasmon polaritons has been observed for the excitation light with the left and right handed circular polarization, respectively. Based on the conservation of total optical angular momentum in this circular system, the coupling effect of the spin and orbital angular momentum can be deduced from the measured and simulated distribution of electric fields.

Abstract-In this work, we designed three types of terahertz (THz) nano-slot-antenna arrays to obtain rotation-free performance in transmission. Honeycomb- and the chlorophyll-shape patterned arrays show multi resonance features in transmission, induced by the strong resonance coupling between adjacent slots, and those are azimuthally rotation-free to normal incidence. For interpreting this interesting phenomena, coupled harmonic oscillator model was applied and the resultant spectra were analyzed in terms of coupling strength.

The electromagnetic near-field enhancement behaviors via nano-slot-antenna structured metamaterials, consisted of subwavelength width of slots in orders of $\lambda/10$ - $\lambda/10{,}000$, can be applied to highly sensitive and selective optical sensors [1, 2]. In such applications, collinearly aligned slot antenna arrays have been usually considered, by taking advantage of maximized transmittance magnitude with clearly defined resonance behavior according to their geometry and effective refractive index of materials [2, 3]. Normally this collinearly aligned antenna array shows strong rotation dependence on both transmission and reflection, which can be issued regarding somewhat inconvenient aligning and unexpected decreasing of efficiency in molecular sensing.

Here, we demonstrate THz transmission control by several uniquely patterned slot antenna arrays, including asterisk, chlorophyll, and honeycomb patterns. These patterns were designed to compensate rotation-induced transmission decreasing of each elementary slot in an array. The elementary slots are identical, which have fundamental resonance at 0.92 THz with 64 μm-length and 500 nm-width, and are fabricated onto the thin gold film (150 nm thickness). Typical collinear pattern shows clear resonance with transmission decreasing by azimuthal rotation as shown in Fig. 1(a). The asterisk pattern also has a single resonance similar to collinear pattern, but has constant transmission efficiency over all measured angles. The honeycomb pattern depicts rotation-free transmission with dual mode resonances: a fundamental mode and an additional secondary mode near 0.7 THz which is induced by strong resonance coupling with adjacent slots, as shown in Fig. 1(b). The transmission efficiencies of fundamental resonance mode in terms of the rotation angle, for four different nano-slot-antenna arrays, are plotted in Fig. 1(c). The suggested three unique patterns represent completely rotation-free performance. We also put the theoretical interpretation for the dual resonance behavior (Fig. 1(b)) using coupled harmonic oscillator model [4] (Fig. 1(d)). The calculated results with the model has an excellent agreement with measured spectra. The resonance peak is split into dual resonance mode with individual transmittance decreasing and the secondary mode has a redshift as coupling constant increasing in the model.

In conclusion, we have made three different types of nano-slot-antenna arrays which have constant transmission efficiencies by rotation angle. Honeycomb- and chlorophyll patterned arrays show dual-resonance spectra, well interpreted using coupled harmonic oscillator model. The model gives analytical information for the resonance tunability for spectral changes by the coupling strength. Finally, we hope that the results presented here will help further applications including rotation-free and controllable multi spectral optical sensors.

Abstract- We present a bilayer metasurface that modulates phase of light at two different wavelengths independently. A unit cell of the metasurface is composed of stacked poly-silicon nanofins with different geometric parameters, including height, length, width, and rotation angle. Each nanofin gives different amplitude and phase at each target wavelength, so that phase of each wavelength can be tailored independently. The proposed metasurface can be applied to dichroic splitters, full-color holography, and achromatic optical elements.

Metasurface, which is an artificially engineered material with a subwavelength scale thickness, gives an entirely new approach to design optical elements. Properties of light, such as polarization, phase, and amplitude profiles can be tailored within a wavelength of propagation using properly designed metasurfaces [1]. More recently, one of the most fundamental optical element, a lens is realized using a metasurface based on titanium dioxide nanofins and their geometric Pancharatnam-Berry phase [2]. The geometric phase is a powerful tool to achieve spatial modulation of phase because rotation angle of a scatterer is directly proportional to phase of output light. However, due to evenness of spatial phase profiles, metasurfaces based on the geometric phase inevitably suffer from the chromatic aberration after diffraction. In order to reduce the chromatic aberration, metasurfaces composed of dielectric resonators with a slot [3], nanopillars, [4] and sub-pixel structure [5] have been proposed, which can give different phase profiles according to wavelengths.

Here, we propose a bilayer metasurface that can manipulate phase of incident light independently at two wavelengths. Two stacked poly-silicon nanofins with a period of 380 nm constitute a unit cell of the metasurface as shown in Fig. 1(a). Each nanofin has different geometric parameters which cause transmission to differ with respect to the wavelength. By superposing two transmitted waves from each nanofin with additional geometric phase 2θ due to rotation angle of the upper nanofin, it is possible to achieve arbitrary phase difference between two wavelengths. If complex-valued transmission coefficients are given by a_1 and a_2 for each nanofin layer, geometric parameters and the rotation angle θ can be found by satisfying the relation:

$$r = \left| a_1 + a_2 e^{i2\theta} \right|, \tag{1}$$

where r is a constant representing modulation efficiency.

Wavelengths are set as 800 nm and 980 nm, and corresponding dielectric constants are $3.58 + j0.001$, $3.68 + j0.005$ for the nanofins, and 2.1124, 2.1045 for the host medium, respectively. At first, a_1 and a_2 at two wavelengths are investigated with auxiliary geometric parameters of h_1 = 350 nm, h_2 = 400 nm, d = 50 nm. Figures 1(c)-1(f) show transmitted phase of left-hand circularly polarized light when right-hand circularly polarized light is incident normally from the bottom. It is seen that phase differences between two wavelengths

are tuned by 161 °, 49 °, −48 °, and −160 °. As well as these examples, more arbitrary phase difference can be achieved based on the proposed design principle.

It is expected that the proposed design method can be applied to more generalized achromatic metasurface, including compact dichroic splitters, full-color holography, and achromatic optical elements.

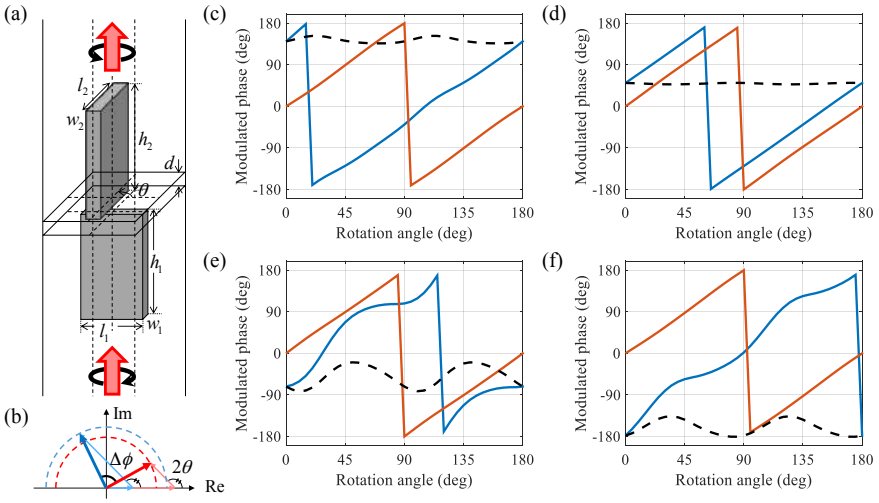

Figure 1. (a) Schematic illustration of a unit cell structure. (b) Vector representation of superposition of two transmitted waves by nanofins at different wavelengths. (c-f) Geometric phase profiles with respect to the rotation angle of the nanofins. Blue solid lines denote 800 nm wavelength, red lines 980 nm, and dashed lines are their difference. Geometric parameters (w_1, l_1, w_2, l_2, θ) are given by (c) (250 nm, 80 nm, 200 nm, 55 nm, 85 °), (d) (230 nm, 60 nm, 200 nm, 60 nm, 115 °), (e) (250 nm, 60 nm, 240 nm, 80 nm, 110 °), and (f) (250 nm, 80 nm, 200 nm, 60 nm, 75 °), respectively.

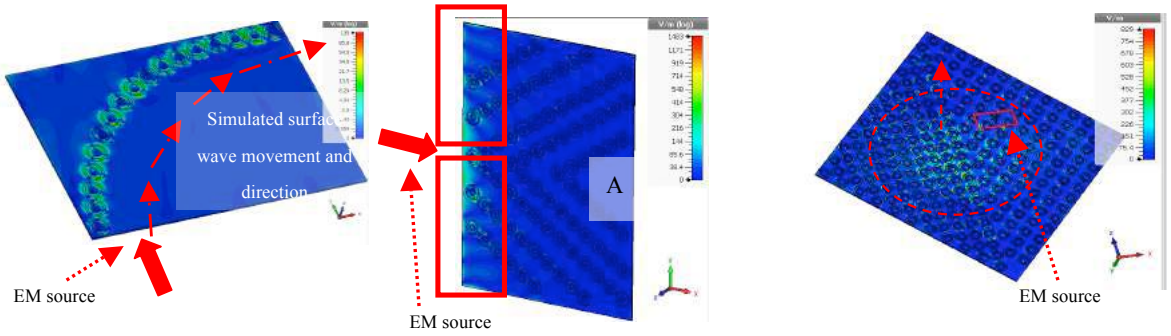
Abstract-This paper discover ways of exploiting corresponding unequal divided circles (CUDC) unit cells with different formations and its related electromagnetic surface wave behavior using 3D tetrahedral eigenmode computation. Strategically placed unit cells using identified formation, known electromagnetic surface wave can either be allowed to pass through, blocked and redirect to desire angle within designated area. Engineered CUDC presented shows strong resonance at 5.9 GHz and produced stable electromagnetic bandgap (EBg) region from 5.9265 GHz to 5.9516 GHz.

Through extensive literature and Babinet's guideline [1], findings shows that engineered CUDC unit cell will exhibit a semi-static reverberation trademark once energized with an outer period changing electromagnetic field streaming ordinarily towards CUDC unit cell plane. After a CUDC unit cell is etched on the microwave laminate surface closed to or on the positive, negative plane. The EBG condition produced by such unit cells was discovered able to differ undesirable electromagnetic field, spreading on the vertical plane to such conductive layer. To model this CUDC EBg plane, various optimization and algorithm were examined [2]. Hence only a single full wave solver was found suitable which CST MWS is. CST MWS can provide a mish mash full wave electromagnetic wave numerical prediction accompanied by an enhancement calculation algorithm. Utilizing this features, CUDC was found able to produce a bandgap region within the 5.9 GHz possible. CUDC-EBg was imprinted on a FR4 laminate, thickness = 1.6 m and permittivity = 4.3.

CUDC unit cell are proposed to be organized in certain arrangement and it is observed to be adequate in manipulating surface wave. The distinct electromagnetic reaction of CUDC unit cell can be inspected utilizing prominent electromagnetic field hypothesis [3]. Nonetheless, constructing EBg based devices may include larger amount of comprehension of every part [6-8] to function effectively. Therefore, exact quantitative examination of 3D EM field impacts of EBg unit cell can be done utilizing numerical full wave means, for example, computer simulation technology microwave studio (CSTMWS) utilized here to check both scientific and basic modeling [4].



(a) (b) (c)

Figure 1: Simulations of CUDC surface wave (a) Electrical surface movement at 5.9 GHz (b) Electrical field at the wedge are seen lees visible where A is the location with no surface wave and (c) with a denser CUDC region, strong electrical field are found resonating at the middle.

Conclusion: CUDC unit cells frequency response and EBg capability can be simulated by using eigenmode solver. An alternative transmission route can be constructed where energy movement can be seen flowing at its peak from Figure 1(a). From Figure 1(b), A surface wave beam separator was created that can reduce scattering from an object dividing incident wave in a given direction. This type of formation can be used to shield regions on a surface from surface wave incident externally or to prevent interference between two devices on the same platform. Lastly, form Figure 1(c), a rectangular flat panel with CUDC unit cells was patterned with the aim to alter forward and backwards scattering. This can be achieved by placing an angled electromagnetic source near the CUDC surface that reflects incident wave in a different direction. The CUDC unit cells was arranged into two different regions with different formation and volume.

[*]mezanuddin85@gmail.com

Abstract- Not all engineered metallic structures with the same resonance can exhibit acceptable electromagnetic bandgap (EBg). In this paper, several metallic structures consisting of rectangular, deformed, slit patch and unequal divided circles (UDC) were assessed its proneness in manipulating surface wave and producing targeted EBg. Utilizing FR4 laminate, decent EBg can be achieved by using optimized structure with the correct resonance. Results shows a stable and decent EBg region can be gained from UDC specifically from 5.9 to 6 GHz.

There can exists numerous diverse propagation constants at the similar resonance. Each one is known as a particular mode with its own phase velocity, group velocity and electromagnetic field distribution. The relation between phase and frequency response when plotted out and can be referred to as its dispersion attribute. This attributes determines the bandgap behavior of the engineered metallic structure. This dispersion attribute chart is a graph based on frequency versus spatial phase variations of the predefined parameter of phase. Here in this paper, the phase part is selected to be swept from 0 to 180 degrees in 19 steps for an even and understandable pace. Figure 1 shows the simulations done using periodic boundaries in the z-direction. The frequency range of investigation starts from DC to 14 GHz for the first three metallic sample, and then Dc to 8 GHz for the proposed structure. It is essential to monitor the dispersion curve along the phase axis with a periodicity of $2\pi/p$ namely $0 < \beta_{xn} < 2\pi/p_x$, which is also known as the Brillouin zone [xxx]. By simulating the structure in the periodic mode, field distribution of a surface wave is also periodic with a proper phase delay determined by the wavenumber and periodicity. Thus each surface wave mode can be decomposed into an infinite series of space harmonic waves as shown in equation (1):

$$\vec{E} = (x, y, z) = \sum_{-\infty}^{+\infty} \overrightarrow{E_n}(y, z) e^{-j\beta_{xn}x}, \beta_{xn}(\omega) = \beta_x(\omega) + n \quad (1)$$

Conclusion: From all the simulation work done, only metallic structure named unequal divided circles dispersion attribute lead to the formation of desired EBg. A good and stable bandgap region exist which is situated at 5.9265 GHz to 5.9516 GHz as highlighted in Figure 1(d). From all 7 modes investigated, apparently there are six bandgap region. As seen, not all the region can satisfy a proper bandgap along its operating frequency. Most of the modes are found either too wide (plot Γ to X) or too narrow (plot M to Γ) since this unequal divided circles structure uses two different radius size that effect frequency scattering response while introducing coupling effect.

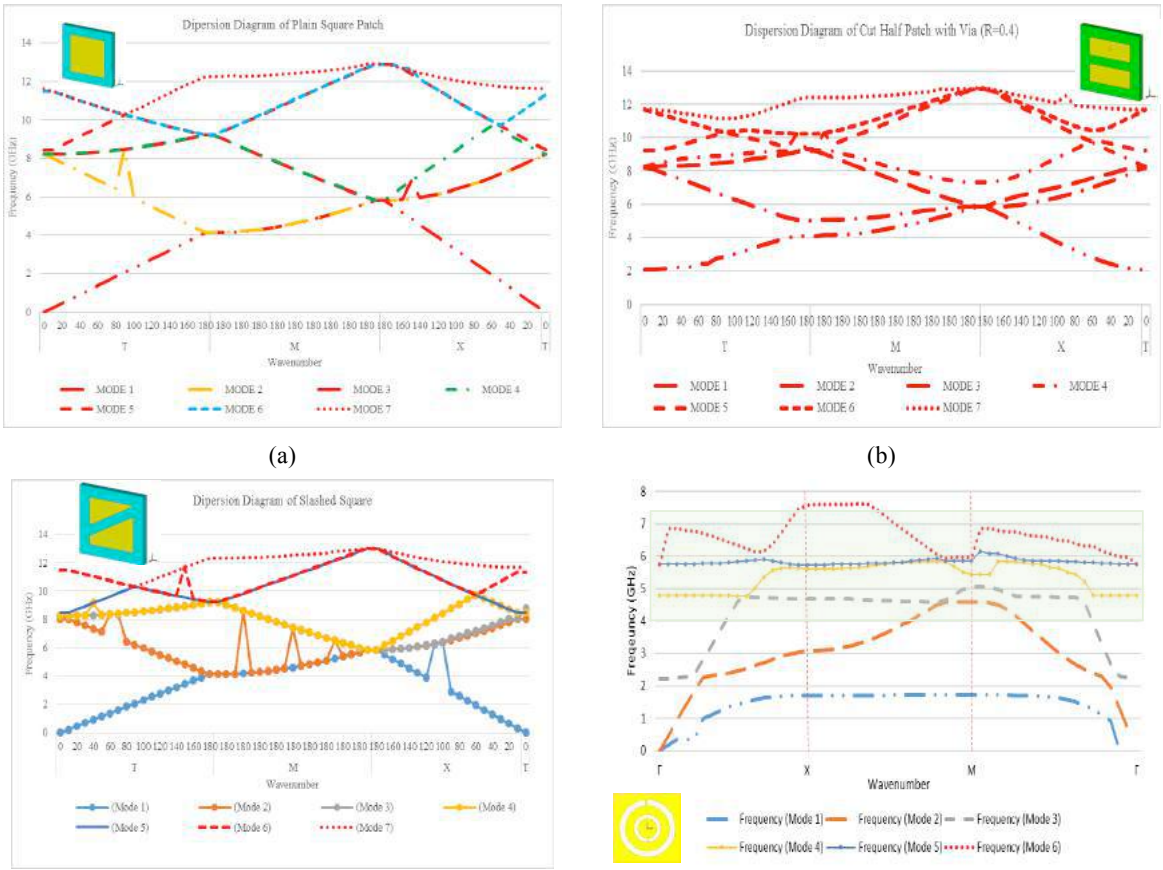

Figure 1: Simulated metallic structures and its corresponding dispersion attribute, a) Rectangular patch – exist potential EBg region, b) Deformed patch – no EBg region due to its narrow phase are, c) Slit patch – no EBg region due interfering resonance spike from different modes, and d) Unequal divided circles – exist a small EBg.

Abstract: UV plasmonic technology has enabled many advanced applications however, the design and implementation of UV interactive metasurfaces remains challenging. To aid in the design of such metasurfaces we demonstrate a model accurately describing the far-field response of a chiral structured metasurface at UV wavelengths. This model is applicable to any arbitrary shape and significantly reduces the reliance on FDTD calculations required to characterize a plasmonic device.

UV plasmonics has produced many useful technological applications such as label-free detection of biomolecules [1], tip-enhanced Raman scattering [2], and enhanced circular dichroism spectroscopy [3]. An application of UV plasmonics that has, until recently, remained largely unrealized at the experimental level is the UV interactive metasurface composed of periodic arrangements of subwavelength surface structures. These structures are designed to act as spatial modulators of both the incident polarization and phase wavefront over subwavelength distances. The design of devices for sophisticated applications such as right and left circular polarization (RCP/LCP) filtering at UV presents several challenges: fabrication remains difficult due to device scaling required at UV, material choice is crucial since typical plasmonic metals are not suitable at UV, and the design of metasurface structures requires immense calculation resources. In regards to the latter, previous work describing chiral nanoparticles as collections of coupled oscillators presents an intuitive picture for chiral nanoparticle behavior [4,5]. Understanding the underlying mechanisms of chiral nanoparticles can lead to significantly reduced design times due to less reliance on numerical solvers.

In this work an analytic model is presented describing the polarization dependent far-field response of a UV interactive metasurface consisting of a periodic arrangement of chiral structures demonstrating strong circular diattenuation (CD) at 350 nm (see Fig. 1), where $\mathrm{CD} = \pm(P_{RCP} - P_{LCP})/(P_{RCP} + P_{LCP})$ and P_{RCP} (P_{LCP}) is the transmitted or reflected power from the metasurface with RCP (LCP) incident light. The metasurface is characterized in Cartesian coordinates by a 2x2 polarization matrix:

$$\vec{\vec{\alpha}} = \begin{pmatrix} \alpha_{1,1} & \alpha_{1,2} \\ \alpha_{2,1} & \alpha_{2,2} \end{pmatrix} \quad (1)$$

where the metasurface far-field response is given by $\vec{E}_{far} = \vec{\vec{\alpha}}\vec{E}_{inc}$ for incident field $\vec{E}_{inc}$. The CD is calculated from eq (1) for RCP and LCP incident fields $\mathrm{CD} = \pm(|E_{RCP}|^2 - |E_{LCP}|^2)/(|E_{RCP}|^2 + |E_{LCP}|^2)$ giving

$$\mathrm{CD} = \frac{1}{2\pi}\int_0^{2\pi}\int_0^{\pi} Im\left\{\frac{\alpha_{1,1}\alpha_{1,2}^* + \alpha_{2,1}\alpha_{2,2}^*}{\|\vec{\vec{\alpha}}\|^2}\right\} sin\theta d\theta d\varphi \quad (2)$$

where the integration is over the transmission or reflection half space, $\#\|\vec{\alpha}\|^2 = \sum_{i,j}|\alpha_{i,j}|^2$ and -1 ≤ CD ≤ 1. The polarization matrix of equation (1) is easily extracted using FDTD calculations for any two incident orthogonal linear polarizations The resulting matrix then describes the device far field response for any arbitrary incident polarization. This work will show the CD response of a plasmonic metasurface is not due to circular dichroism or optical activity, but is characterized by equation (1) and hence originates from the interaction of strongly coupled oscillatory modes in the metasurface structure. The device response can be characterized by constructive or destructive interference in the far-field. This understanding of the far field response of plasmonic metasurfaces can lead to a more general model describing the polarization response for any arbitrary incident angle.

In this talk we discuss the model assisted design, fabrication, and experimental realization of an aluminum chiral structured metasurface exhibiting strong CD at UV wavelengths. The complex interaction of oscillatory modes leading to the circular polarization dependent modes in Figure 2 will be explored in the context of eq (1).

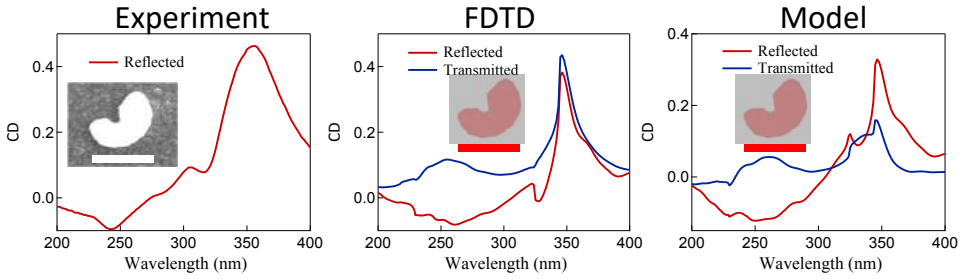

Figure 1. (a) The CD response of a periodic array of Aluminum chiral structures measured with an ellipsometer. The structures are patterned on a fused silica substrate using ebeam lithography and ebeam evaporation (see image inset, scale bar corresponds to 200 nm). (b) Using the SEM image in (a) as a template and ellipsometer measured permittivity of Al, the CD response of the fabricated structure is characterized with FDTD calculations. (c) The CD response of the fabricated structure as predicted by the model described in equations (1) and (2).

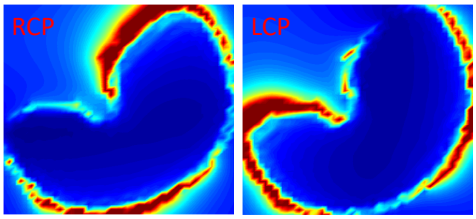

Figure 2. The FDTD calculated field profile $|E|^2$ of the fabricated structure template at wavelength 350 nm demonstrates strongly distinct resonant modes at RCP and LCP.

Abstract We propose all-optical AND gates based on a 120-nm thick metasurface beam deflector. The binary contrast can be maximized up to 9.5 dB by introducing an additional bias input. The insertion loss is also evaluated as 1.5 dB with use of silver at the wavelength of 633 nm. As far as we know, this is the thinnest linear optical logic gate satisfying the better performances. It could be effective to configure lower latency optical computing circuits.

All-optical logic gates have been one of fundamental researches to realize scalable optical computing. Most of them are based on nonlinear optical effects since logic operations should be performed with the nonlinearity between input and output signals [1]. However, it is very though to achieve the device length of < 10 μm because the effective nonlinear coefficient cannot be high enough even with using current nanophotonic devices. On the other hand, linear all-optical logic gates also have been proposed and demonstrated by several groups based on polarization [2], photonic crystals [3], and plasmonic waveguides [4]. Linear devices can operate constantly even with very small input power. The length can be very short as < 5 μm if we use metal-air-metal waveguides [2]. However, most of them do not care the huge insertion loss which constrains the cascadability.

For shorter length with smaller loss, we propose an extremely thin linear optical logic gates as illustrated in Figure 1(a) - the cross section consists of a metasurface beam deflector (trapezoid antenna array), a silica spacer, and a partial reflector on a quartz substrate. The total thickness except for the substrate is only ~120 nm [6]. This gate has 6 ports in total, so we can input 3 signals independently. *BC* can be maximized with an additional bias input (a beam splitter, which has 4 ports, cannot have such a bias input). (b) shows the I/O configuration for AND operation. 2 in-phase signals and 1 out-phase bias input from Port A, B, and D are respectively input. All the inputs are *y*-polarized plane waves with same wavelength of 633 nm. The input intensity from A and B are set as unity. The output to Port C is simply determined by the multiple interference of the inputs at the metasurface. Therefore, the bias intensity from D should be fixed according to the transmittance relationships for the best *BC* (typically around 0.25 – 0.75). By investigating the structural dependences of the transmittances, the three layer thicknesses are determined as (d_{MS}, d_{SP}, d_{BPR}) = (30, 70, 18) nm to obtain the best *BC* with the smallest insertion loss. (c) shows steady state responses of E_y field against all (A, B) combinations. When (A, B) = (1, 1), we have a larger output toward Port C, otherwise less. Table (d) compares the output intensity with different input combinations. The material difference between gold and silver is also investigated in here (in the case of silver, the layer thicknesses are optimized as (d_{MS}, d_{SP}, d_{BPR}) = (30, 80, 10) nm). For both materials, we can obtain *BC* ~ 9.5 dB. When we have an unity output with (A, B) = (1, 1), the insertion loss is regarded as 0 dB. According to this definition, the insertion loss is evaluated to be ~1.5 dB with the use of silver. If we choose a telecom wavelength, the loss can be less because of smaller absorption loss in metal.

In conclusion, we proposed a novel linear optical AND gate by utilizing an extremely thin metasurface beam deflector with a partial reflector. Even with the thin thickness, it has better *BC* of ~ 9.5 dB and smaller loss of ~ 1.5 dB. As far as we know, this concept should be the ultimate one to have the shortest all-optical logic gates. Optical inverters (NOT gate) are also achievable based on the concept of bias input. Such shorter gates would be a key technology for lower latency optical computing.

Abstract-In the field of nonlinear optics, the capability of tailoring nonlinear optical properties in confined area is an important issue. Here, we propose a novel strategy for designing a metasurface that can control magnitude of nonlinear susceptibility continuously. The continuous control of the nonlinear susceptibility is demonstrated by using X-shaped nanoantennas, which induce the third harmonic generation due to its circular symmetry. The proposed metasurface is expected to be applicable to nonlinear applications such as nonlinear holography and data storage.

Metasurfaces are artificially fabricated planar structures whose optical characteristics can be modified by individually adjusting the scattering characteristics of constituent nanoantennas. Recently, metasurfaces have attracted extensive interest owing to their numerous functionalities and potentials [1]. One of the most important application of metasurfaces is holography. Holography is an important technique that can record and reconstruct wavefronts of light with both amplitude and phase information. However, conventional holography, which is based on typical optoelectronic devices such as diffractive optical elements and spatial light modulators, has been suffering from several issues: low resolution and occurrence of noise caused by the diffraction orders and DC components. More importantly, conventional holography techniques are based on the phase- or amplitude-only modulation with incomplete approximations.

Owing to the benefits of metasurfaces such as compactness and the variety of the functionalities, metasrufaces have offered novel methods for holography that overcome the defect of conventional holography. Some studies report metasurfaces that are able to modulate phase, polarization of light, or both [2, 3]. For simultaneous phase and amplitude modulation, metasurface with C-shaped or V-shaped nanostructures were proposed [4, 5], but they have been still deficient; the V-shaped structure only provides imperfect modulation in the sense that the accessible range of complex-amplitude is partial, and the C-shaped structure only operates on Terahertz region. Therefore, full modulation of electromagnetic waves for perfect holography still remains challenging. Recently, several studies have shown that nonlinear metasurfaces can open the new way to realize optical holography with unique advantages. These approaches add functionalities to the optical field modulation and permit the exploration of interesting new possibilities such as generating tailored light at new frequencies, all-optical mode control, and generation of waveform-entangled states [6]. For this reason, nonlinear meatsurfaces are expected to make an advantage which linear metasurfaces are hard to have.

In this study, we propose a metasurface that enables to control both phase and magnitude by manipulating third-order nonlinear susceptibility. We have found that such metasurface can be successfully designed by using X-shaped nanoantennas of which schematic is represented in Figure 1(a). This structure has circular symmetry, especially C2 symmetry, so it can strongly enhance the third harmonic generation (THG).

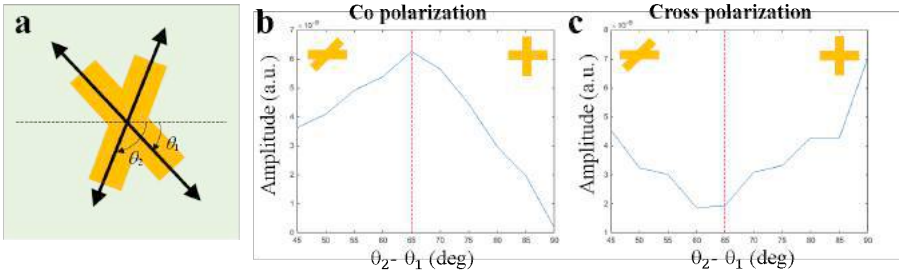

Figure 1. (a) Schematic of X-shaped nanoantenna. (b, c) Amplitude of the transmitted light with (b) co-polarization and (c) cross-polarization from X-shaped structure as a function of the differences between two orientation angles of the X-shaped nanoantenna.

The basic principle of the X-shaped structure is related to Pancharatnam–Berry phase. Pancharatnam–Berry phase can be applied to both linear and nonlinear optical regions due to its robust and dispersion-less nature, so this remarkable nature of the Pancharatnam–Berry phase allows that the X-shaped structure can make it possible to modulate the complex nonlinear third-order susceptibility continuously. The operating scheme was modeled with theoretical analysis based on dipole moment modeling, and the performances of the proposed structure were verified by using a numerical simulation based on finite difference time domain (FDTD) method. As shown in Figure 1(b) and (c), amplitude of the transmitted circularly-polarized light is successfully controlled by the disparity of two orientation angles of the X-shaped nanoantenna. In addition, the phase component can be fully covered by rotating the entire structure because of the nature of Pancharatnam–Berry phase. It means that full modulation of the complex nonlinear susceptibility can be realized. In the presentation, we will explain basic principles of the proposed structure, and then results by numerical simulations will be discussed.

Abstract- Electromagnetic coupling of nanoparticles in plasmonic nanostructures leads to effective hybridization and modification in optical properties of the nanostructured metasurfaces in visible region. In the present paper, we study the outstanding optical properties of nanodimers and nanotrimers composed of Ag nanorods in terms of the circular dichroism (CD) and the electromagnetically induced transparency (EIT)-like response. It is shown that breaking symmetry of this configurations boost these optical properties. Therefore, these arrangements can be considered as building blocks for proposing novel optical metasurfaces.

In recent years, the modifications corresponds to different phenomena have been investigated in optical properties to develop various applications in nanooptics, bio-electromagnetism, and complex photonics. Recent studies have revealed that (EIT)-like optical responses as well as chiroptical features such as CD can be obtained classically using on-chip plasmonic and photonic nanoresonators [1-4]. In plasmonic nanostructures, EIT can be controlled with the interaction of the radiant and superradiant modes in the arrangments. Similarly, CD can be tunes with the coupling intensity between nanoparticles and the degree of asymmetry in the nanostructure [4]. In this way, nanodimers and nanotrimers are two of the best candidates for achieving interesting optical properties including CD and EIT. Here, we address the optical interaction of nanoparticles in the dimer and trimer arrangements in order to investigate the optical chirality and EIT. As a classical model, we use the known quasi-static coupled dipoles approximation (CDA) method to study the interaction of nanoparticles and the resulted hybridization phenomenon. In the case of inverted-T nanotrimer, there is a special feature that breaking the symmetry leads to occurring a new mode in contrast to the trimer case composed of nanospheres. Due to the capability of the tuning the hybridized LSPR mode in desired direction and thus having more effective interaction between nanoparticles, we use structures composed of nanorods in the nanodimer and nanotrimer cases to study the optical chirality and EIT. There are different mechanisms applied to the structures in order to break the symmetry in the structure to achieve considerable/effective EIT and CD. Fig. 1(a) illustrate the schematics of a dimer and a trimer composed of Ag nanorods and a plane wave, polarized along the vertical nanorod, incident normally to the structures. Extinction cross section of the considered dimer and trimer versus different separation distance are presented in column two and three, respectively. Figs. 1(c, f) show the numerical results and Figs. 1(d, g) represent the theoretical results obtained via CDA approach. In the CDA method nanorods are approximated with prolate nanospheroids (see Fig. 1(b)), which the quasi-static polarization of them is well known [4]. As seen in Fig. 1, due to the interaction between nanorods two hybridized plasmonic modes are induced in the nanostructures, although the polarization of the incident field is along the

z axis. For a dimer it is shown that for the symmetric T-shape dimer, two hybridized modes merge and a single resonance at the LSPR wavelength of a single nanorod is observed. However, for asymmetric configurations, g=-20, 0 nm, in-phase and out-of-phase hybridized modes separate further. Similarly, in the case nanotrimer, as seen in Figs.1 (f, g), the bright mode of the nanostructure, LSPR resonance of the vertical nanorod, splits to hybridized or dark modes. The bandwidth and the amplitude of the induced modes can be tuned with the separation distance s. Unusual optical properties of the dimer and trimer are shown in Figs. 1(e, h). It can be seen that asymmetric nanodimers reveal significant CD; though, for symmetric configurations, g= 20 nm and g= -30 nm as plotted schematically, CD vanishes. The outstanding results in Fig. 1(h) show the transmission spectra of horizontal double nanorods, a vertical nanorod, and the corresponding trimer while the polarization of the incident field is along the vertical nanorod. Interestingly, the nanotrimer has a EIT-like behavior at the dark modes of the nanostructure; although it is opaque at the bright mode of the nanotrimer. Consequently, the results of this paper are posed to have a general significance for the field of chiral nanoplasmonics and electromagnetically induced transparency.

Abstract – In this work, we demonstrate self-assembly of the closely-packed plasmonic nanoparticles (NPs) superlattice that could exhibit unnaturally high-refractive-index at optical frequencies. We successfully synthesized highly uniform and smooth AuNPs with sphere and cube shapes; by benefitting from this unprecedented quality of AuNPs, we approached to the practical limits of the accessible minimum gap between AuNPs, self-assembled into large-area, close-packed monolayer. Thus, the effect of AuNP shape on capacitive coupling, essential for unnaturally high-refractive-index, was systematically studied; the experimentally available upper limit of permittivity, tuned via capacitive coupling, was figured out in a deterministic fashion.

Subwavelength-scaled noble metallic nanoparticles (plasmonic NPs) have emerged as a promising building block of metamaterials which operate at visible to NIR domain (optical metamaterials).[1] For example, it has already been reported theoretically that the 2D superlattice of metallic NPs with sub-10 nm gap can exhibit unnaturally high-refractive index at optical frequencies.[2,3] Because an incident electromagnetic wave can be resonantly confined to deeply sub-wavelength volume by a strong capacitive coupling between neighboring plasmonic NPs, available effective permittivity ε_{eff} can be significantly enhanced. However, there are stringent requirements to achieve a ultrahigh effective permittivity ε_{eff}, including highly uniform and smooth plasmonic NPs, exquisite control over NP shape, and ultrasmall (less than 10 nm) and uniform gap between NPs. Unfortunately, conventional chemical synthesis (e.g. controlled growth of sodium citrate capped small seed NPs) have allowed for a relatively polygonal shape and disperse size of AuNP.[4] As such, the previous researches on the plasmonic NP superlattice-enabled ultrahigh-refractive-index optical metamaterials have been limited to a theoretical peculiarity.[5]

To address this challenge, we synthesized the highly uniform and smooth Au NPs with a different shape (i.e., nanospheres (NSs) and nanocubes (NCs)) by iterative growth and etching methods. Then, as shown in Figure 1(a)-(d), convective-assembly technique was exploited to obtain large-area Au NSs and NCs superlattice. As capillary force, driven by selective evaporation of solvent at meniscus, can continuously push AuNPs to be closely packed, the gap between AuNPs in principle can be minimized.[6] In particular, the thickness of organic ligand (1~2 nm) defines the minimum gap. More importantly, the unprecedented quality of AuNSs and AuNCs in terms of smoothness and size uniformity allowed us to achieve an experimentally accessible minimum gap over the large area. Thereby, we figured out the practically limits of capacitive coupling between AuNPs and the resultant effective permittivity ε_{eff}. The far-field measurement results including reflection and transmission (Figure 1. (e)-(h)) and their comparison with numerical simulation confirmed an effectively available gap between AuNPs (less than 5 nm). Furthermore, we used a dressed

polarizability theorem to rationalize capacitive coupling and effective permittivity ε_{eff};[7] experimental verification of effective permittivity ε_{eff} also was carried out thorough quantitative phase imaging method (QPIU).[8]

Abstract- We present coherence-controlled holographic microscopy as an ultimate tool for 3D wide-field phase imaging finding direct application in characterization of optical fields formed by metasurfaces. Proof-of-concept experiments were performed on individual plasmonic antennas and on a specific metasurface – a focusing zone plate made of plasmonic nanodiscs.

Coherence-controlled holographic microscopy (CCHM) is a real-time, wide-field, and quantitative light-microscopy technique enabling 3D imaging of electromagnetic fields, providing complete information about both their intensity and phase. It has been patented by a member of our team and until now utilized exclusively in bio-applications only [1]. However, these attributes make also CCHM a promising candidate for performance assessment of phase-altering metasurfaces, a new class of artificial materials that allow to manipulate the wavefront of passing light and thus provide unprecedented functionalities in optics and nanophotonics.

In our study, we report on our investigation of phase imaging of plasmonic metasurfaces using this technique. We demonstrate its ability to obtain phase information from the whole field of view in a single measurement on a prototypical sample consisting of silver nanodisc arrays. The experimental data were validated using FDTD simulations and a theoretical model that relates the obtained phase image to the optical response of metamaterial building blocks. Finally, in order to reveal the full potential of CCHM, we employed it in the analysis of a simple metasurface represented by a plasmonic zone plate (Fig. 1). By scanning the sample along the optical axis we were able to create a quantitative 3D phase map of fields transmitted through the zone plate. The presented results prove that CCHM is inherently suited to the task of characterization of optical fields formed by metasurfaces. Moreover, as the temporal resolution is limited only by the camera framerate, it can be even applied in analysis of actively tunable metamaterials.

CCHM has no similar limitations one can find in other techniques for the phase imaging, such as ellipsometry (poor lateral resolution and complex evaluation), scanning aperture-less near-field optical microscopy (inherently slow) and current interferometric methods (one sample spot at a time only). Hence, CCHM brings a considerable progress for the quantitative phase imaging in the important and vivid field of photonic metasurfaces and other optical systems.

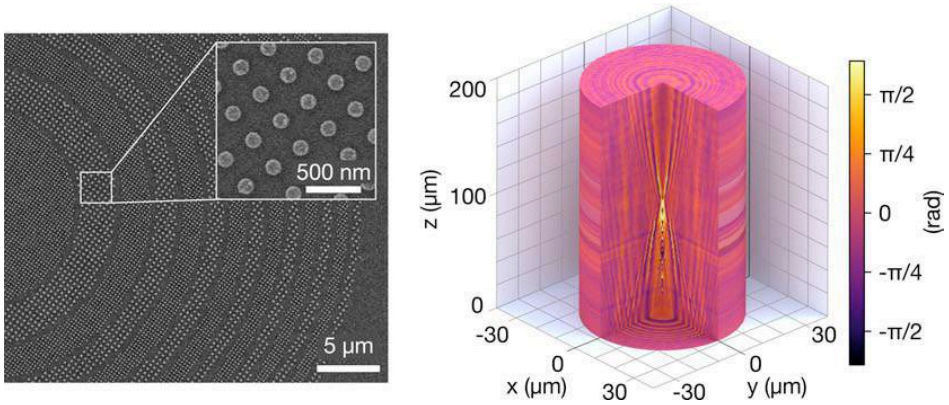

Figure 1. Left: Plasmonic zone plate consisting of concentric rings alternatively filled with silver plasmonic nanodiscs of two different diameters (two distint plasmon resonance frequencies) on a transparent substrate. The plate is illuminated from bottom and the transmitted light (comprising of incident and scattered component) then interferes with the light in the reference arm at an oblique angle, allowing to retrieve the phase and amplitude of the wave at each point of the sample (zone plate) and above it. Right: 3D visualization of the measured total phase distribution in the half-space above the plasmonic zone-plate.

Abstract - Reflection-type reconfigurable metasurfaces are proposed for spatial light modulation of visible light at subwavelength scale. The structure is based on a subwavelength metal grating that can couple the incident light to the gap plasmon mode and modulate it through cavity resonance. By using chalcogenide phase-change materials, the optical characteristics of the structure can be switched between two states so that it can generate the desired spatial light distributions. Numerical simulations are performed to verify the proposed structure.

Spatial light modulation with subwavelength resolution has the fundamental advantage of continuous wavefront manipulation, which is free from the unwanted high-order diffraction that occurs in conventional diffractive optical devices. In this regard, in recent years, various novel methods have been proposed for subwavelength-scale wavefront control, based mainly on metamaterials and metasurfaces [1]. However, most of them are currently taking a way of passive-type modulation, which is inadequate for dynamic applications.

In this study, a subwavelength plasmonic structure is proposed in order to generate two-level spatial distributions of a wave field that can be reconfigured. Figure 1(a) shows the design of the unit cell, basically a subwavelength grating in which light modulation is performed by cavity resonance of gap plasmons [2], and tunability can be achieved by a thin layer of the phase-change material $Ge_2Sb_2Te_5$ (GST). By either electrical or optical pulses, the state of the GST can be reconfigured between amorphous and crystalline, switching the optical property accordingly [3]. It should be noted that the protective layer of indium tin oxide (ITO) can provide the function of electrical switching of the GST by using Joule heating. Figure 1(b) shows the numerically calculated spectral reflectance and phase difference of the proposed structure with respect to the two GST states. Here, a transverse magnetic wave is normally incident on the structure, and periodic boundary conditions are applied for both x and y directions. The numerical results show that, based on the structure, reflection-type reconfigurable plasmonic metasurfaces can be realized, which can be promising candidates for an advanced holographic display.

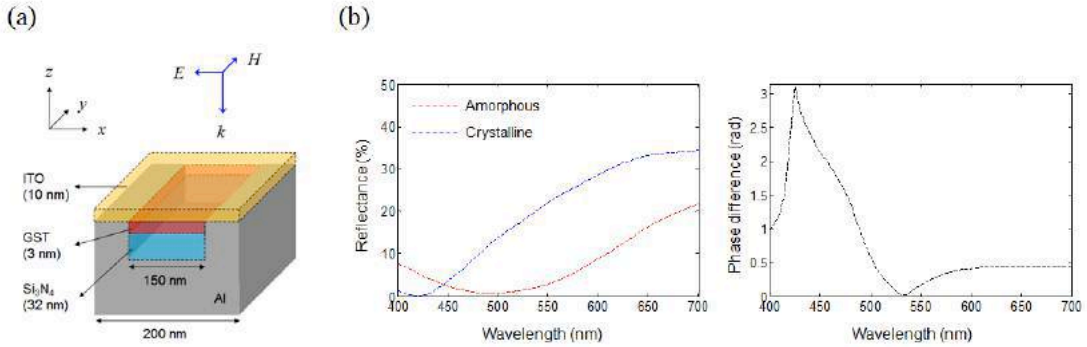

Fig. 1. (a) Unit structure for reconfigurable subwavelength-scale spatial light modulation, using phase-change materials. The thickness of each layer is indicated in parenthesis. (b) Numerically calculated spectral reflectance and phase difference for the two states of the GST layer.

Polarization Dependent Light-Matter Interaction with Metal Surfaces and Metasurfaces

Pieter G. Kik[1,2,*], Chatdanai Lumdee[2], Vrinda Thareja, Majid Esfandyarpour, and Mark L. Brongersma

Abstract-The large free charge concentration in metals enables strong light-matter interaction, allowing for nanoscale engineering of emission efficiency and radiation patterns. However, the large conductivity of metals also strongly suppresses lateral fields, reducing excitation and emission rates related to lateral polarization. Here we show that subwavelength patterning of metal surfaces can overcome the deleterious effect of lateral field suppression, resulting a large, reproducible, and quantitatively understood enhancement of Raman scattering from graphene in close contact with a metasurface.

Metals can dramatically alter the optical response of near-surface emitters and scatterers. For example, scattering by plasmon resonant metal nanoparticles can be strongly modified near metal surfaces due to interaction of the nanoparticle with image charges.[1] However, since good conductors efficiently suppress tangential field components, emission and scattering processes that involve polarization along the metal surface are strongly suppressed. As a result, the optical response of scatterers and emitters near metallic surfaces is often dominated by surface-normal polarization contributions. This limitation can be circumvented by modification of the effective surface impedance. Under normal incidence illumination from vacuum, the electric amplitude reflection coefficient is governed by the impedance of vacuum $Z_0 = \sqrt{(\mu_0/\varepsilon_0)}$ and that of the substrate $Z_S = \sqrt{(\mu_S/\varepsilon_S)}$ according to

$$r = \frac{Z_S - Z_0}{Z_S + Z_0} \qquad (1)$$

For metals with large negative permittivity (small negative impedance) this results in large reflection with reversed field amplitude, corresponding to suppressed tangential fields. However by subwavelength patterning of a metal film, its impedance can be modified, and under certain conditions an electric field maximum can be attained near the surface. Thus by engineering the impedance of such metallic metasurfaces, it becomes possible to significantly modify emission and scattering of lateral polarization contributions.

Here we investigate the enhancement of gold photoluminescence (PL) and Raman scattering. We compare the role of polarization in gap-plasmon-enhanced gold PL and magnetic-mirror-enhanced Raman scattering from graphene. Graphene is an ideal reporter of near-surface tangential field enhancement on metasurfaces. First, its two-dimensional extended nature allows it to be in close contact with a large nanostructured region. Second, it features distinct Raman peaks with relatively large shifts. Finally, its 2D nature results in a strongly anisotropic Raman response, making it especially sensitive to tangential fields.

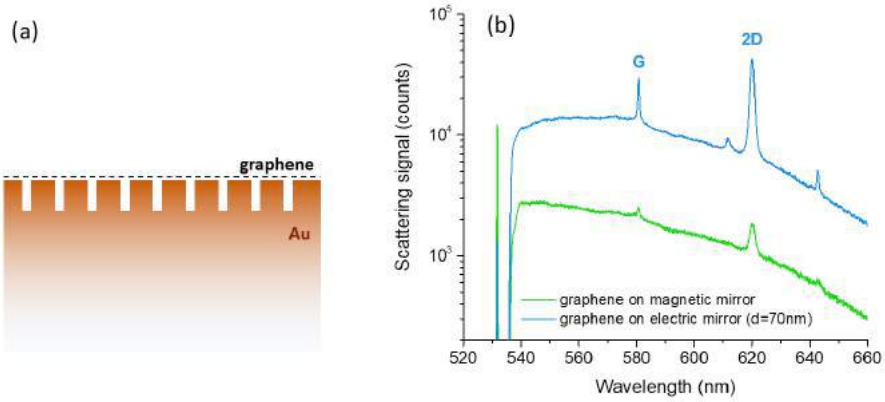

Figure 1: (a) Schematic of a graphene draped metallic metasurface. (b) Scattering spectrum of single-layer graphene on a gold film (green curve) and on a gold metasurface acting as a magnetic mirror (blue curve), showing different enhancement of the gold photoluminescence and of the Raman signal from in-plane graphene phonons.

First it is shown that gold PL enhancement by gap plasmons can be quantitatively described using a combination of numerical simulation and the assumption of reciprocity. Second it is shown that graphene Raman scattering enhancement on metasurfaces consisting of subwavelength groove arrays can be quantitatively described by simulated electromagnetic fields and invoking reciprocity. We show how the full tensorial nature of the graphene Raman response must be taken into account. The results highlight the unique nature of graphene as a reporter of tangential near-fields, and demonstrate the potential of surface impedance engineering for the control of polarization dependent light matter interaction.

Abstract

In this paper, a triangular shaped left handed meta-surface based on the meta-atom cluster has been demonstrated for C-band application. A modified version of the resonators is connected together to form like a triangular shape structure. The Finite integration technique based CST Microwave Studio electromagnetic simulator has been used for design, simulation, and investigation. Measurement is also done and the measured and simulated results are well complied together. The measured results show resonance peaks of transmission coefficient in 7.40 GHz and the left handed characteristics is exhibited from 16.66 GHz to 18.0 GHz. In addition, electric lumped circuit model based on the inductor and capacitor of the proposed meta-surface is also design and analysed. Due to the resonance in C-band the proposed meta-surface structure is flexible for EM-cloaking, Imaging, radio communication, etc.

1. Introduction

The concept of metamaterials was originally introduced for electromagnetic waves, which is now classified as electromagnetic meta-surface. In nature, electromagnetic metamaterials are man-made structures patterned on the sub-wavelength scale in order to achieve exotic functionality, which possess peculiar electromagnetic properties not seen in natural materials. The electromagnetic characteristics of electronic materials are primarily determined by the physical parameters of the permittivity, permeability, and conductivity. All loss less electromagnetic materials can be classified as shown in figure 1. According to the signs of permittivity and permeability, where DPS denotes double positive ($\varepsilon>0$ and $\mu>0$), ENG denotes Epsilon negative ($\varepsilon<0$ and $\mu>0$), DNG denotes double negative ($\varepsilon<0$ and $\mu<0$), and MNG denotes Mu negative ($\varepsilon>0$ and $\mu<0$). In particular, materials with simultaneously negative permittivity and permeability are also called left handed or negative-index or double negative metamaterial. With the rapid growth of the communication systems the demand of the meta-surface has been extensively increased not only for the meta-surface exotic electromagnetic properties but also for their promise for applications like invisible cloaking, electromagnetic absorption, specific absorption reduction (SAR), enhanced the antenna performance by using as radiating patch or parasitic elements or ground plane, filter design, perfect lenses, hyper lenses, aberration free lenses, etc. Moreover, few research on these studies has been reviewed for understanding the properties of these man-made artificial materials.

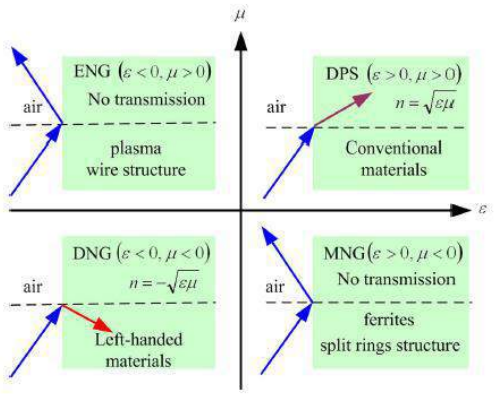

Figure 1. Wave propagation properties through the medium.

Ziolkowski et al. developed a metamaterial by capacitor loaded strips and split ring resonators in 2003, which exhibited negative permittivity and negative permeability both at the X-band frequencies [1]. A periodic array, where the unit cells consists of two symmetrical π-shape wire and the negative-refractive band lies between 11.20 GHz and 13.05 GHz. Besides, high transmission with low loss occurs between 11.95 GHz and 12.50 GHz in case of the designed structure proposed by Chun et al. [2]. A dual band meta-atom as a negative permittivity metamaterial and had two stop bands at around 5.41 and 6.70 GHz, whereas the measured results are almost, 5.55 and 6.80 GHz was introduced in 2015 [3]. In addition, a compact z-shaped double negative metamaterial for wide band applications was presented by Hasan et al. The 10×10 mm^2 structure metamaterial unit cell was applicable for C- and X-band operations and the effective medium ratio was 4.0. Besides, the designed DNG metamaterial different structure are also investigated with the equivalent lumped circuit model [4]. A metamaterial embedded microstrip patch antenna was introduced for microwave C-band (from 3.77 to 6.58 GHz) applications that composed of a rectangular metamaterial

embedded patch, microstrip-fed line and a partial ground plane. The antenna shown fractional bandwidth 54.97 % at the central frequency and the radiation efficiency varied from 85 % to 97 %, whereas the peak gain from 1 dB to 4.5 dB in different frequencies [5]. In addition, a z-shaped left handed metamaterial for wide band applications was presented, which applicable for C- and X-band application. The designed structure shown left handed characteristics in 8.50 GHz, bandwidth of 5.67 GHz, and the effective medium ratio was 9.10 [6]. A metamaterial based microstrip patch antenna, optimized for bandwidth and multiple frequency operations by criss-cross metamaterial structure had been proposed, whereas the criss-cross shape metamaterial structure was inspired from the famous Jerusalem cross. This metamaterial antenna improvement in bandwidth without reducing the gain in the C-band. The results shown the bandwidth of the metamaterial embedded was 610 MHz but the bandwidth of the simple patch was 300 MHz, as a result the enhancement of 310 MHz was achieved with a gain of 4.45 dB [7]. A meta-atom sensor based on planar hexagon split ring resonators was reported which structure was designed to operate in terahertz regime. In addition, a modified version of split ring resonator was simulated for sensing dielectric changes by placing thin dielectric layers as sample materials on the full frontal surface of the sensor. The real part of permittivity and permeability remains from 3.90 to 4.10 THz and the quality factor was 95.0 [8]. A negative index metamaterial with two components analysis for C- and X-band had been introduced by Islam et al. and the structure had two arrows and a metal arm was connected the two arrows that looked like a double arrow shape printed on the epoxy resin fibre and the epoxy resin formation processes were also explained step by step in 2017 [9]. A single layer negative index meta atom was analysed that was developed by an outer and inner split ring resonators with inverse E-shape metal strips of copper were connected with the outer ring resonator. This designed meta-atom structure illustrated the bandwidth of 5.81 GHz, which was applicable for C-, X- and Ku-band applications. Moreover, due to the total dimension of 0.2λ×0.2λ×0.035λ and effective medium ratio of 5.0 the proposed meta-atom structure was suitable for the practical applications [10]. In addition, a microwave metamaterial absorber was designed that resonance at C-, X- and Ku-band with double negative characteristics as well as the absorption peaks were respectively, 82%, 67%, and 93% at 6.22, 8.76, and 13.05 GHz in [11]. In [12] a robust nature inspired optimization technique had been discussed for evolving optimal design for soft, hard and balanced meta-surfaces that would be used as broadband low-loss liners in anisotropic and dispersive boundary mode horn antennas. A double-negative metamaterial for 0.5 to 7 GHz frequency range applications was presented by Ikbal et al. in 2015. They investigated the effects of the size of the single unit cell of the metamaterial structure on the resonance frequency and on the double negative characteristics. However, the designed unit cells were exhibited negative permittivity and permeability simultaneously in the S-band (2.95 to 4.00 GHz), and C-band (4.00 to 4.95 GHz and 5.00 to 5.57 GHz) in microwave frequency range [13].

The aim of this paper is to demonstrate a meta-surface based on meta-atom cluster for C-band application numerically and experimentally. The proposed structure is designed by the metallic strips, where the metallic strips are connected together at a central point and look like a triangular shape. The size of a single unit cell is 7×7 mm^2 and the effective medium ratio is 5.80 that means the proposed meta-surface structure compact in size. Moreover, the measured transmittance (S_{21}) shows resonance in 7.40 GHz and the left handed characteristics exhibits from 16.66 to 18.0 GHz for any of frequency points in this frequency range. In addition, the lumped circuit model for the proposed meta-surface has been designed with the total inductance and capacitance determined equations. In the circuit model the gaps and splits in every resonator produce the capacitance and each metal strip is responsible for generating the inductance. This paper is organized as these manner, the meat-surface structural design with schematic and fabricated view is shown in section 2 and Section 3 illustrated the proposed meta-surface extraction process with the mathematical explanation. Besides, the equivalent lumped element circuit model through the developed total inductance and capacitance equation to calculate the resonance point of the proposed meta-surface in the same section. The measured and simulated results with the effective medium parameters (permittivity, permeability, and refractive index), and reactance impedance (surface impedance) of the designed meta-surface has been discussed in section 4, and section 5 conclude the paper.

2. Meta-surface Design

The meta-atoms are periodically arranged in the form of cluster with optimized geometric dimensions is shown in Fig. 2(c). Every single unit cell of the proposed structure contains metallic strips, where the strips are connected together and form like a triangular shape structure. The designed structure printed on an FR-4 material that permittivity of ε_r= 4.25, loss tangent of tanδ= 0.02, and thickness of t= 1.60 mm. The effect of the dielectric thickness response, as the thickness increases resonance frequency of the proposed structure shifts to the lower frequencies since the increment of the thickness increases the inductance of the structure. This results in reduction of the resonance frequency of the lumped resonance circuit.

3. Methodology and Equivalent Circuit Model

The Finite integration technique based commercially available computer simulation technology Microwave Studio is adopted for all the design and numerical investigations. Two boundary conditions are commonly used for the computation of meta-surface parameters: periodic boundary condition and perfect electromagnetic conductor boundary condition. Periodic boundary conditions are usually applied for simulating a part of the mass framework by modelling its small part with the absence of proper surface. The perfect electromagnetic conductor boundary condition is the generalization of perfect electric conductor and perfect magnetic conductor. For the simulation of the proposed fractal meta-surface absorber EM-waves are propagating along the z-axis, whereas the x- and y-axis are respectively considered as a perfect electric conductor and perfect magnetic conductor boundaries. Frequency domain solver with tetrahedral mesh have been utilized for the simulation and the impedance has been set to 50Ω. However, the retrieving procedure of the effective parameters are given as follows [14],

$$\textit{Reflection Coefficient, } S_{11} \approx \left\{ \frac{R_{01}\left(1-e^{i2nk_0d}\right)}{1-R_{01}^2 e^{i2nk_0d}} \right\} \quad 1$$

$$\textit{Transmission Coefficient, } S_{21} \approx \left\{ \frac{\left(1-R_{01}^2\right)e^{i2nk_0d}}{1-R_{01}^2 e^{i2nk_0d}} \right\} \quad 2$$

$$\textit{Impedance, } Z \approx \pm\sqrt{\frac{\left(1+S_{11}\right)^2+S_{21}^2}{\left(1-S_{11}\right)^2+S_{21}^2}} \quad 3$$

$$e^{\gamma d} = \left\{ \left(\frac{1-S_{11}^2+S_{21}^2}{2S_{21}} \right) + \left(\frac{2S_{11}}{\left(Z-\frac{1}{Z}\right)S_{21}} \right) \right\} \quad 4$$

$$\phi_N = \phi_0 + \sum_{i=1}^{N} \arg\left(\frac{e^{\gamma id}}{e^{\gamma i-d}} \right) \quad 5$$

Refractive index n of N_{th} sample,

$$\sqrt{\left(n_N\right)^2-\left(\frac{\omega_c}{\omega_N}\right)^2} = \frac{1}{k_0 d}\left[-i\ln\left(\left|e^{\gamma Nd}\right|\right)+\phi_N\right] \quad 6$$

$$\sqrt{\left(n_N\right)^2-\left(\frac{\omega_c}{\omega_N}\right)^2} = \frac{1}{k_0 d}\left[-i\ln\left(\left|e^{\gamma Nd}\right|\right)+\phi_0+\sum_{i=1}^{N}\arg\left(\frac{e^{\gamma id}}{e^{\gamma i-d}}\right)\right] \quad 7$$

$$\textit{Refractive Index, } n_r \approx \sqrt{\frac{n^2-\left(\frac{\omega_c}{\omega}\right)^2}{1-\left(\frac{\omega_c}{\omega}\right)^2}} \quad 8$$

$$\textit{Permeability, } \mu_r \approx \left(Z \times n_r\right) \approx Z\sqrt{\frac{n^2-\left(\frac{\omega_c}{\omega}\right)^2}{1-\left(\frac{\omega_c}{\omega}\right)^2}} \quad 9$$

$$\textit{Permittivity, } \varepsilon_r \approx \left(\frac{Z}{n_r}\right) \approx \left(\frac{\pm\sqrt{\frac{\left(1+S_{11}\right)^2+S_{21}^2}{\left(1-S_{11}\right)^2+S_{21}^2}}}{n_r} \right) \quad 10$$

where 'd' is the thickness of the substrate, 'Z' is the normalize impedance, 'k_0' is the wave vector, 'R_{01}' is the sample interface, 'S_{11}' is the reflection coefficient, and 'S_{21}' is the transmission coefficient. From the equivalent lumped circuit of the designed structure [6, 10, 15], the three branch equivalent impedance are respectively,

$$Z_1 = \frac{Z_{C1}Z_{L1}}{Z_{C1}+Z_{L1}}, Z_2 = \frac{Z_{C2}Z_{L2}}{Z_{C2}+Z_{L2}}, Z_3 = \frac{Z_{C3}Z_{L3}}{Z_{C3}+Z_{L3}}.$$

$$Total\ Impedance, Z_T = \frac{Z_1Z_2 + Z_1Z_3}{Z_1 + Z_2 + Z_3} \quad 11$$

$$I_T = C_1\frac{d^2V}{dt} + C_2\frac{d^2V}{dt} + C_3\frac{d^2V}{dt} + \frac{1}{L_1^{'}}V + \frac{1}{L_2^{'}}V + \frac{1}{L_3^{'}}V \quad 12$$

The total inductance of the designed structure can be figure out from the equation,

$$L_T \approx \mu_0 t\left\{\frac{(p+h)^2}{(2t^2 - g^2 - \pi d^2)} + \frac{\sqrt{L^2+W^2}}{\sqrt{p^2+g^2}}\right\} \quad 13$$

In addition, total capacitance can be calculated by,

$$C_T \approx \varepsilon_0\left[\frac{\pi(W+L-d)}{2(g+p+t)}\ln\left(\frac{L+W}{p+d}\right)\right] \quad 14$$

where the free-space permeability is $4\pi\times10^{-7}$ H/m and permittivity is 8.85×10^{-12} F/m. As the proposed structure consist of inductive-capacitive circuit, so the resonance frequency would be,

$$f_r = \frac{1}{2\pi\sqrt{L_TC_T}} \quad 15$$

From figure 3, the inductive effect is formed by the metallic part and the capacitive effect is induced by the gaps and splits. The rise of the inductive and capacitive effect minimizes together. Because, if the inductance raise resonance point shifts toward lower frequency and the resonance points shift to a higher frequency for the increase of capacitive effect. However, the total inductance and capacitance describes the resonance points of the proposed meta-surface structure depend on the design specifications. The variation of any geometrical parameters corresponding to the change of the total inductances and capacitances causes the shift of the resonant frequencies.

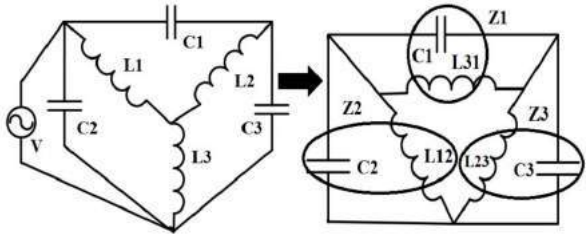

Figure 3: Equivalent lumped circuit model of the proposed triangular shape meta-surface single unit cell structure.

4. Measurement Validation and Result Analysis

The fabricated triangular-shape array of meta-surface is placed between the horn antennas for the measurement validation. The EM-waves are propagated along z-axis to incident on the fabricated structure and the electric and magnetic boundaries are considered x-and y-axes. An Agilent N5227A vector network analyzer was connected to the antennas to measure the scattering and effective medium parameters. From figure 4(a,b) the current is flowing inner and outer direction in every branch of the triangular-shape meta-surface. The arrows indicate the direction and the color describe the intensity of the flowing current. At the resonance point the intensity of the current is the highest, whereas the stop bands are created at the null point by the minimization of the current through flowing currents opposite direction. The field distributing in the substrate board of the proposed structure is plotted in figure 4(c-d). The inductive net electric dipole moments yield when the current flows on the triangular-shaped metal patterns and are anti-parallel to the incident electric fields, providing the negative permittivity. Although the gap is capable of providing a capacitance, it is unable to excite the oscillation of current and play the role of accumulating charges whose dipole moments are anti-parallel to electric fields.

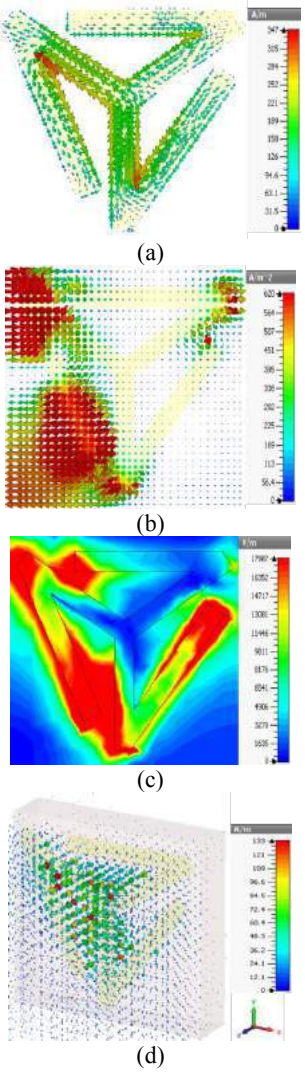

Figure 4: (a) Surface current distribution, (b) Current density, (c) Electric field, and (d) Magnetic field of the proposed meta surface unit cell at 7.40 GHz.

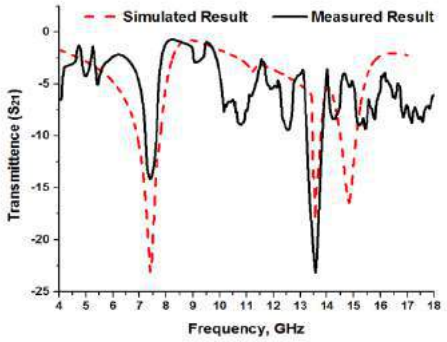
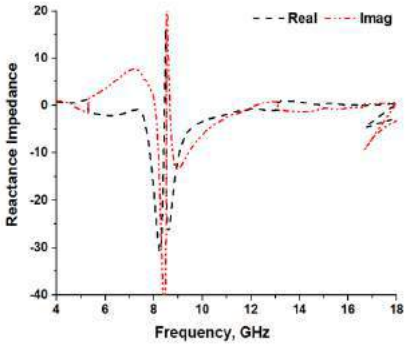
Figure 5(a) represents the simulated and measured transmittance of the triangular shape meta-atom cluster, where the results are well complied together. The simulated result shows transmittance resonance in 7.41 GHz and 13.60 GHz and the magnitude of those resonance points are respectively, -23.17 dB, and -15.22 dB. In addition, the measured results resonance points are around 7.40 GHz (C-band) and 13.61 GHz (Ku-band), whereas the estimation of the magnitudes is respectively, 14.0 dB and 23.5 dB. Figure 5(b) exhibits the reactance impedance of the designed meat-surface structure, where the reactance impedance at 8.61 GHz is -26.69+10.44j.



(a)



(b)

Figure 5: (a) Simulated and measured transmittance of the meta-atom cluster, (b) Magnitude of the reactance impedance of the proposed structure.

In figure 6(a) the real value of negative permittivity range from 4.68 to 7.68 GHz, 8.58 to 12.15 GHz, and 16.66 to 18.0 GHz respectively bandwidth covers 3.0 GHz, 3.57 GHz, and 1.34 GHz. In addition, the negative real permeability from 8.42 to 16.76 GHz, and 16.66 to 18.0 GHz, where the bandwidth covers respectively, 8.34 GHz and 1.34 GHz in figure 6(b). Further, figure 6(c) shows the negative refractive index absolute value from 4.06 to 7.15 GHz (bandwidth of 3.09 GHz), from 8.08 to 11.63 GHz (bandwidth of 3.55 GHz), and 16.66 to 18.0 GHz (bandwidth of 1.34 GHz). However, from 16.66 to 18.0 GHz the effective medium parameters (permittivity, permeability and refractive index) shows negative regime. So, according to the left handed characterise the proposed meta-surface based on meta-atom cluster can be characterized as left handed meta-surface for any frequency points in the frequency range from 16.66 to 18.0 GHz.

5. Conclusions

The triangular-shape meta-surface by meta-atom cluster exhibits left handed characteristics at microwave frequency is reported in this paper. The results display the transmittance in 7.40 GHz and the size of the single unit cell is 7×7 mm^2. Moreover, the complete circuit model allows to derive an analytical expression of the total inductance and capacitance for the resonance point of the proposed design. It is clearly shown that the proposed meta-surface is insensitive to both TE and TM polarizations as

well as TEM mode throughout the whole of the operating frequency band. This characteristic of the designed meta-atom cluster is very significant since the proposed model has many advantages compared to those in the literature. Moreover, the electric field and surface current distributions are introduced and analysed to better understand of the mechanism. Finally, due to the compactness the designed left handed meta-surface has been potential for the performance enhanced of antenna performance, filter, EM-cloaking, long distance radio communication applications.

Phase Gradient Silicon Nitride Nanostructures at Visible Wavelength

Jungwoo Park[1] **and Ki-Hun Jeong**[1*]
[1]Department of Bio and Brain Engineering, KAIST, Republic of Korea
[*]corresponding author: kjeong@kaist.ac.kr

Abstract-This work reports a silicon nitride metasurface that can control the refraction angle of transmitted light at visible wavelength for high transmission efficiency. We numerically simulated the refracted wavefront transmitted through metasurface by tuning the length and the width of rectangular nanoantennas and aligning different-sized nanoantennas in a sub-array. The refraction angle can be adjusted by a unit cell size and number of element antennas in a sub-array.

Metasurface, which is a two-dimensional structure composed of subwavelength-sized antennas, can control the amplitude, phase, and polarization of light. For a phase gradient metasurface which manipulates the wavefront of the transmitted light, it is possible to refract light in an anomalous direction by varying the shape or size of the antenna. However, metal metasurfaces are inappropriate for practical uses in visible light, due to Ohmic losses. Dielectric metasurfaces with relatively high refractive indices have been studied, based on silicon[1, 2] and titanium dioxide[3], but their absorption loss at visible wavelength is not negligible. We use silicon nitride, which fully covers 0 to 360 degree phase delay as well as exhibiting high transmittance at visible wavelength.

In this work, we report silicon nitride metasurface composed of rectangular nanoantennas on a quartz wafer (**Fig. 1**). To cover entire 0 to 360 degrees of phase delay at a wavelength of 633 nm, the height and unit cell size should be comparable with the wavelength[4]. Six antennas of different sizes are made up of sub-array of metasurface, and each antenna shows 60 degrees phase increments. The wavefront of light transmitted through this sub-array is refracted in an anomalous direction.

To optimize silicon nitride antennas with consistent phase increments. The width and length of a rectangular nanoantenna with a fixed height of 633 nm and a unit cell size of 500 nm are varied by a finite difference time domain (FDTD) method (**Fig. 2**). Silicon nitride antenna shows an electromagnetic resonance with an abrupt phase change showing zero phase (green) as shown in Figure 2 (b). The transmittance at a width of 380 nm (black line) of Figure 2 shows a consistent values even if the length is varied, and the lowest value shows a relatively high transmittance of 0.72. In addition, the phase at the width of 380 nm includes a phase shifts of 0 to 360 degrees, which is suitable for a phase gradient sub-array.

We choose four, six, and eight antenna elements (phase increment of 90, 60, and 45 degrees) in a sub-array Si_3N_4 metasurface of 380 nm width. The phase of plane wave propagating though the metasurface is numerically calculated **(Fig. 3**). For a sub-array with a unit cell size of 450 nm in Figure 3, the refraction angles are 17.6, 11.9, and 8.9 degrees, respectively. In addition, by changing the unit cell size and number of elements in a sub-array, the refraction angle can be manipulated through the metasurface. This results show possibilities of manipulating shape of an optical wavefront using silicon nitride metasurface.

Widely Tunable Semiconductor Antennas for Reconfigurable Metasurfaces

J. A. Schuller
Electrical and Computer Engineering Department, UC Santa Barbara, CA, USA
*corresponding author: jonschuller@ucsb.edu

Abstract-The ability to engineer the optical phase at subwavelength dimensions has led to metasurfaces that provide unprecedented control of electromagnetic waves. To reach their ultimate potential, metasurfaces must incorporate reconfigurable functions. The central challenge is achieving large tunability in subwavelength elements. Here, we describe two different approaches for achieving order-unity refractive index shifts: free-carrier refraction and thermo-optic tuning

We experimentally demonstrate wide tuning of single-particle infrared Mie resonances through doping[1], and demonstrate simulations of electrically reconfigurable III-V heterojunction metasurfaces based on these effects[2,3]. We conclude with recent experimental demonstrations of dyamic, ultrawide tuning of Mie resonators based on two distinct thermo-optic effects: 1) modifying the electron mass and carrier density in InSb and 2) exploiting the anomalous temperature-dependent bandgap of PbTe.

[*]corresponding author: linf@pku.edu.cn

Abstract- Raman scattering, a fingerprint method to nondestructively obtain information about the lattice vibration of a crystal, has been widely used to characterize a monolayer of MoS_2. However, the intensity of Raman scattering from the MoS_2 monolayer is usually very weak for the atomic thickness of this materials. Based on localized plasmon resonances of silver nanoparticles (Ag NPs) with the size of several tenths of nanometer, we obtained a dramatic enhancement for Raman scattering of MoS_2 as the Ag NPs were dispersed on the monolayer of MoS_2. We also observed that the intensity of Raman scattering is deeply dependent on the polarization of incident light, which is due to the property of localized plasmon resonances of Ag NPs.

As shown in Fig. 1(a), the sample was prepared by dispersing Ag NPs on the monolayer MoS_2. We focused the laser on the place indicated by the arrow and then got the Raman spectra of the monolayer MoS_2 enhanced by the Ag NPs showed in the Fig. 1 (b) by changing the directions of the linearly polarized light marked above the curves in the Fig.1 (b). The Raman spectra of the MoS_2 without Ag NPs was also obtained as shown by the green curves in the Fig.1 (b).

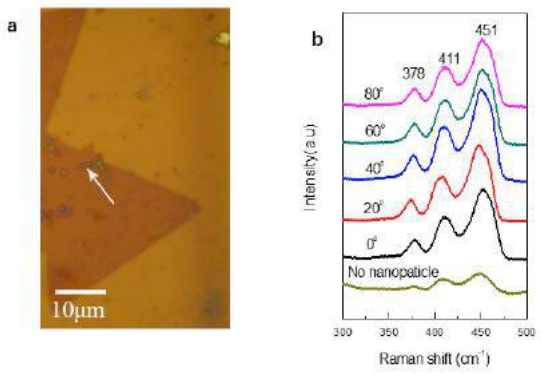

Fig. 1. (a) Optical image of the monolayer MoS_2 with Ag NPs. The light illumination point is indicated by arrows. (b) Raman spectra of the monolayer MoS_2 excited by 633nm laser without Ag nanoparticles(green curves) and with Ag nanoparticles（other curves）. The directions of the linearly polarized light are marked above the curves.

Obviously, a dramatic enhancement for Raman scattering of MoS_2 with the Ag NPs was observed with the enhancement factor about 4~5. Furthermore, the enhancement factor increases when the polarization was varied from 0 to 40°. However, it begins to decrease from 40° to 80°. This phenomenon can be attributed to that the coupling strength of localized plasmon resonances between interparticles which is dependent on the polarization of incident light.

Analyzing a 3D Far Field of Plasmonic Ruler Based on Double Metal Blocks

Eunso Shin[1], Young Jin Lee[1], Seokhyeon Hong[1], Kihwan Moon[1] and Soon-Hong Kwon[1]*
[1]Dept. of Physics, Chung-Ang University, Republic of Korea

Abstract- In a manufacturing process of a nano-size product, sensing a structure is challenging theme. For sensing the nano-size structure, we propose analyzing the 3D far field of plasmonic ruler which composed of two silver nanoblocks separated by 10 nm thickness of an air gap. When upper nanoblock slightly shifted to x or y-axis, it causes the considerable change of far field of the specific wavelength, which occurs plasmonic coupling, in comparison with original one. This change of far field cans simply detecting structure.

Between the two silver nanoblocks, there is plasmonic coupling at a particular resonant wavelength when the incident light propagated to the structure. We can measure a slight movement of an interval between two metal blocks via observing cavity mode of the resonant wavelength [1]. In addition, since the length of block width and height are different from each other, there is two kinds of resonant wavelength; caused by incident light in the direction of x axis and y axis. When the upper block moved towards x or y axis, it leads to distinct results of resonant wavelength and far field.

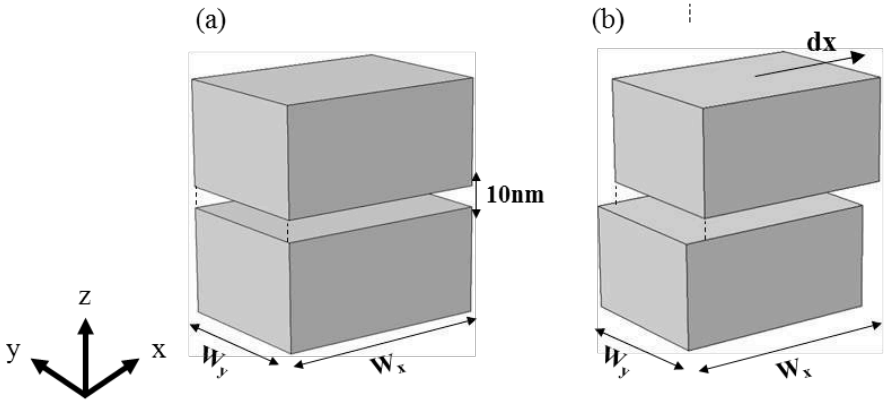

Figure 1: Schematic diagram of proposed a plasmonic ruler composed of two silver nano-blocks. Between the blocks there is an air gap with 10 nm thickness. (a) Original Structure, (b) Shifted Structure.

As shown in figure 1 (a), we propose plasmonic ruler that comprises of two parts, upper silver nanoblock and the lower one. Two blocks, which have the same scale of three dimensions W_x=200 nm, W_y=150 nm and height=100 nm, are separated by 10 nm air gap. When an incident light of X or Y axis heads to the proposed

structure, cavity mode of the resonant wavelength of plasmonic coupling is confined between the silver blocks.

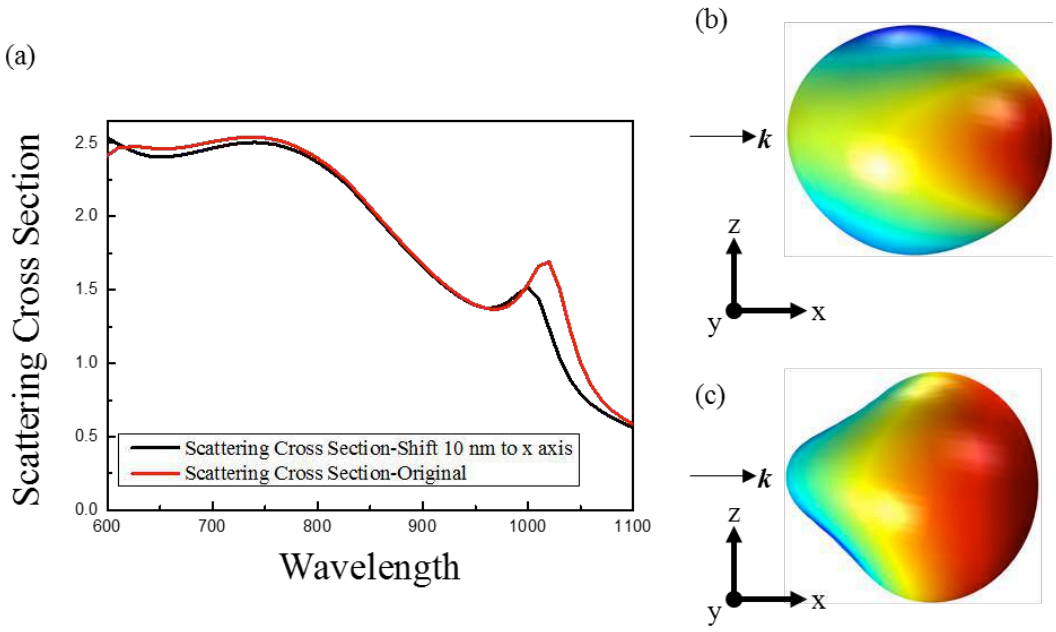

Figure 2: (a) Graph of Scattering Cross Section. The red line presents the original structure of scattering cross section and the black one presents the shifted structure. The 3D far field of resonant wavelength of 1020 nm is confined inside the air gap (b) in the original structure and (c) in the 10 nm shifted structure.

We investigated the 3D far field of the structure with a three-dimensional finite elements method (FEM). For an incident light of X axis, the red line of scattering cross section graph in Figure 2 (a) is shown that plasmonic cavity mode with the resonant wavelength of 1020 nm is highly confined through the gap of air. On resonant wavelength of 1020 nm, the far field is illustrated in Figure 2 (b). As upper block shifts 10 nm to the X axis, resonant wavelength slightly decreases from 1020 nm to 1000 nm, according to scattering cross section graph of Figure 2 (a). In addition, Figure 2 (c) shows the 3D far field of 10 nm shifted structure with the resonant wavelength of 1020 nm, which indicates significant change compared with the former 3D far field. Therefore, analyzing 3D far field allows understanding the structure since slightly shifted structure results in considerable difference of far field

Light scattering by magnetic resonance of crescent-shaped split-ring resonator

Toshihiro Okamoto*, Naoki Tamura and Masanobu Haraguchi
Tokushima University, Japan
*toshi-okamoto@tokushima-u.ac.jp

Abstract- We investigated the optical scattering property of crescent-shaped split-ring resonator (SRR) fabricated by the nanosphere lithography method. The magnetic resonance of single gap SRR was able to be excited in an optical magnetic field by using the total reflection of the prism. It was clarified to contain a polarized component different from the incident light as a result of observing the scattered light from SRR.

The split-ring resonator (SRR) cause magnetic resonance near the LC resonance frequency and change the permeability of the SRR metamaterial. The electric and magnetic fields are expected to be enhanced when magnetic resonance occurs in SRRs. Then, SRR not only is used as a unit cell of the metamaterial but also using it as an antenna of the unit is also interesting. We investigated the optical scattering property of single-gap SRR.

We fabricated single-gap crescent-shaped gold SRR of the diameter of about 100 nm on the glass substrate using the nanosphere lithography (NSL) technique [1,2]. The light of the TE polarization was entered by the configuration shown in Fig.1 (a), and evanescent wave that occurred along with total reflection was entered into SRR. The scattered light spectra of single isolated SRR are shown in Fig.1 (b). The spectral peak of the *Ey* polarization of the same component as the incident light was a wavelength of around 700 nm. This peak means the electric dipole in the same direction as the incident light was excited by the localized surface plasmon resonance of SRR. On the other hand, the scattered light of *Ex* polarized component different from the incident light appeared in the wavelength around 900 and 600 nm. This phenomenon means the loop electric current flowed in SRR by the magnetic resonance of SRR excited in an incident magnetic field.

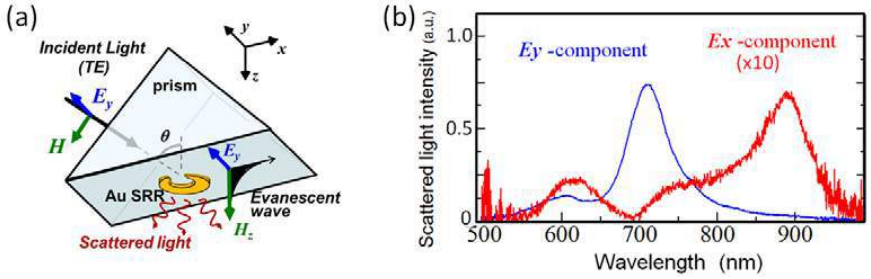

Fig.1 Experimental setup(a) and scattered light spectra of a single SRR(b)

Abstract

This paper presents the design of plasma antenna array for Wi-Fi application, operating at 2.4 GHz. In this experiment, four pieces of a commercially available fluorescent tube function as a plasma antenna, with same length and diameter was used. The proposed antenna is simulated using CST Microwave Studio to study its performance. The measured return loss, radiation pattern and signal propagation of this proposed antenna is also presented. The experimental and analysis of this study are discussed.

1. Introduction

The Plasma is the fourth state of matter after solid, liquid and gases. Therefore, plasma antenna is a type of antenna in which the material conducting element of a metal is replaced by plasma, to either transmit or receive a radio signal. When a plasma tube is energized with sufficient electrical power, the gas inside the tube will be ionized into plasma state, where it becomes conductive. There are many plasma antenna that have been reported, which use plasma elements instead of metal conductors [1–3]. Plasma antennas are also useful in application for stealth [4], radar [5] and re-configurability [6-8]. Reconfigurable antennas have very attractive features such as the capability to reconfigure themselves alone, to adapt to change or with the system to perform entirely different functions. The reconfigurable antenna is also capable of providing a single antenna for the use with multiple systems [9].
Plasma is ionized gas. The ionization degree can vary from 100% which are fully ionized gasses, to very low values or partially ionized. Plasma frequency is a natural frequency of the plasma and is a measure of the amount of ionization in plasma. Equation (1) shows the plasma frequency equation.

$$\omega_p = \sqrt{\frac{e^2 n_e}{\varepsilon_0 m_e}} \tag{1}$$

Where ω_p the plasma frequency [rad/s], e is the charge on electron [C], m_e is the electron mass [kg], n is the electron density [m^{-1}] and ε_0 is the free space permittivity [F/m]. The collision frequency equation is given in Equation (2).

$$v_c = n_e K(T_e) \tag{2}$$

Where n_e is the electron density [$1/m^3$], K is Boltzman's constant and T_e is electron temperature of the plasma elements.
In this paper, an array plasma antenna using a fluorescent tube, operating at 2.4 GHz is designed. This paper is divided into five sections as follows: Section 1 discus the introduction of Plasma Antenna and theory. Section 2 presents the antenna pattern and the structure of array antenna, section 3 presents the analysis of the plasma antenna array, section 4 discusses the simulation and measurement results and Section 5 provides the conclusion of this paper.

2. Antenna Design and Structure

At first, a single monopole plasma antenna with dimension of 586mm length (L) and 24.2mm diameter (D) was constructed on commercially available fluorescent tube. A coupling sleeve was attached to one end of the tube which is made from a copper wire, to energize the plasma ion which then converts it to plasma state. Thus, the fluorescent tube behave as an antenna. Table 1 and Fig. 1 present the dimensions of the monopole plasma antenna.

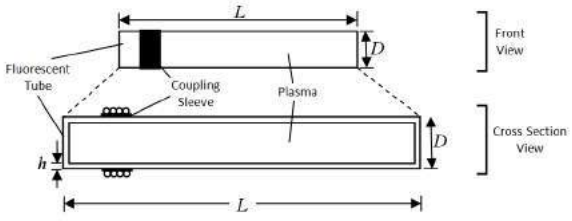

Figure 1: The Geometry of Monopole Plasma Antenna.

Table 1: Dimensions of Monopole Plasma Antenna.

parameter	symbol	dimension
Fluorescent tube length	L	586 mm
Fluorescent tube diameter	D	24.2 mm
Tube thickness	h	1 mm

Then, another 3 pieces of fluorescent tube with the same dimension as the original tube was added parallel to each other with separation distance of 100 mm. A coupling sleeve was attached to one end of each of the tube. The coupling sleeve of all the four tubes were combined as an input signal with a 4-port power divider. The antenna array was constructed to increase the overall gain. Fig. 2 and Table 2 present the dimensions of the plasma antenna array.

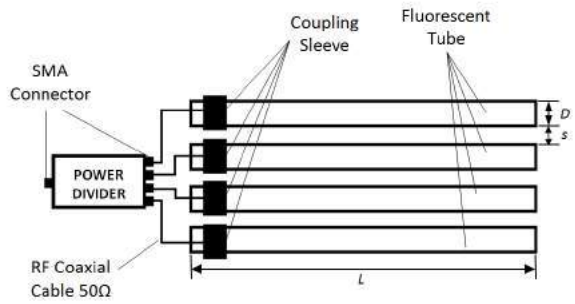

Figure 2: The Geometry of Plasma Antenna Array.

Table 2: Dimensions of Plasma Antenna Array.

parameter	symbol	dimension
fluorescent tube length	L	586 mm
fluorescent tube diameter	D	24.2 mm
Spacing between tube	s	100 mm

3. Analysis of Plasma Antenna Array

In this section, the analysis of parametric study is presented to investigate the effects of design of the plasma antenna. The simulation is performed by using CST Microwave Studio. A parametric study was accomplished to achieve the optimum performance of the antenna.

Fig. 3 shows the simulated parametric studies on the reflection coefficient S11, when the diameter of the copper wire was varied from 0.35 mm until 0.55 mm. Based on the graph, it is noticed that when the diameter of the coil is increased, the operating frequency is shifted to higher frequency.

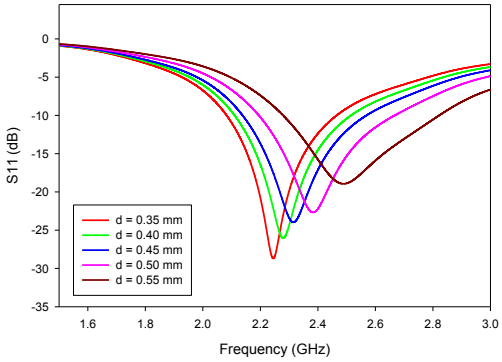

Figure 3: Simulation results as a function of different size of diameter coil.

The spacing of each lamps is determined to avoid mutual coupling effect between antennas. The optimization of the spacing was made to obtain an optimum performance of the plasma antenna array. Fig. 4 shows the simulated result of the return loss when the spacing between the lamps was varied from 90mm to 130mm with increment of 10mm. It can be clearly seen that when the spacing between the lamps was increased, the operating frequency shifted to lower frequency. From the analysis, the optimum result for the antenna to operate at frequency of 2.4 GHz was when s = 100 mm.

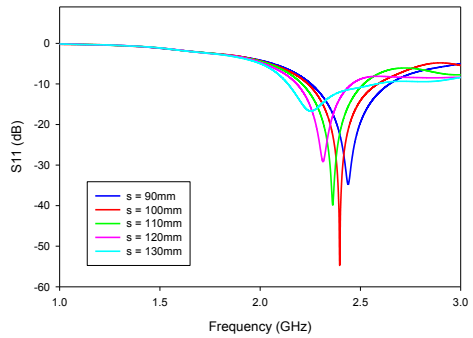

Figure 4: Simulation results as a function of different spacing between lamps.

4. Result and Discussion

The prototype of the 1x4 plasma antenna array has been constructed and measured to validate the simulated result. Fig. 5 shows the photograph of the antenna prototype when all the lamps were switch on.

Figure 5: Photograph of the Fabricated Antenna.

4.1. Return Loss

Fig. 6 shows the comparison between simulated and measured results of S11 when the antenna was operating at 2.4GHz. The blue line represents the simulated result while the red dotted line represents the measured results. Based from the graph, both antennas resonate at 2.4 GHz.

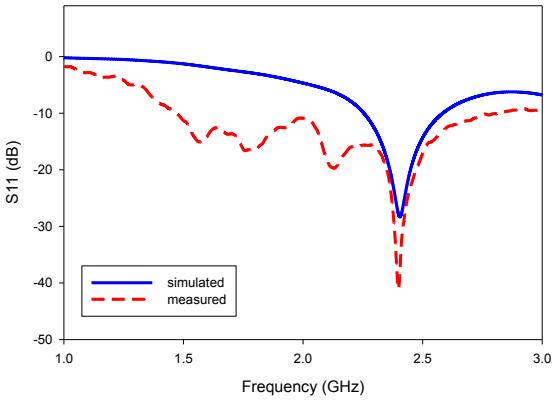

Figure 6: Comparison of simulated and measured S-parameter result for plasma antenna array.

Fig. 7 shows the comparison of S_{11} between monopole plasma antenna and plasma array antenna. It can be seen that both antennas can be operated at 2.4 GHz. The measuremed result agree well with the simulation result.

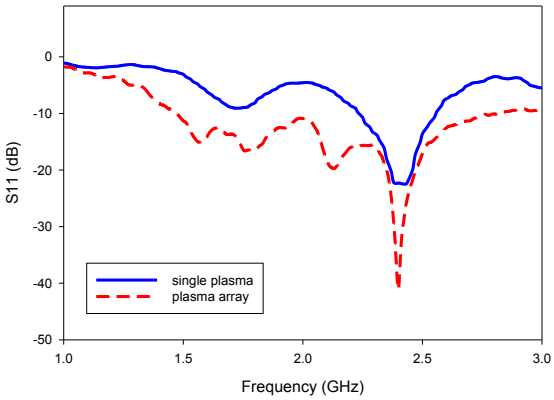

Figure 7: Comparison of measured S-parameter result between single plasma antenna and plasma antenna array.

4.2. Radiation Pattern

Fig. 8 presents the simulated and measured radiation pattern in polar plot at frequency of 2.4GHz. The results shows that there is a slight difference in the radiation pattern between the simulation and the measurement result. This may be attributed to measurement error, since the radiation pattern were measured in a partially anechoic chamber that may lead to inaccuracy.

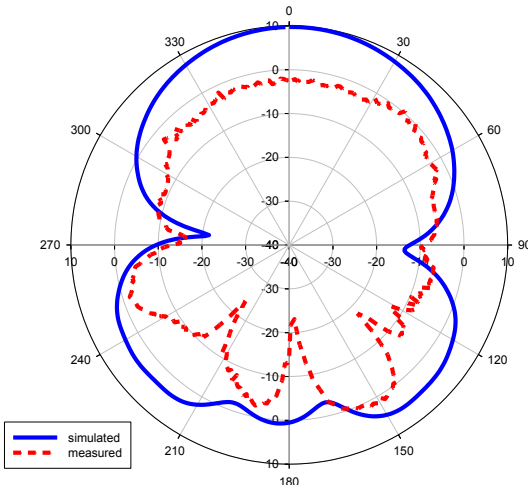

Figure 8: Comparison of simulated and measured radiation pattern for plasma antenna array.

4.3. Antenna Propagation

Outdoor propagation measurement was done in a free space to measure the signal strength of the antenna. The plasma antenna array was used as the receiving antenna. The transmitted antenna and received antenna were set up in point-to-point connections. This experiment was done by

varying the length between transmitted and received antenna and measuring the received power. The signal was measured from 1 meter up to 16 meters. Table 3 represents the results of the propagation measurement. The results show that as the distance between transmitted and received antenna increase, the loss power at the receiving antenna will increase.

Table 3: Result of Propagation Measurement.

Distance between Transmitter and Receiver	Received Power
1 meter	-41.72 dBm
2 meters	-43.44 dBm
3 meters	-44.95 dBm
4 meters	-46.42 dBm
5 meters	-46.53 dBm
6 meters	-47.96 dBm
7 meters	-48.51 dBm
8 meters	-50.09 dBm
9 meters	-51.32 dBm
10 meters	-55.55 dBm
11 meters	-55.23 dBm
12 meters	-55.33 dBm
13 meters	-56.40 dBm
14 meters	-57.61 dBm
15 meters	-58.31 dBm
16 meters	-62.54 dBm

4.4. Antenna Gain

Table 4 shows the difference of antenna gain between a monopole plasma antenna and plasma antenna array. Both antennas were operated at frequency of 2.4 GHz. Antenna gain for plasma antenna array was higher compared to monopole plasma antenna. This proves that by designing an antenna array will increase the overall gain.

Table 4: Plasma Antenna Gain.

plasma antenna	antenna frequency (GHz)	Antenna gain (dB)
monopole	2.4	1.956
array	2.4	9.685

5. Conclusions

In this paper, the design of 1x4 plasma antenna array using fluorescent tube was presented and discussed. Good agreement has been achieved between simulation and measurement results. Future works will concentrate on the measurements of the gain of the plasma antenna array.

Abstract

The integrated rectangular stacked microstrip antenna with Light Emitting Diode (LED) for Wi-Fi application is presented in this paper. In this paper more LEDs were placed on the top layer to improve the lighting capability, while maintaining the feasibility of working as a Wi-Fi router. Wi-Fi antenna simulated to resonate at 2.45 GHz using Computer Simulation Technology (CST) with permittivity, $\varepsilon_r =$ 4.3 and thickness, h = 1.6mm on FR4 substrate. The LED placed on the top substrate behave as parasitic element to the antenna design. The radiating patch is placed on the second layer of substrate and aperture coupled feeding network was used in this design. The antennas are reasonable well matched at their corresponding frequency of operations. The simulation results have shown that the antenna works well with the integrated LED giving 4.21dB gain, -25.61dB return loss and 106MHz bandwidth while 3.33dB gain, -16.90dB return loss and 103MHz bandwidth design without LED placement. Antenna was measured using Vector network analyzer (VNA) and Anechoic chamber.

1. Intoduction

Development of integrated antenna in order to works with multi-function characteristic had been widely studied nowadays. Currently, plasma antenna is one of the antennas that have dual function development in wireless communication technology especially an indoor Wi-Fi communication as antenna and at the same time as illumination sources. However, plasma antenna technology has limitation due to expensive and difficulties to manufacture. Meanwhile plasma requires energy to be ionized and the gas is more complex and expensive [1]. The volume of mercury inside plasma also can harm the safety and not supporting green technology [3]. Developing antenna with same capabilities and low cost and at the same time support green technology is much more needed.

LED is known as the semiconductor device that can emits light. It has many advantages compare with other traditional light source, such as long life expectancy, high-efficiency light sources, low maintenance, low power consumption and generally very robust and environmentally friendly[3-5]. The structure of LED itself is in principle, can be integrated with other product to create a new multifunctional product. In the communication field the integration LED with antenna has a potential of dual functionality device, as transmission and reception medium for wireless network and simultaneously as light source [1-3]. However, the feasibility of this integrated design is still continuously investigated due to the copper conductor on the LED that can affect the performance of the antenna [1-3].

In this paper, the integration of antenna with LED is studied. The copper material on the bottom of the LED has resulted in resonant frequency shifted as the number of LED are increased has been reported by [1-3]. Therefore, this stacked configuration has been proposed to overcome the frequency shifted problem [4-5]. The simulation has been studied by [5] to design LED circuit connectivity. In this design, the antenna has been design to resonant at 2.45GHz for Wi-Fi application and the LED works as parasitic element to improve antenna performance and as illumination sources. The implementation of LED at the top layer of design, for enhancing the performance in term of gain and return loss and at the same time adding the LED structure on the antenna structure will maintain the resonant frequency.

2. Antenna Design

The antenna with LED as parasitic elements in series parallel connection are designed as shown in figure 1. The antennas are designed on FR4 substrate with permittivity of 4.3 and thickness 1.6mm. LEDs are soldered on the top substrate where the size of substrate fixed at 50mm x 50mm, while patch radiator located on the second substrate. Meanwhile, ground plane and feed line are located on the bottom substrate as shown in figure 2.

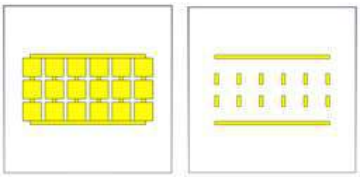

Figure 1: Antenna with LED as parasitic element designed

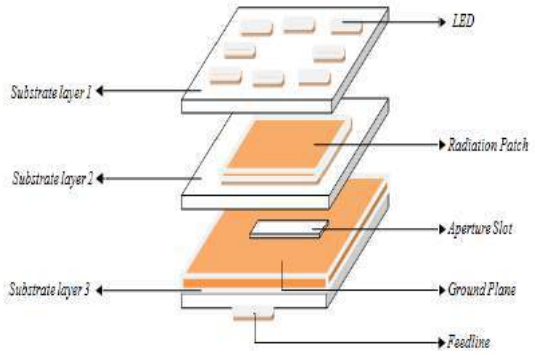

Figure 2: Antenna with LED parasitic element designed on the three substrate layers

The size of patch radiator is determined from numerical analysis using equation (1) to (4).

$$W = \frac{1}{2f_r\sqrt{\mu_o\varepsilon_o}}\sqrt{\frac{2}{\varepsilon_r+1}} \quad (1)$$

$$l = \frac{1}{2f_r\sqrt{\varepsilon_{reff}\sqrt{\mu_o\varepsilon_o}}} - 2\Delta L \quad (2)$$

$$\Delta L = 0.412(h)\frac{(\varepsilon_{reff}-0.3)\,(\frac{W}{h}+0.264)}{(\varepsilon_{reff}-0.258)(\frac{W}{h}-0.8)} \quad (3)$$

$$\varepsilon_{reff} = \frac{\varepsilon_r+1}{2} + \frac{\varepsilon_r-1}{2}\left[1+12\frac{h}{W}\right]^{-1/2} \quad (4)$$

Table 1: Antenna parameter.

Parameter	Value(mm)
Width of Substrated,W	50
Width of LED,W1	5
Width of patch,Wp	38
Width of feedline,Wf	4.23
Width of aperture slot,Ws	15
Length of substrated, L	50
Length of LED, L1	5
Length of patch, Lp	22.28
Length of feedline, Lf	30
Length of aperture slot, Ls	2

In this design, the advantages of allocating LEDs above the designed antenna in order to reduce the shifting frequency effect. The new antenna design focus on designing LED circuit without altering the resonant antenna frequency and at the same time improve the performance of the antenna due to parasitic effect. The LED used in this design is the SMD 5050 LED which is white LED [1] as shown in Figure 3. Meanwhile Figure 4 shown LED circuit diagram. 18 LEDs have been used in the designed antenna in order to get better parasitic effect. Optimization on the LED circuit has been studied using computer simulation software. The simulation process is performed using Computer Simulation Technology (CST) and all the design result is present as shown in table 2

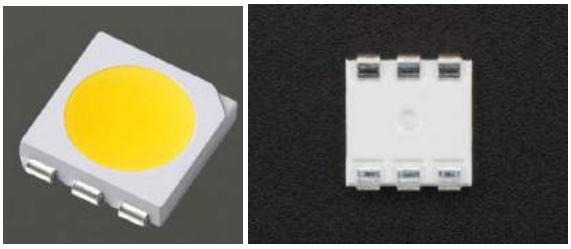

Figure 3: SMD 5050 LED

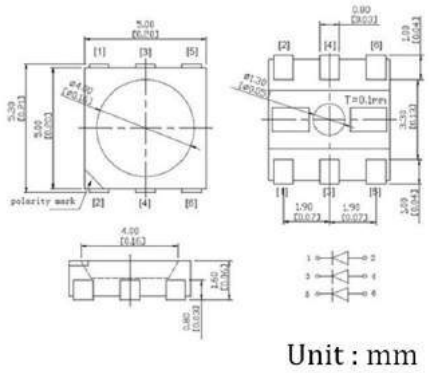

Figure 4: SMD 5050 Circuit diagram

Table 2: Simulation result.

Design Result	Antenna Design *With LED*	*Without LED*
Frequency (GHZ)	2.455	2.453
Return Loss(dB)	-25.61	-16.90
Gain(dB)	4.21	3.33
Bandwidth(MHz)	106.6	103.1
VSWR	1.020	1.054

3. Result and Discussion

3.1. Simulation Result Using Computer Simulation (CST)

The proposed antenna is simulated using CST simulation software and the simulation of the purpose antenna has been studied for antenna design with and without LED. Figure 5 shown antenna return loss result for both condition, with and without LED structure. The figure shown good in result where there are no shifting frequency when the LED is located on the top antenna structure. Furthermore, the return loss, S11 for antenna with LED is higher as compared with without LED. The technique that place LED on the top antenna structure as parasitic element, will improve the antenna performance without altering the antenna resonant frequency, therefore LED can work equally well on other antenna stack design. The radiation pattern of antenna is shown in figure 6 respectively.

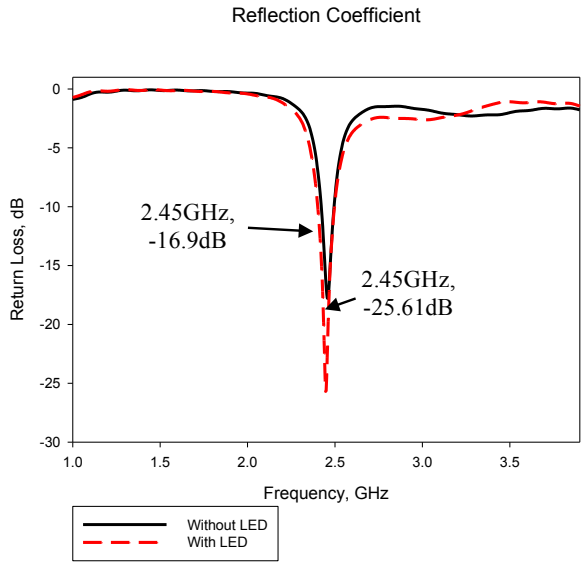

Figure 5: Simulated result return loss, S11 without LED and with LED

Meanwhile Figure 6 shown the antenna radiation pattern for simulation result. From the figure it shown that locating the LED have improve in the antenna gain. Although the figure shown radiation pattern with back loop, the front loop is more dominant compare with back loop. The antenna gain has been increase from 3.33dB without LED to 4.06dB in the design with LED structure.

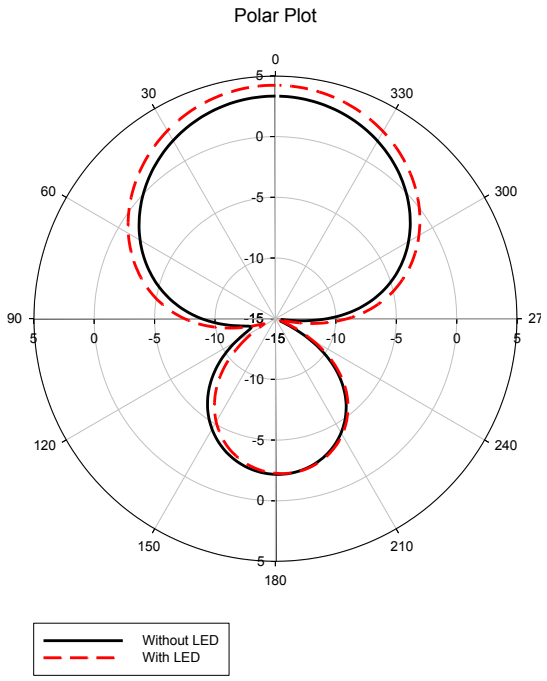

Figure 6: Simulated radiation pattern result with and without LED

3.2. Measurement Result Using Vector Network Analyzer and Anechoic Chamber

The optimized antenna design structure has been fabricated and measured in this section. The return loss of antenna design has been carried out using VNA Keysight module. The return loss of the integrated microstrip antenna with and without LED measurement results were shown in Figure 7. However in measurement result, the resonant frequency is shifted to the right from the simulation result about 2%. This situation is believe due to improper handling on fabrication process. However, the frequency response for both resonant was unchanging at 2.50GHz for antenna structure with and without LED, respectively. On the other hand, return loss value with LED structure is much better as compared to the antenna without LED structure. The corresponding operating bandwidths were 132 MHz without LED and 152MHz on with LED for both conditions as shown in Figure 7.

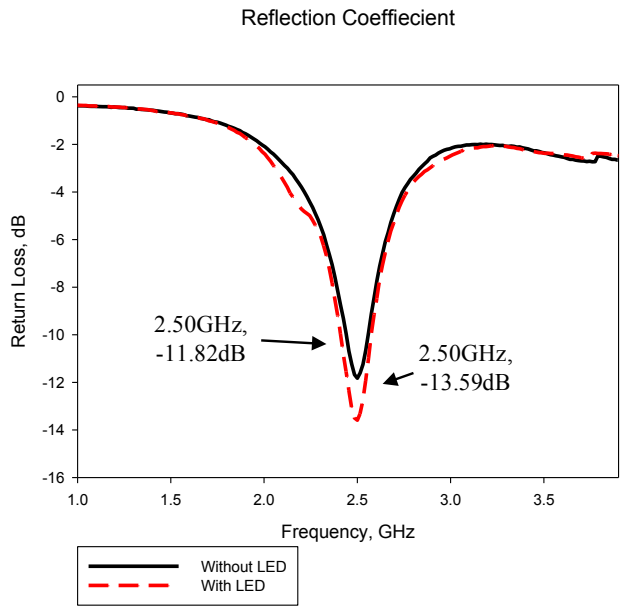

Figure 7: Antenna with and without LED measurement result.

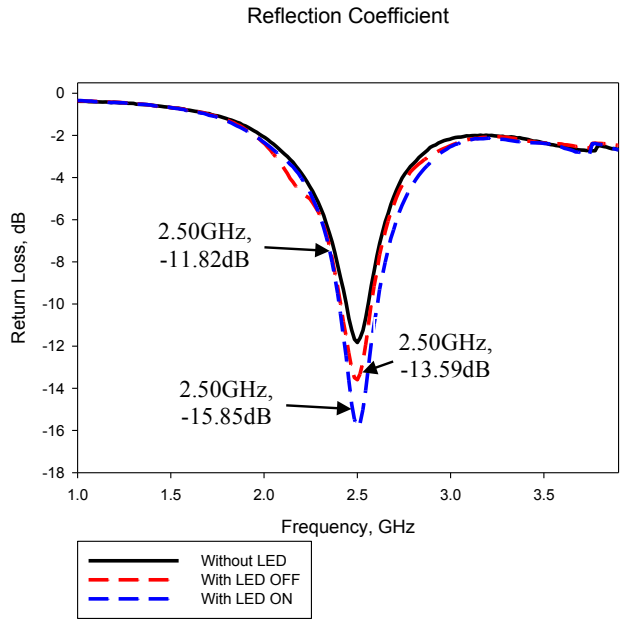

Figure 8: Measurement ON/OFF LED

Meanwhile in Figure 8 shows well matched result at the input of antenna where the return loss for 'OFF' LED is -13.59dB at 2.50GHz and return loss of -15.58dB and 2.50GHz respectively for 'ON' LED. The corresponding operating bandwidth was border to 195 MHz when LED are 'ON' state and 153 MHz at LED OFF state. The results shows that by turning 'ON' and 'OFF' LED the resonant frequency of the antenna is not changing, without and with LED. The bandwidth is slightly increase when LED is in 'ON' stage, it may be caused due to current distribution when turning ON the LEDs and also the fabrication process and soldering effect of LED terminal on the patch and also the return loss is better with LED ON condition.

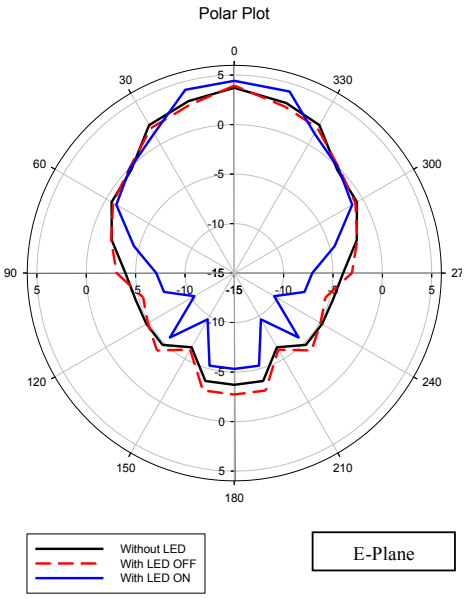

Figure 9: Measurement result with/without LED for E-Plane.

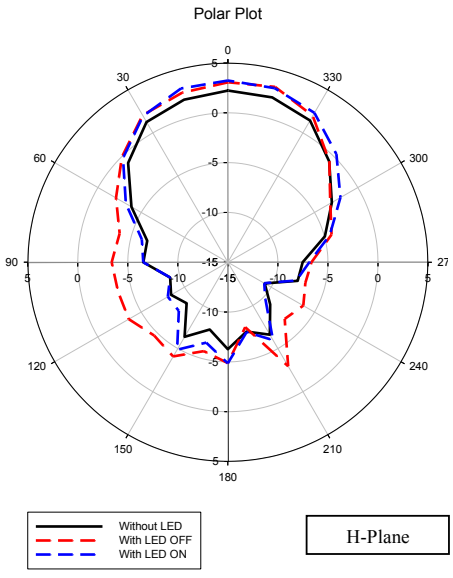

Figure 10: Measurement result with/without LED for H-Plane.

The measured gain curves are also given in figure 9 for E-plane and figure 10 for H-plane result. The maximum power was received by the antenna is match form the simulation result. From the measurement result of the purposed antenna, the maximum gain achieve when adding the LED on the top layer antenna structure was 3.92dB. Meanwhile, the gain for the measurement result on "ON" LED has been increased to 4.41dB. The measured gain was increase in ON LED is believed due to current distribution effect when the current flow into LED structure. Table 3 shown the antenna measurement result for purposed antenna design.

Table 3: Measurement result.

Design Description	Without LED	With LED OFF	With LED ON
Frequency (GHz)	2.50	2.50	2.50
Return Loss (dB)	-11.82	-13.59	-15.85
Gain (dB)	3.70	3.92	4.41
Bandwidth (MHz)	135	153	195

Meanwhile in figure 10 shows antenna radiation pattern in 3D view, (a) without LED (b) with LED OFF mode and (c) with LED ON mode. From the 3D figures we can see that the antenna has more radiates towards z-plane when turning ON the LED. This situation will lead to the improvement in gain value when making the measurement process. Meanwhile figure 11 shown the antenna that has been fabricated (a) with (b) without LED structure.

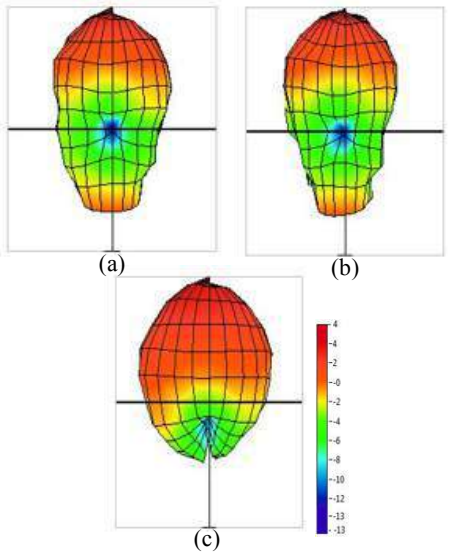

Figure 10: 3D view antenna design

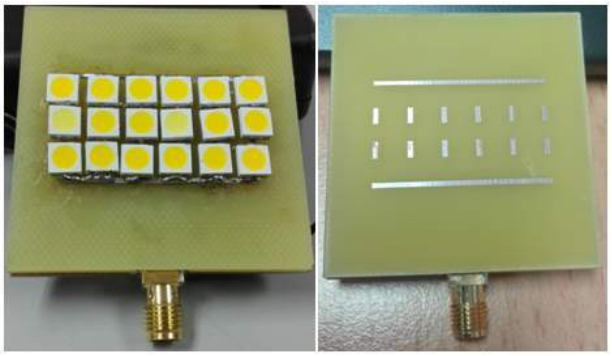

Figure 11: Antenna design With/Without LED

4. Conclusion

The rectangular stack microstrip patch antenna integrated with LED has been designed and investigated. From this research works, it can be concluded that, the designed antenna contributes to dual-function in a device. It can function as an antenna at Wi-Fi application and the same time it gives illumination to user with improved the overall performance of the antenna with and without LED. The measurement proves that LED can assume as a parasitic element to the antenna and well matched to the patch to improve the gain of the antenna. The use of the integrated LED in the design supports the green environment and will contribute better in terms of energy consumption. However, future works will be considered to improve this antenna to have better performance for the both conditions in terms of gain and radiation pattern.

Abstract-Surface plasmon polaritons (SPPs) on a metal/TiO_2 heterostructure enable plasmon-mediated chemical reactions in a system whose resonance may be continuously tuned simply by altering excitation source and incident angle. We found a strong excitation angle dependence and linear power dependence in the photocurrent, confirming that the photoelectrochemical reactions are SPP-driven. Applicability of the SPP system for energy-tunable hot carrier generation and hot-carrier driven solution chemistry was further investigated using refractory plasmonic materials and SP band gap structures.

The ability of plasmonic nanostructures to create electron-hole pairs with energies much larger than those in thermal equilibrium - so-called "hot carriers" - offers new possibilities to utilize photon energy to drive useful chemical reactions. While the rate of photocatalytic reactions on nearby semiconductors can be optimized by varying the morphology of metal nanoparticles that support localized surface plasmon resonance (LSPR), the LSPR of individual nanoparticles is not tunable. The lack of tunability of the LSPR system hinders the efficient charge transfer from the photoexcited metal nanoparticles to the adsorbate, which is a carrier energy dependent process by aligning hot carrier potentials with redox potentials of adsorbed molecules. Recently, we have shown surface plasmon polaritons (SPPs) generated at the interface between a noble metal/titanium dioxide (TiO_2) heterostructure film and aqueous solution for the simultaneous optical and electrochemical interrogation of plasmon-mediated chemistry in a system whose resonance may be continuously tuned via the incident excitation angle.[1] We found a strong excitation angle dependence and linear power dependence in the photocurrent, confirming that the photoelectrochemical reactions are SPP-driven. A single plasmonic structure was used to generate plasmons with two different energies of 1.6 and 2.3 eV, and at both energies SPP-induced hot carriers drove both solution-based oxidation of methanol and the anodic half-reaction of photoelectrochemical water-splitting in sodium hydroxide solution. The applicability of the SPP system for energy-tunable hot carrier generation and hot-carrier driven solution chemistry was further investigated in a refractory plasmonic material platform using titanium nitride (TiN) and in the periodically textured metal films exhibiting surface plasmon photonic band gaps. Our results demonstrate that the broad and continuous energy tunability of the SPP system can be used to increase the basic knowledge of plasmon-induced hot carrier generation not only for photocatalysis but for many other applications including solar energy conversion, photodetection, and scanning probe imaging.

Figures and Tables:

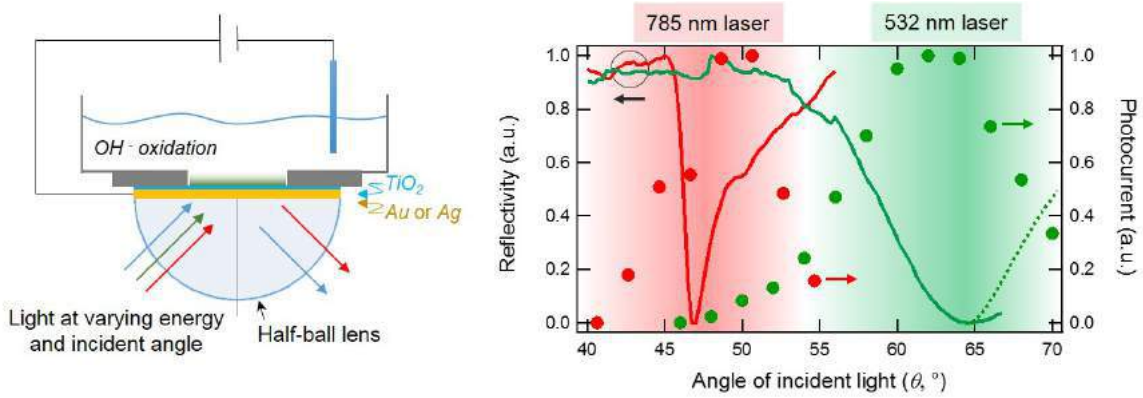

Figure 1. Energy tunable hot carrier generation for photocatalysis: The SPP on a metal/TiO_2 heterostructure enables plasmon-mediated chemical reactions (methanol oxidation and anodic half-reaction of water-splitting) in a system whose resonance may be continuously tuned via excitation angle. A single plasmonic structure can be tuned between two different resonances simply by altering excitation sources (785 and 532 nm laser) and incident angle.

Abstract- Spectroscopic imaging is used to investigate surface plasmon polariton (SPP) enhanced energy transfer upconversion (ETU) of rare-earth doped $NaYF_4$:Yb^{3+},Ln^{3+} upconverting nano-particles (UCNPs) on noble metal nano-structured substrates, including arrays of Au nano-pillars and nano-cavities with optical resonances coincident with rare-earth ion absorption (Yb^{3+}) or emission (Er^{3+},Tm^{3+}) energies. The mechanisms for the observed enhancement and power dependence are understood through analytical and computational models, relating the observed enhancement to kinetics of the ETU system and the photonic properties of the substrates.

While upconversion can be achieved through a variety of optical processes, such as two-photon absorption, second-harmonic generation, cooperative luminescence, two-step absorption and energy transfer upconversion, at low excitation intensity, the energy transfer upconversion process is by far the most efficient [1]. With the advent of nano-sized UC materials, the range of applications wherein such materials can be deployed has greatly increased. For instance the areas of bio-imaging, bio-labeling and photodynamic therapy benefit greatly from upconverting nano-particle (UCNP) materials due to the long penetration depth of near-infrared light in biological tissues [2,3]. There are also prospects for spectral conversion in increasing efficiency in solar energy applications [4]. However, low luminescence efficiency still limits the full potential of these materials.

In the vicinity of a metallic nanostructure, luminescence enhancement can be achieved through the amplification of the incident field, where local electromagnetic fields at the UCNP position are intensified due to plasmon resonances, and through the modification of the radiative rates of the phosphors [5-8]. By optimizing the geometry of the metallic nanostructures, and placing them within suitable proximity to the UCNPs, significant enhancement in UC efficiency should be achievable. In this work, we investigate the efficacy of specific plasmonic nanostructures towards radiative control of energy transfer upconversion processes in β -phase $NaYF_4$:Yb:Er[Tm] nanoparticles, using spectroscopic imaging to directly visualize the local enhancement associated with specific noble metal nanostructures.

Figure 1 shows a survey of the UCNPs (figure 1a) and the plasmonic nano-arrays we have investigated (figure 1b-d, and f-g), including representative spectra on and off the arrays [7-14]. Figure 1h shows the power dependence of the energy transfer upconversion enhancement of $NaYF_4$:Yb,Er UCNPs on Au nano-cavity arrays (figure 1f-g)[14]. The nano-cavity arrays support a surface plasmon (SP) resonance at 980nm, coincident with the peak absorption of the Yb^{3+} sensitizer. Spatially-resolved upconversion spectra show a 30X to 3X luminescence intensity enhancement on the nano-cavity array compared to the nearby smooth Au surface, corresponding to varying excitation intensities from 1 W/cm^2 to 300kW/cm^2, spanning the non-linear and saturation power dependence regimes. Figure 1I shows the measured and simulated power dependence of the ETU enhancement on the nano-cavity arrays, the latter obtained by simultaneous solution of a system of coupled rate equations developed by our team [13]. Our analysis shows the power dependent enhancement in upconversion luminescence can be almost entirely accounted for by a constant shift in the effective excitation intensity, which is maintained over five orders of magnitude variation in excitation intensity, limited by the kinetics of the ETU process.

In these measurements, it is shown that the amplification of the excitation field is independent of the emission wavelength, indicating the enhancement in upconversion emission is due to entirely to increased absorption by the Yb^{3+} sensitizer. Analysis of the statistical distribution of emission intensities in the spectroscopic images on and off the nano-cavity arrays provides an estimate of the average enhancement factor independent of fluctuations in nano-particle density. More recent work in random aggregates of Ag nanowires show evidence for collective plasmon resonances which manifest as local “hot-spots” with enhancements factors exceeding

thirty times [15]. These and our most recent results suggest significantly higher upconversion enhancement factors can be achieved under proper conditions by utilizing the surface plasmon polariton interaction with the ETU UCNPs while maintaining optimal ETU kinetics.

Broadband enhancement of photocatalytic efficiency by 3D patterned light trapping structure

Yunha Ryu and Kyoungsik Kim*
Department of Mechanical Engineering, Yonsei University, Seoul, Korea
*corresponding author: kks@yonsei.ac.kr

Abstract- Here we report enhancement of photocatalytic efficiency of TiO_2 by utilizing three dimensional light trapping structure which brings increased the light absorption. We successfully fabricate the 3D structures via self-assembly technique. The fabricated structures show high light absorption and large surface area which are beneficial to photocatalytic effect. Also, we combined TiO_2 structures with plasmonic metal nanostructures to achieve higher light absorption and hot carrier injection.

We fabricated TiO_2 nanotube structures by anodic-anodization method and gold nanoparticles are decorated on the nanotubes to increase the light harvesting efficiency (Fig.1). The optical and electrical properties of the fabricated structure are measured to evaluate the enhancement of photocatalytic efficiency.

Abstract:

We report the plasmonic resonance behavior of nano-structured iron oxide films decorated with Au nanoparticles. Iron oxide (Fe_2O_3) nano-structured films have recently drawn interest for electro-catalytic processes including reactions that involve carbon-carbon (C-C) bond breakage. We deposited iron oxide films using electron-beam evaporation followed by annealing at 450°C in mixed and pure oxygen environments. We deposited Au NPs either in embedded or on top of the Fe_2O_3 nano structured thin films with thicknesses ranging from 25-500 nm. We used ellipsometric as well as UV-Vis reflectance spectroscopy techniques to determine the plasmonic characteristics of the nanostructured films.

Iron oxide (Fe_2O_3) film has recently received much attention among various semiconductor photo-electrode materials due to its favorable optical band gap (~2.2 eV), excellent chemical stability in high pH media, natural abundance, and low cost [1]. However, Fe_2O_3 exhibits a relatively poor absorptivity of photons near its band-edge due to an indirect band gap, poor electronic conductivity (PEC), and picosecond recombination of excited states, thus leading to a photo-generated hole diffusion length of ~2-4 nm [2]. These non-ideal optoelectronic properties hinder the transport of photo-generated carries and increase the recombination rate, which results in a lowering of the PEC efficiency compared to theoretically predicted values. Controlling the nanostructure of Fe_2O_3 may provide an effective technology for overcoming the aforementioned problems of Fe_2O_3 film due to the geometry and mechanism-dependent semiconductor structure [3]. The shape of the Fe_2O_3 structures with cone, cylinder, sphere, etc. features alters the electric field dependent absorption and transport processes.

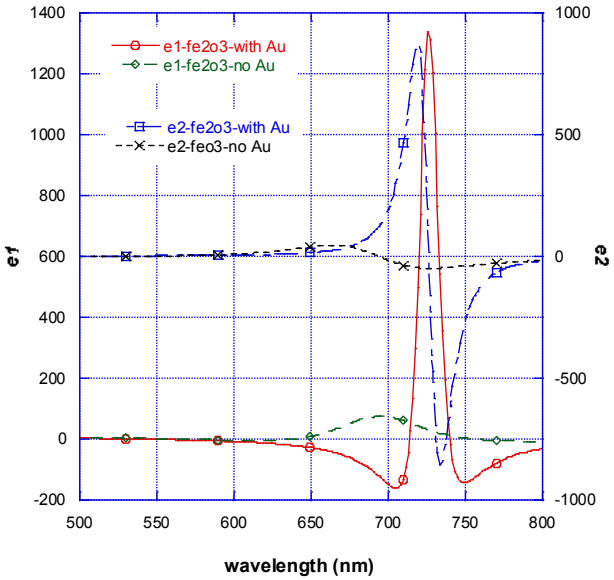

Fig. 1 Real (e1) and Imaginary (e2) parts of the dielectric constant of a representative sample (e.g., a 100 nm of Fe_2O_3 film with and without Au NPs)

In Figure 1, we show the e1and e2 both real and imaginary of dielectric constant of the Fe2O3 film with and without Au nano particles measured by variable angle ellipsometry. The plasmonic resonance occurs in between 700-750 nm as seen in the above figure. In addition, we discuss theoretical modeling of the extinction, scattering and absorption characteristics of the Fe_2O_3 films with varying thickness with and without Au NPs. The Au NP-Fe_2O_3 structure has significant absorption characteristics in visible spectral region. Detailed deposition, annealing, and characterization results of Fe_2O_3 nano plasmonic structures will be presented in a full paper.

Abstract- The expansion of the graphene family by adding silicene, germanene, and stanene (2D allotropes of Si, Ge, and Sn) lends itself as a platform to probe Dirac-like physics in honeycomb staggered systems in the Casimir interaction. We discover Casimir force phase transitions between these staggered 2D materials induced by the complex interplay between Dirac physics, spin-orbit coupling, and externally applied fields. Furthermore, due to the topological properties of these materials, repulsive and quantized Casimir interactions become possible.

The discovery of systems with reduced dimensions and physics different from the one of standard 3D dielectric, metals, and semiconductors has given a new impetus to the field of van der Waals and Casimir phenomena [1]. In particular, the graphene-family materials has recently been expanded through the synthensis of silicene, germanene, and stanene. Unlike graphene, these new 2D materials gave spatial buckling between the two sublattices and exhibit non-trivial topological insulator features. The application of external fields together with the inherently strong spin-orbit coupling can be used as effective "knobs" for various Hall transitions. We have recently discovered [2] a new effect in the Casimir physics of these materials, namely Casimir force topological phase transitions driven by the complex interplay between Dirac physics, spin-orbit coupling, and externally applied electric fields and circularly polarized light. Novel distance scaling laws, abrupt magnitude changes, force quantization and repulsion, are all manifestations of Casimir force phase transitions occurring in these 2D staggered materials. Thermal effects result in the smoothing out of phase transition boundaries and disappearance of quantized and repulsive Casimir interactions. In order to detect experimentally Casimir force phase transitions, cryogenic atomic force microscope set-ups, such as the one developed in [3], are required. Given the magnitude of the predicted effects [2] and the reported sensitivities of experiments [3], the measurements of Casimir force phase transitions in the graphene family materials should be within reach with current state-of-the-art low-temperature Casimir force experiments.

A group theoretical route to deterministic Weyl points in chiral photonic lattices

M. Saba[1], **J. M. Hamm**[1], **and O. Hess**[1]

[1]Department of Physics, Imperial College London, Prince Consort Road, SW7 2BB, UK

Abstract— Point degeneracies in the photonic bandstructure give rise to a variety of exotic properties such as topological phases. Previously identified exceptional points are based on accidental degeneracies and subject to engineering on a case-by-case basis. We here show that symmetry induced (deterministic) pseudo Weyl points with non-trivial topology and hyperconic dispersion exist at the Γ point in the Brillouin zone of chiral cubic systems. We demonstrate the universal behavior by means of interacting plasmonic spheres on a chiral cubic lattice.

The broad interest in topological phases over the past decades, triggered by the discovery of the quantum Hall effect [1] and its theoretical investigation [2], is mainly attributed to the fact that topological features are, due to their discrete nature, insensitive to system perturbations. One of the striking physical implications of non-trivial topology is the existence of topologically induced uni-directional edge states for bulk systems [3, 4]. The plasmonic [5] and single electron surface states of Weyl semi-metals, with an isolated exceptional point of non-trivial topology, in particular are known to be stable against perturbations and to give rise to peculiar dynamics.

In 2004, Onoda *et al.* showed that topological phases occur in entirely classical systems such as 2D photonic crystals [6], sparking a new wave of research on topological photonics [7]. In particular, topologically protected Weyl points with hyperconic dispersion have been identified in double gyroid photonic crystals with broken parity-time symmetry [8].

More recently, Huang *et al.* [9] exploited the linear dispersion in the bandstructure close to accidental pseudo-Dirac points at the Γ point of a square lattice of dielectric rods to form a 2D metamaterial with vanishing refractive index $n = 0$ and finite impedance $Z \neq 0$, with remarkable implications on interface scattering and wave propagation.

On the basis of group and perturbation theory, we here predict the existence of 3D *pseudo Weyl points* with hyperconic dispersion relation at the center of the BZ of chiral cubic lattices. Pseudo Weyl points are in contrast to previously reported pseudo Dirac points [9] deterministic, *i. e.* symmetry protected and hence not subject to careful engineering of geometric parameters. They are shown to be isotropic, to exhibit a Chern characteristic of $C = \pm 2$ (*i. e.* they are topologically non-trivial), and exist in classical and quantum systems with chiral cubic symmetry.

We demonstrate the predicted behavior via a minimalistic model system based on a simple cubic array of plasmonic nano-spheres on a $P2_13$ lattice (Fig. 1**A**). In the limit of small spheres of radius ρ much smaller than the lattice constant a, the polarization vectors $\vec{p}_\mu$ of individual spheres μ (in the frequency domain) are subject to dipole interaction [10]. Using Bloch's theorem, the underlying equation of interaction reduces to a low-dimensional non-linear hermitian eigenproblem, with eigenvalues k_0 and dimension $N = 12$:

$$\alpha^{-1}(k_0)\,\vec{p}_\mu = \sum_\nu M_{\mu\nu}(\vec{k}, k_0)\,\vec{p}_\nu \ . \tag{1}$$

Here, α is the polarizability, and $M_{\mu\nu}(\vec{k}, k_0)$ a lattice sum over Maxwell Green functions. For the particular system, group theory predicts three 3-fold degeneracies, one 2-fold degeneracy and a non-degenerate mode at the Γ point. These are reproduced by the numerical solution of equation (1). The dispersion relation close to one of those points is shown in Fig. 1**C**: a flat band (black) is sandwiched between a pair of hyperconic bands (red) with linear and isotropic dispersion of equal magnitude.

In summary, we show that isotropic hyperconic dispersion can be found at the Γ point of chiral cubic lattices for a broad class of physical systems. Although not strictly speaking in the Weyl class, the associated exceptional points share most features with genuine Weyl points including non-trivial topological characteristics. A natural application for the unique dispersion behavior of these

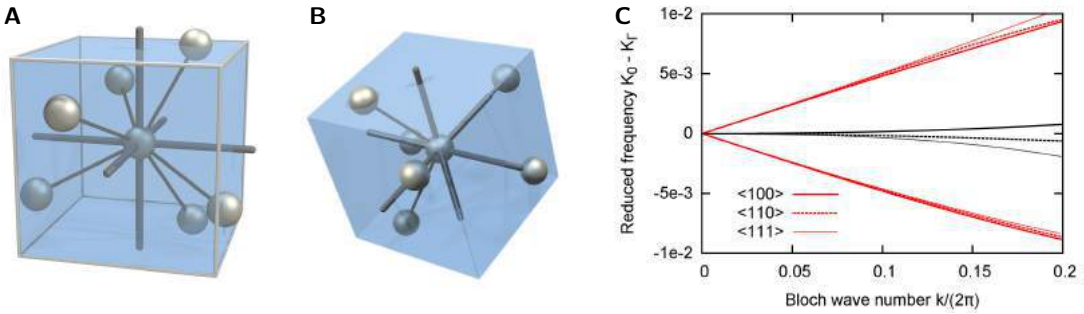

Figure 1: (**A**) Unit cell of the 3D plasmonic sphere packing on a $P2_13$ lattice considered here. Connecting rods, glass cube and Cartesian grid for illustration purposes only. pseudo Weyl points are zero refractive index materials that have been suggested previously in the context of accidental Dirac points in two-dimensional photonic crystals [9]. A cubic arrangement of nano-spheres similar to the proposed model could be for example realized by means of DNA origami [11].

Abstract

We report here the band structures and transport properties of $In_{0.53}Ga_{0.47}As$ (d_1=10 nm)/InP (d_2=5 nm) lattice matched superlattice, based on the envelope function formalism and the effective mass approximation. We investigated the effect of well thickness, valence band offset and temperature on the band structures as well as the effect of barrier thickness and magnetic field on the density of states. In the later, the existence of a small dispersion indicates weak interactions between adjacent wells. The position of Fermi level predicts that this sample exhibits n-type conductivity. We find out some correlations between band structures and both Shubnikov-de Hass and quantum Hall effects. These results were compared and discussed with the available data in the literature.

1. Introduction

$In_xGa_{1-x}As$/InP superlattices (SLs) have attracted many attention due to their electronic and optical properties, which can be tuned by adjusting layers thicknesses or indium compositions x. The relative small band gap and high mobility of the constituent quantum well ($In_xGa_{1-x}As$) demonstrate that those nanostructures are attractive for high operating temperature devices [1].

These nanostructures have been used in the development of different optoelectronic devices such as photoconductive switches, transistors, and photodetectors [2,3]. They are expected to be promising with the superlattice-emitter resonant tunneling bipolar transistor (SE-RTBT) which have demonstrated a significant potential in high-speed switches and to reduce the functional device circuits complexity [3].

Nevertheless, the lattice matched $In_{0.53}Ga_{0.47}As$/InP quantum well infrared detectors become the choice for low cost, low dark current, high speed and high temperature operation detectors in short wavelength infrared (SWIR) [4]. Such detector's performances can be enhanced significantly when the infrared absorber material is made from a superlattice and the detection wavelength can be extended out to cover 5-9 μm as reported by Majumdar et al. [5], or even further with binary superlattice [6]. The key advantage of superlattice based infrared detectors over conventional ones is that the layer thickness and alloy compositions are chosen to yield the desired energy band gap.

One of the quantities which characterize the reduced dimensionality of the structure is the density of states (DOS). Several optical and electrical properties follow DOS. Thus, it is possible to get useful information by studying this quantity.

Several experimental observations show, at low temperatures and under high magnetic fields, some new features in $In_xGa_{1-x}As$/InP superlattices. Among them, Shubnikov de Haas effect (SDH) and quantum Hall effect (QHE) [7,8]. However, only few attempts have been devoted to study the formation of mini-bands in such system, obtained by magnetotransport and photoluminescence measurements [7], or analysis of Raman data [9].

2. Superlattices band structures theory and computation

The general expression of dispersion relation of $In_xGa_{1-x}As$/InP superlattice, within the envelope function formalism and effective mass approximation, is given by [10,11]:

$$\cos(k_z d) = \cos(k_1 d_1)\cos(k_2 d_2) - \frac{1}{2}\left[\left(\xi + \frac{1}{\xi}\right) + \frac{k_p^2}{4k_1 k_2}\left(r + \frac{1}{2} - 2\right)\right]\sin(k_1 d_1)\sin(k_2 d_2) \quad , \quad (1)$$

With k_z the wave vector in the growth direction and $k_p(k_x,k_y)$ the superlattice in-plane wave vector. The origin of the energy E has been chosen at the top of InP valence band as shown in the Fig.1. In each host material and for a given energy, the two–band Kane model [12] gives the wave vector ($k_i^2+k_p^2$). Therefore, the energy E of the light particles (electron and light hole) is given by:

$$\begin{cases} \frac{2}{3}P_1^2\hbar^2\left(k_1^2 + k_p^2\right) = \left(E - \varepsilon_1 - \Lambda\right)\left(E - \Lambda\right) & for\ In_xGa_{1-x}As \\ \frac{2}{3}P_2^2\hbar^2\left(k_2^2 + k_p^2\right) = E\left(E - \varepsilon_2\right) & for\ InP \end{cases}, \quad (2)$$

The expression of ξ and r in the Eq(1) are:

$$\xi = \frac{k_1}{k_2} r \text{ and } r = \frac{E - \varepsilon_2}{E - \varepsilon_1 - \Lambda}$$

From the same equation (1), the superlattice heavy holes mini-bands can be calculated with the following relations:

$$\begin{cases} -\frac{1}{2}\frac{\hbar^2}{(m^*_{hh})_1}\left(k_1^2 + k_p^2\right) = (E - \Lambda) \quad for\ In_xGa_{1-x}As \\ -\frac{1}{2}\frac{\hbar^2}{(m^*_{hh})_2}\left(k_2^2 + k_p^2\right) = E \quad for\ InP \end{cases}, \qquad (3)$$

with $\xi = \frac{k_1}{k_2} r$ and $r = \frac{(m^*_{hh})_2}{(m^*_{hh})_1}$

The direct band gaps parameters ε_i (i= 1 and 2) used here, as a function of temperature, for x=0.53, are given by the empirical expressions reported in [13,14]. P_i is the Kane matrix element [15]. The heavy holes effective masses of $In_{0.53}Ga_{0.47}As$ and InP are, respectively, $(m^*_{hh})_1 = 0.47 m_0$ and $(m^*_{hh})_2 = 0.6\ m_0$, as given in [1,15].

In this work, we have used the valence band offset Λ between heavy holes sub-bands edges of $In_{0.53}Ga_{0.47}As$ and InP. We adopted in the computation, the experimental Λ= 346 meV measured by Lang et al. [16] with admittance spectroscopy and supported by the theoretical calculations of Ichii et al. [17].

The computation of band structures consists of solving the general dispersion relation with the reported parameters. In the Eq. (1), state energy exists if the right-hand side lies in the range -1 to 1. In other words, $-1 \le \cos(k_z d) \le 1$ which implies $-\pi/d \le k_z \le \pi/d$ in the first Brillouin zone, with $d = d_1 + d_2$ is the superlattice period. In the study of energy E as a function of wave vector in the direction of growth k_z (k_p=0), the solving procedure consists of going with small steps of energy through the studied range. Then finding, for a given E, the value of k_z which is root of the dispersion relations. The same procedure is used for studying E versus the in-plane wave vector k_p (k_z=0 and $k_z = \pi/d$). Note that strain effects are not taking into account here, since

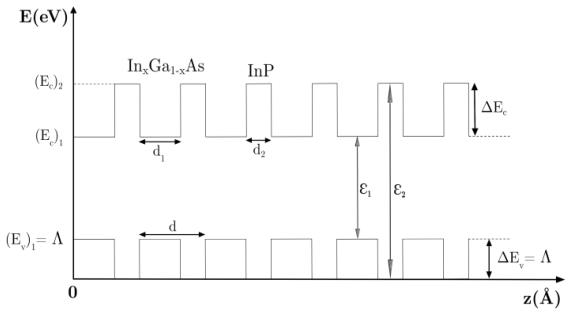

Figure 1: Illustration of band lineup between $In_xGa_{1-x}As$ and InP along the growth direction with different parameters related to electronic band structures. $(E_c)_i$, $(E_v)_i$ and ε_i where i= 1, 2 are the conduction and valence bands edges and band gap of bulks, respectively.

$In_{0.53}Ga_{0.47}As$ is lattice matched to InP [1,14].

The sample studied here consists of alternating $d_1(In_{0.53}Ga_{0.47}As)$= 100Å and d_2(InP)= 50Å with d= d_1+d_2= 150Å.

3. Results and discussions

3.1. Band gap engineering

In the Fig. 2a, we represent the energy of conduction (E_i), light-hole (lh_i) and heavy-hole (hh_i) mini-bands at the center $\Gamma(k_z = 0)$ and the limit ($k_z = \pi/d$) of the first Brillouin zone as a function of well thickness d_1. The calculated band gap, from bottom of the first conduction (E_1) to top of valence mini-bands (hh_1) at T=1.7 K is $E_g(\Gamma) = E_1 - hh_1$= 849 meV. The photoluminescence measurements Pusep et al. on the same sample [8], show a direct band gap of 822 meV.

The observed difference of 27 meV may be due to parameters considered here, particularly, the valence band offset (VBO). The effect of this parameter on the superlattice band gap is shown in Fig. 2b. A Good agreement can be obtained with the optical band gap when the VBO is taken to be 605 meV at 1.7 K. However, in the literature, the experimental Λ of $In_{0.53}Ga_{0.47}As/InP$ hetero-junction is ranging between 0.24 eV and 0.38 eV [18]. Such

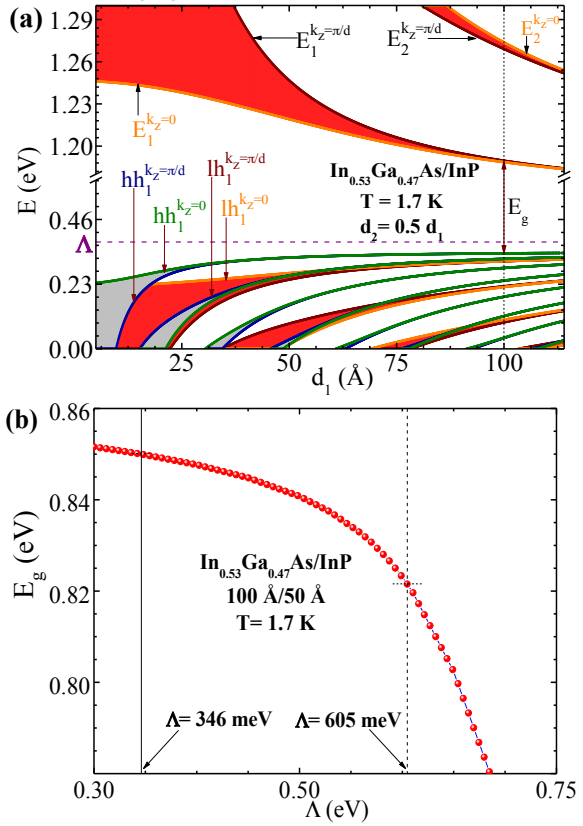

Figure 2: (a) Energy of both conduction (upper part) and valence (lower part) mini-bands versus the well thickness at 1.4 K. Solid areas show the mini-bands width. (b) Band gap as a function of the valence band offset of the studied superlattice.

difference, can be also attributed to the strain effects which could be significant in such low temperature and could modify the band structures by introducing interface states [19]. Also, fluctuations during the growth of both wells and barriers could affect the superlattice band gap, since it depends significantly on thickness.

In addition, we can see, in Fig. 2a that the mini-bands width and band gap decrease and tend to discrete levels of a quantum well as d_1 increases. This can be explained by the creation of more allowed states, available to be occupied by electrons in the forbidden region, since the overlapping orbitals between nearest atoms grow with thickness. As result, the valence and conduction mini-bands separation, starts to narrow, leading to a reduction of band gap.

The effect of temperature on the superlattice band gap is shown in the Fig. 3. At low temperatures, the gap varies hardly and then it decreases when the temperature increases.

For T≥40 K, our theoretical results (green solid squares) are in agreement with the photoluminescence measurements (solid red circles) of Fernandes dos Santos et al. [20]. The difference between the calculated and measured band gaps energies decreases from 8 meV to 3.8 meV when T increases from 40 K to 300 K, may be, are due to the factors discussed above.

Nevertheless, in their paper Pusep et al. [8] suppose that the difference between the experimental and the calculated inter mini-bands gaps is due particularly to the imprecisely known band offsets of $In_{0.53}Ga_{0.47}As/InP$ heterostructure. In Fig. 3, we did the fit of valence band offset Λ and the best agreement is achieved for Λ= 400 meV (brown solid line).

In addition, these results were fitted by the empirical Varshni formula [21] expressed as:

$$E_g(T) = E_g(0) - \alpha \frac{T^2}{T+\beta}, \qquad (4)$$

Where $E_g(T)$ is the band gap at a given temperature T, $E_g(0)$ the gap at absolute zero, α and β are Varshni fitting parameters. The best fitting for the temperature dependence of band gap was obtained with: α= 0.49 meV K^{-1}, β= 323 K and $E_g(0)$= 851 meV. These values are consistent with the reported ones in Ref. [20] of Γ−Γ PL peak energies Varshni fitting.

In order to explain the effect of temperature on the band gap in semi-conductors, Ünlü et al. [22] proposed a thermodynamic model and demonstrate that, the observed behavior is due to the thermal energy and the expansion of the lattice constant with temperature, which cause an increase in the inter-atomic spacing and the potential seen by electrons decreases, leading to a smaller band gap.

In the Fig. 3, the calculated cut-off wavelength is given by:

$$\lambda(nm) = \frac{1240}{E_g(eV)}, \qquad (5)$$

In the investigated temperature range of 1.7 K to 300 K, 1.46 μm ≤ λ_c ≤ 1.59 μm, this is located in the short infrared region.

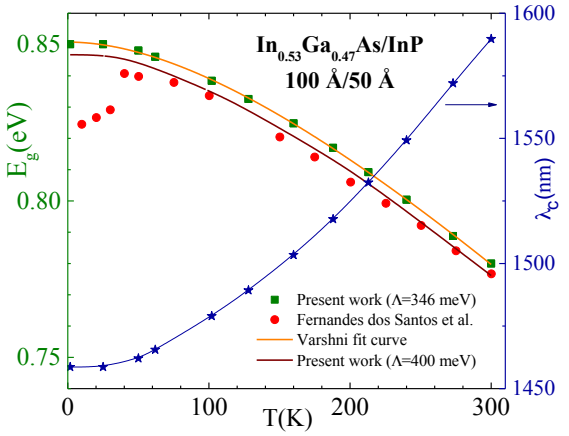

Figure 3: Superlattice band gap Energy and cut-off wavelength λ_c versus temperature.

The Fig. 4a shows the computed band structures from the dispersion relation (Eq. 1). We can see that, the electronic states are quantized and the dispersion $E(k_z)$ along the growth axis, is small compared to the in-plane dispersion $E(k_p)$. This show that, the system's wells are weakly coupled. Consequently, electronic transport is dominated in-plane of this superlattice (InGaAs layers). In addition, for E< 35 meV the heavy holes mini-bands (hh_i) dominate the edge of the valence band.

Carrier's effective mass of the first conduction and valence mini-bands for the in-plane motion and along growth direction are shown in Fig. 4b. The latter, is derived from Fig. 4a, by using following expression:

$$\left(\frac{1}{m^*}\right)_{ij} = \frac{1}{\hbar^2}\frac{\partial^2 E_{k_{ij}}}{\partial k_i \partial k_j}, \qquad (6)$$

Along k_p, effective masses of heavy holes and electrons are almost constant and equal to -0.47m_0 and 0.114m_0, respectively. For light holes it decreases from -0.07m_0 at the center to -0.09m_0 at the limit k_p= -0.03 $Å^{-1}$. The corresponding electron $(m^*_{E1})_{EF}$, light hole $(m^*_{lh1})_{EF}$ and heavy hole $(m^*_{hh1})_{EF}$ effective masses are 0.093m_0, -0.079m_0 and -0.47m_0, respectively.

3.2. Fermi level and density of states

In order to estimate the Fermi level, we used the magneto-resistance measurements of Pusep et al. [8]. It is well known that the transverse magnetoresistance oscillations are periodic with respect to 1/B at very low temperatures and under high magnetic fields. The electron sheet density n_{2D} is related to the period $\Delta_{1/B}$ by:

$$n_{2D} = \left|e/\left(\pi\hbar\Delta_{1/B}\right)\right|, \qquad (7)$$

Thus, the inverse of the minima $1/B_{min}$ as a function of the entire N, Landau level index, follows this expression:

$$1/B_{min} = \Delta_{1/B}\left(N + 1/2\right), \qquad (8)$$

The slope evaluated from the linear line is $\Delta_{1/B}$= 0.11 T^{-1} and

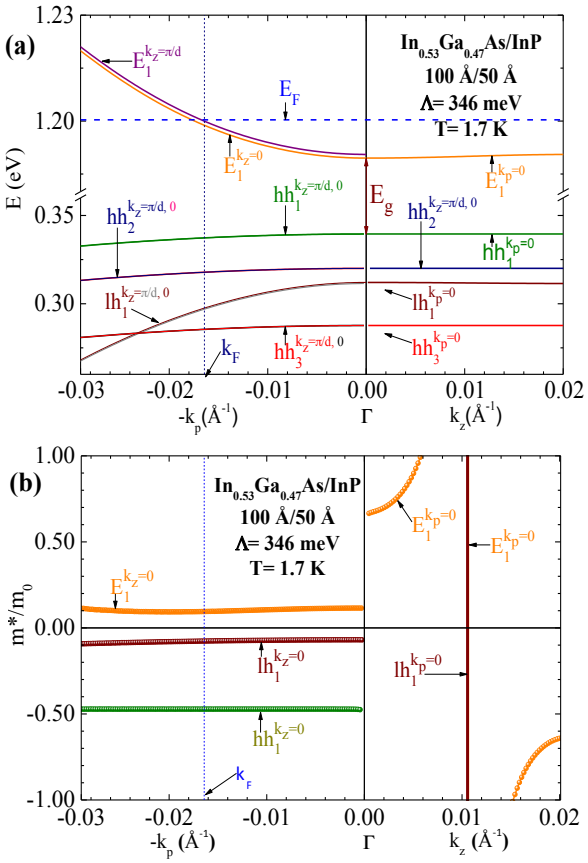

Figure 4: (a) Band structures of the investigated superlattice along the growth direction (k_z) and in-plane (k_p) (b) Carrier's effective mass ratio of the first conduction and valence mini-bands with m_0 the mass of the free electron.

the electron concentration is n_{2D}= 4.3 10^{11} cm^{-2}.

The two dimensional electron gas Fermi wave vector k_F can be calculated with: $k_F^2 = 2\pi\, n_{2D}$. Thus, $|k_F|$= 0.0164 Å^{-1} as indicated in Fig. 4a and b, by vertical dashed line.

At low temperature, the Fermi level is given by:

$$\left|E_F - E_c\right| = \left|e\hbar / \left(m^*_{E_1}\Delta_{1/B}\right)\right| = \left|n_{2D}\pi\hbar^2 / \left(m^*_{E_1}\right)_{E_F}\right|, \qquad (9)$$

Since the edge of conduction band is E_c=1.189 eV, the position of Fermi level E_F= 1.200 eV shows that the studied sample exhibits n type conductivity.

The superlattice density of states (DOS) of ith mini-band with a finite mini-band energy width $\Delta E^{(i)} = E^{(i)}_{max} - E^{(i)}_{min}$, is given by [23]:

$$\rho^{(i)}_{DOS}(E) = \begin{cases} 0 & for \quad E^{(i)}_{min} > E > E^{(i)}_{max} \\ \left(m^*/\pi^2\hbar^2\right)k_z(E) & otherwise \end{cases}, \qquad (10)$$

The sum over all mini-bands of the superlattice can be expressed as:

$$\rho_{DOS}(E) = \sum_{i=1}^{n} \rho^{(i)}_{DOS}(E), \qquad (11)$$

In the Fig. 5, we have computed DOS of the two lowest conduction mini-bands of $In_{0.53}Ga_{0.47}As/InP$ superlattices with the same well thickness (d_1= 100 Å) and different barrier thicknesses d_2= 50 Å and 150 Å. For curve A, only the first conduction mini-band is occupied ($E \le E_F$) and the DOS is quantized in term of $m^*/\pi\hbar^2 d$. Note that, for d_2= 50 Å, the system is quasi two dimensional and very small k_z dispersion occurs. However, as d_2= 150 Å, the mini-bands become discrete states and DOS is a staircase like function (curve B). Therefore, the quantum wells are decoupled from each other and the electrons motion is completely two-dimensional. In the same figure 5, we show $In_{0.53}Ga_{0.47}As$ bulk density of states (curve C), with parabolic shape, which can be obtained from formula 10 with $k_z(E) = (2m^*E)^{1/2}/\hbar$. It is noteworthy that, when the barrier thickness decreases, the superlattice ρ_{DOS} curve becomes higher and approaches to that of bulk material.

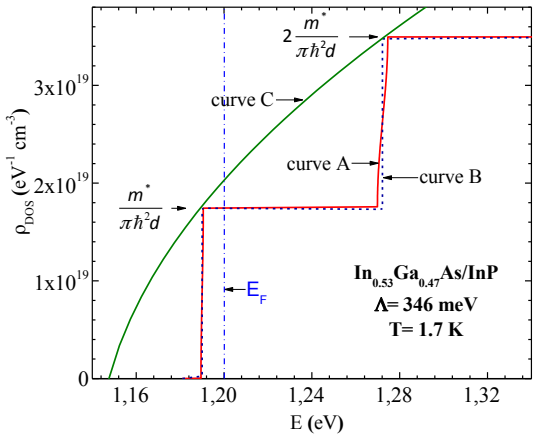

Figure 5: Density of states versus mini-bands energy of $In_{0.53}Ga_{0.47}As/InP$ superlattices with d_1= 100 Å, d_2=50 Å (curve A) and d_2=150 Å (curve B). The parabolic curve C represents $In_{0.53}Ga_{0.47}As$ bulk density of states.

3.3. Quantization of energy and density of states under magnetic field

In the presence of an external magnetic field along the growth axis z, a quantization of DOS in-plane energy spectrum takes place. The quantum states, in the first Brillouin zone, are distributed to distinct sets of Landau mini-bands as represented in Fig. 6a, c and e. The expression of the total energy $E^{(i)}$ of the ith miniband is given by:

$$E^{(i)} = E^{(i)}(k_z) + \left(N^{(i)} + 1/2\right)\hbar\omega_c + E^{(i)}_{Zeeman}, \qquad (12)$$

Where $E^{(i)}(k_z)$ is the carriers charge energy associated with z-motion which remain unaffected and can be obtained from the dispersion relations discussed above. The in-plane carrier's motion energy is completely quantized in terms of $(N^{(i)}+1/2)\hbar\omega_c$ with $N^{(i)}$ the Landau index of ith miniband. In the case of this sample we can assume, that Zeeman spin splitting energy $E_{Zeeman} = \pm\, g^*\mu_B B/2$ is negligible compared to Landau mini-band splitting $\hbar\omega_c = \hbar eB/m^*$.

In an ideal two dimensional systems with no impurities

or other defects, the quantization of DOS can be described as a set of δ functions separated by cyclotron energy $\hbar\omega_c$, and can be written as [24]:

$$\rho_{DOS}^{2D}(E,B) = \frac{|e|B}{\hbar}\sum_i\sum_{N^{(i)}}\delta\left(E - E^{(i)}\right), \qquad (13)$$

The resulting curves, at different magnetic field, are represented in Fig. 6. We can see that the spacing between two adjacent Landau mini-bands increases (Fig. 6a, c and e) and DOS (Fig. 6b, d and f) increases with the magnetic field. It's known that, the highest occupied quantum state corresponds to Fermi level. Thus, when each Landau mini-band pass through Fermi level (Fig. 6c and d) it depopulates and the electrons become free to flow as current, resulting to minima in the longitudinal magnetoresistance R_{xx} and a plateau in the transverse magnetoresistance R_{xy}.

3.4. Interpretation of SDH and QHE

Under high magnetic field, only the ground Landau mini-band with $N^{(1)}= 0$ is populated, as shown on Fig. 6a and Fig. 7. Therefore, when the intensity of magnetic field varies, the number of occupied states changes with B, since the degeneracy of each Landau mini-band, given by $|e|B/h$, changes with B. This will lead to an oscillatory behavior of magnetoresistance known as the Shubnikov-de Haas effect. Such oscillations and quantum Hall effect can be observed only if distinct landau mini-bands exist, which implies that, the mini-band width should be less than the Landau mini-bands spacing $\Delta E^{(i)}<\hbar\omega_c$. According to our calculation for B≤1.2 T, both of SDH and QHE are no longer observed, since all energies above $E^{(1)}_{center}+(1/2)\hbar\omega_c$ are permitted (continuous energy spectrum) as can be seen in Fig. 6e and f. The latter show the limit between classical Hall and quantum Hall effects. These results are in good agreement with the experimental measurements of Pusep et al. [8].

The effect of high magnetic field on band structures and Fermi level is shown in Fig. 7. These results are obtained by using the in-plane wave vectors quantification rule of superlattice given by: $k_p^2= (2N^{(i)}+1)(eB/\hbar)$.

We have calculated the Fermi level energy as a function of B, by using the following formula:

$$n_{2D} = \int_0^{+\infty}\rho_{DOS}^{2D}(E,B)f(E)dE, \qquad (14)$$

with f(E)=1/(1+exp(E-E_F/k_BT)) the Fermi-Dirac distribution.

Table 1. Comparison between experimental observations (ref.[8]) and the calculated magnetic field of R_{xx} minima and maxima, labeled here by B_{min} and B_{max}, respectively.

B_{min}(T)		B_{max}(T)	
Experimental (ref.[8])	Theoretical	Experimental (ref.[8])	Theoretical
7.4	7	5.4	5.1
4	3.9	3.2	3.3
2.6	2.7	2.3	2.4
2	2.1	1.8	1.9

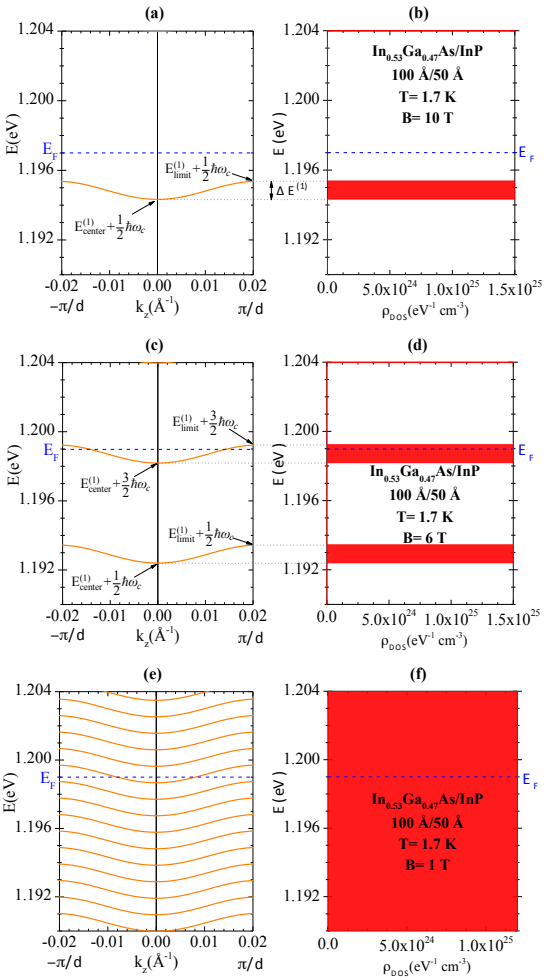

Figure 6: (a), (c) and (e) Quantification of the 1st conduction mini-band (E_1) into Landau mini-bands in first Brillouin zone. (b), (d) and (f) Total energy versus density of states.

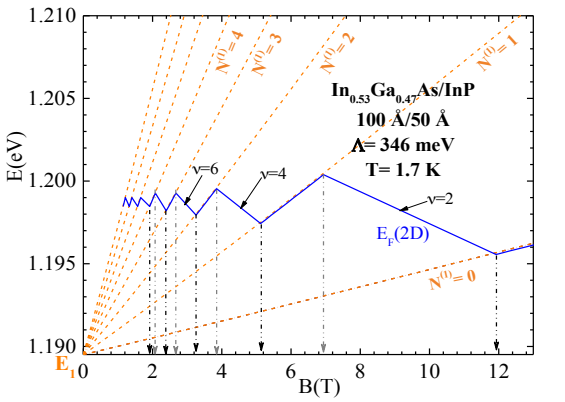

Figure 7: Energy of the conduction Landau mini-bands as a function of magnetic field. The position of Fermi level is also shown. The labeled arrows ν denote the Landau mini-bands filling factors.

with $f(E)=1/(1+\exp(E-E_F/k_BT))$ the Fermi-Dirac distribution. We can notice in the Fig. 7 that, Landau mini-bands energies increase linearly with B. The crossovers between the calculated Landau mini-bands (for $N^{(1)}= 1$ to 4) and Fermi level indicate, almost the same magnetic field of the longitudinal magnetoresistance extrema observed in ref. [8], up to 10 T, as shown in table 1. Note that, under high magnetic fields the peaks in the Shubnikov-de Haas oscillations (R_{xx} maxima) occur at the jumps in the transverse magnetoresistance R_{xy} of quantum Hall effect and each minima of R_{xx} corresponds to a plateau in R_{xy}.

4. Conclusions

In this work, we investigated the band structures properties of $In_{0.53}Ga_{0.47}As/InP$ superlattice, within the envelope function formalism and effective mass approximation. The band gap E_g and mini-bands width decrease and tend to discrete levels of a quantum well when well thickness d_1 increases. We have discussed the supposition of Pusep et al on the effect of valence band offset on the band gap. The computed DOS shows that the system is quasi two dimensional with small k_z dispersion. In addition, the dispersion curves and effective mass m^*/m_0 in the direction of growth and in the plane of this superlattice, show that, the first conduction and valence mini-bands are parabolic and the quasi-two dimensional electron gas effective mass is $0.093m_0$ at 1.7K. The calculated Fermi level of 1.2eV indicates n type conductivity in this sample.

In the presence of quantizing magnetic field, the spacing between Landau mini-bands increases with B and demonstrate the presence of SDH and QHE. According to our calculations both the two effects can be observed only if B> 1.2T. We have interpreted the oscillations of longitudinal magnetoresistance R_{xx} in SDH and R_{xy} in QHE observed by Pusep et al. These results can be used as a guide for the design of $In_xGa_{1-x}As/InP$ nanostructured short infrared detectors.

Abstract- We show that nonreciprocal light propagation occurs following an adiabatic evolution of the parametric path that encircles an exceptional point. Moreover, a device architecture for the nonreciprocal transmission over a broad spectral range is presented. The device is designed for chip-scale operation, and therefore can be applied to a wide range of integration-compatible active photonic devices.

Optical isolators and circulators are important elements that are required in optical signal processing, telecommunications, and for the protection of ultra-short pulsed laser systems. Traditionally, magneto-optic crystals exploiting the Faraday Effect are used to implement efficient nonreciprocal elements in free-space systems. However, realizing on-chip magneto-optic devices integrated with other photonic functions has remained elusive. Different approaches to realize the on-chip nonreciprocal devices suitable with integration have been proposed, including exploiting indirect photonic transitions mediated by dynamic index modulation [1] and nonlinear resonance shifts in asymmetric high-Q microcavities [2]. Such approaches have led to significant nonreciprocal transmission within a chip-scale device footprint, however, other performance limitations such as a high signal power threshold for operation, a low forward-transmission efficiency, and a narrow bandwidth have limited their applications. These limitations should be compensated or eliminated to process broadband signals (including modulation), to respect tight energy-conservation constraints imposed by applications and for stable operation in ambient conditions involving moderate temperature drifts.

Here, we propose a nonlinear coupled-waveguide device which is integration-compatible and nonreciprocal over a broad spectral range. The structure is designed to follow the parametric path that encircles an exceptional point (EP) during the evolution of its non-Hermitian Hamiltonian. Nonreciprocal transmission is achieved due to the non-adiabatic transition during the eigenstate propagation along the path [3]. The parametric path can be built into the coupled waveguide structure by generating the required complex-index distribution along the propagation axis as shown in Fig. 1(a). To realize this in photonic systems, we briefly introduce a lithographic approach to generate the required complex effective-index profile which encircles an EP.

The approach is illustrated in Fig. 1(b). The unidirectional mode converter region consists of two coupled-channel waveguides with an adjacent side patch. In this design, the real effective index profile is created by a z-dependent waveguide-core width, while the imaginary effective index profiles are created via the z-dependent gap-width between the waveguide core and side patch. As represented in Fig. 1(c), the instantaneous eigenvalue diagram of designed unidirectional convertor shows that the two eigenstates

interchange during the parametric evolution. However, as numerically simulated in Fig. 1(d), the eigenstates are uni-directionally converted due to the non-adiabatic transition during propagation following the designed path, which induces nonreciprocity (and isolation) in the device.

We will present theoretical and numerical details for the device architectures and background theories with some experimental results that confirm the proposed nonreciprocal functionalities.

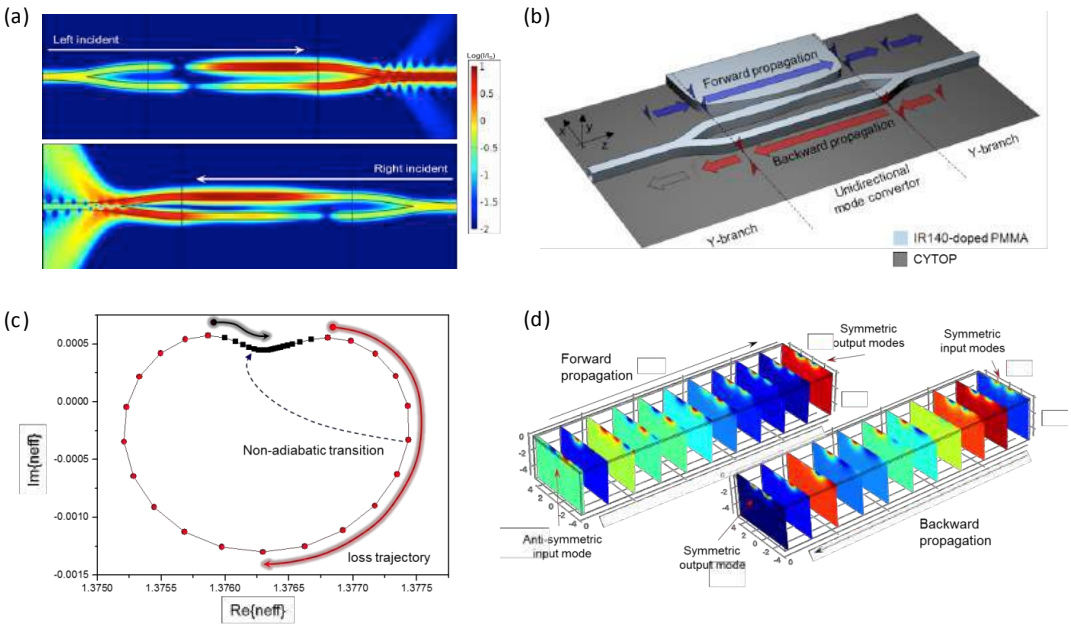

Figure 1. (a) Numerical simulation of nonreciprocity in coupled waveguide system. (b) Schematic illustration of optical isolator with unidirectional mode convertor. (c) Instantaneous eigenvalue diagram for the non-Hermitian path. (d) Unidirectional mode conversion during adiabatic propagation following non-Hermitian path which encircles an exceptional point.

Anti-parity-time symmetry
in optical waveguide and electric circuit structures

Youngsun Choi, Choloong Hahn, Jae Woong Yoon, Seok Ho Song*

Abstract- We demonstrate a spontaneous symmetry breaking and power-difference-conserving light propagation in the anti-parity-time symmetric optical waveguide structures. These optical properties are experimentally realized in the equivalent electric circuit analogy.

Recently, parity-time (PT) symmetric optical systems have been attracted considerable attention due to their unique properties such as unidirectional reflection and nonreciprocal transmission. The anti-PT (APT) symmetry, as a counter part of the PT-symmetry, is expected to exhibit its own unique characteristics. However, experimentally implementing or theoretically designing APT-symmetric optical system is challenging since a strictly APT-symmetric index distribution requires negative index material (NIM) in general [1]. Here we demonstrate an NIM-free optical APT-symmetry and its experimental circuit analogy. In this demonstration, a spontaneous APT-symmetry breaking and anomalous light propagation characteristics are investigated in detail.

To avoid the demand of NIM, which might be an obstacle to experimental implementation, the proposed system is designed to have an APT-symmetric effective Hamiltonian based on all-positive-index materials as shown in Fig. 1(a). The proposed system consists of two gain-guiding waveguides with different core indices. The real refractive index distribution is asymmetric whereas the imaginary refractive index distribution is symmetric. The difference between real parts of core indices is used as a control parameter while imaginary index distributions are maintained.

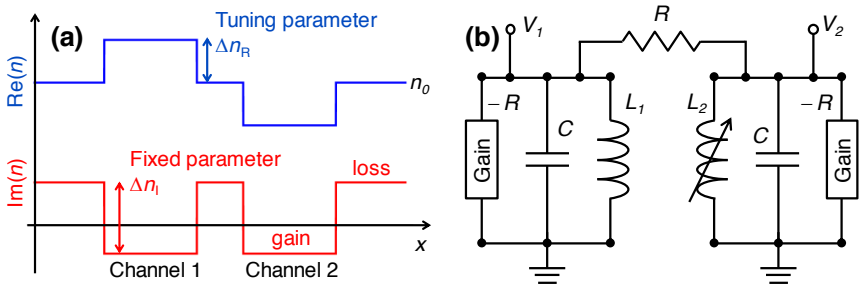

Figure 1. (a) Real and imaginary index distribution in APT-symmetric waveguide coupler. (b) Schematic of APT-symmetric coupled LC-resonators.

In the proposed system, the spontaneous APT-symmetry breaking is manifested as a branch point in the parametric eigenvalue spectrum as shown in Figs. 2(a) and 2(b). The power–difference-conserving light propagations in Figs. 2(c) ~ 2(f) are presented as unique properties that does not appear in the PT symmetric systems. These anomalous dynamics are experimentally investigated with equivalent circuit analogy using two coupled LC-resonators as shown in Fig. 1(b). Taking advantages of the low signal frequency, time-domain measurements are performed with high temporal resolution.

The APT-symmetry may provide opportunities to obtain novel optical properties unattainable in conventional Hermitian or PT-symmetric optical systems.

Quantum states and transport in *PT*-symmetric quasi-one-dimensional lattices

Jung-Wan Ryu[1*], **Nojoon Myoung**[1], **and Hee Chul Park**[1]

Abstract-We study quantum transport in *PT*-symmetric quasi-one-dimensional lattices in which complex band structures appear. Quantum transport in the lattice is measured only in the unbroken *PT*-symmetric phases in the energy band but not in the broken *PT*-symmetric phases. We devise a mechanism for reconfiguration of quantum states that is related to *PT*-phase transition between regions of broken and unbroken *PT*-symmetry.

Non-Hermitian properties in open systems with energy gain and loss has attracted great interest in both theoretical and experimental studies [1]. While we consider a physical system to be isolated, interactions with the environment strongly influence the physical properties of quantum and classical systems by breaking both energy and flux conservation. From a mathematical viewpoint, these open systems can be described by non-Hermitian formalism, with closed ones by Hermitian formalism. In non-Hermitian systems, a potential with a positive imaginary part describes a system that receives energy from its environment but a potential with a negative imaginary part describes a system that loses energy to its environment. Among non-Hermitian systems, parity-time (*PT*)-symmetric systems have the condition that loss and gain are exactly balanced [2]. The *PT*-symmetric systems exhibit a transition from an unbroken *PT*-symmetric phase to a broken phase via exceptional points. While the unbroken phase contains normal dispersive states with real eigenenergies, the broken phase allows for spontaneous symmetry breaking in the eigenstates with complex energies.

In this work, we demonstrate that a bandgap is realized in *PT*-symmetric quasi-one-dimensional lattices by quantum measurement through external leads. The bandgap is shown to be controlled by external parameters such as energy gain and loss, but not by inherent properties such as geometric shape or defects. As a result, we devise a mechanism for reconfiguration of quantum states that is related to *PT*-phase transition between regions of broken and unbroken *PT*-symmetry.

Abstract- A freestanding resonator based on a natural organic polymer for flexible and biocompatible nano-optics is reported. The device has metal-insulator-metal (M-I-M) structure, which demonstrates perfect absorber and color filter. A facile lithography-free fabrication method based on solution-assisted process and a biocompatible material facilitate the realization of a cost-effective and environmentally benign large-area super absorber. The proposed resonant optical device exhibits a narrow bandwidth absorber with absorption near unity and equivalent functionalities with nano-patterned super absorbers.

Utilization of light at subwavelength with extraordinary optical properties is achieved by nanophotonic materials.[1, 2] Particularly, supernatural transmission and absorption filters based on localized/delocalized resonances have been triumphed by plasmonic metamaterials.[3] However, attainment of large area superior optical filters built on nanoplasmonics under visible wavelength is defying because of high-cost lithography techniques and deficiencies of nanofabrication.[4] We report a planar optical resonator built on a Fabry-Perot (FP) etalon with a lithography-less fabrication[5] process, which is extremely cost-effective.

Multi-layered optical devices have earned research attentions owing to their unique performance and lucrative fabrication in employing of light. The conventional planar resonators encounter deficiencies in sensing abilities due to the inconvenient impact of analytes on the physical variables of the insulator film.[5] We exploited the advantage of a natural biomaterial (NBM) as a bio-inspired material to fabricate an optical device with M-I-M structure, which is capable of being utilized in bio-sensing.

We employ NBM as insulator layer or spacer of the suggested device with biocompatibility, non-toxicity, and biodegradability. The utilized NBM offers exceptional features of the homogeneity, transparency, and hydrogel properties, which makes it a proper material for an absorber and color filter. Through reaction of the insulator thin film with humidified environment, it tunes the resonance wavelengths by swelling. The proposed NBM is sandwiched between two Ag layers, while the substrate is made of NBM (Figure 1a). The NBM, which serves as insulator layer or the spacer of the color filter reacts with the environmental liquids (water) and swells (Figure 1b, c). The resonance mode is altered due to a shift of refractive index (RI) causing an increase in the volume of the spacer.[5] The FP resonances can get tuned by liquid absorption of NBM spacer. During the experiment and measurement, the amount of swelling is governed by changing the liquid type and its pH.

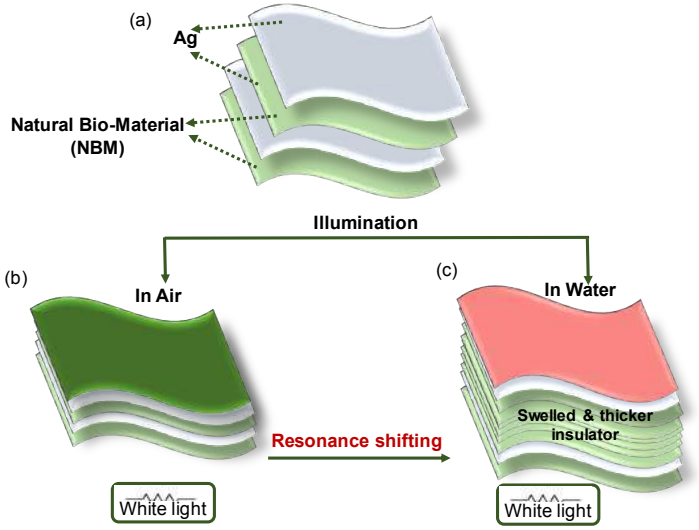

Figure 1. (a) Schematic illustration of a freestanding color filter with M-I-M structure; a natural biomaterial (NBM) is sandwiched between two Ag layers. (b, c) Illumination of the device under white light in air and water, respectively.

In summary, we fabricated and characterized a freestanding perfect absorber and color filter based on NBMs with a facile lithography-less method. Our suggested super absorber shows similar properties of nanostructured plasmonic materials.

Abstract- To detect miRNA-106a, the promising biomarker for gastric cancer, we demonstrate colorimetric sensing platform based on plasmon coupling effect. The on-chip platform with core-satellite structure is made by conjugation of complementary oligonucleotides between target miRNA-106a and probes which are pre-functionalized on gold nanoparticles, thus enabling to observe the scattering color changes and spectral shift.

1. INTRODUCTION

Although gastric cancer is the second most common cause of cancer-related deaths in the world, early stage detection is still lacking due to the inherent property of cancer cells that are initially small in size and asymptomatic. Thus, early stage detection and prognosis monitoring are very important to avoid the death from later stage presentation of gastric cancer.[1] Current practice for screening gastric cancer completely relies on the endoscopy, however, it is difficult for many people to access endoscopic instruments and expertise for proper screening.

In this paper, we demonstrate an on-chip colorimetric biosensing platform of miR-106a based on the principles of localized surface plasmon resonance (LSPR). The LSPR occurs when the metallic nano particles interact with incident light inducing collective oscillation of conduction electrons on the surface of metallic nanostructure.[2] It can be tuned by the size, shape, materials, and also the plasmon coupling with a nanoscale gap between the particles. When the metallic nanoparticles are sufficiently adjacent to each other, the near-field interaction leads to plasmon oscillations in the particles. This plasmon coupling among the gold nanoparticles (AuNPs) enables our sensing platform.[3, 4]

2. RESULT AND DISCUSSION

In advance of development of the sensing platform, the density of core AuNPs in the detection area needs to be controlled by optimizing the mixing ratio of APTES to OTMS. When the concentration of the APTES is high in a mixing solution with the ratio ranging from 1:0 to 5:1, agglomerated nanoparticles are made so that the bound core AuNPs present a red color. When the concentration of the mixing solution ranges from 3:1 to 3:2, the bound particles show green color. When the concentration is ranging from 1:1 to 0:1, the core AuNPs are not bound to the modified substrate. To observe the colorimetric change and spectral shift clearly, we choose APTES/OTMS mixing ratio of 3:1. By using this mixing solution, we made the substrate with maximum spectral intensity near 550 nm wavelength.

To verify the attachment of nanoparticles via complementary sequence, we have investigated the change in the nanostructure by scanning electron microscopy images (SEM) as shown in Figure 1 (a) and (b). The single AuNPs with 50 nm in diameter are uniformly distributed without the agglomeration (Figure 1 (a)). When the miR-106a is attached, the core-satellite assemblies are made (Figure 1 (b)). These nanoscale assemblies lead to the colorimetric

change, thus enabling the detection of miRNA corresponding to the miRNA concentration. The colorimetric changes are shown in Figure 1 (c) with spectral change and in Figure 1 (d)-(e) with dark-field microscopy. Figure 1 (c) shows the detection of miR-106a by measuring the spectral response from the hybridized core-satellite AuNPs. The single core AuNPs show the green colour (Figure 1 (d)) while the scattering spectrum is red shifted with the formation of core-satellite nanostructure assembly when the 10 μM concentration of miR-106a is applied (Figure 1 (e)).

3. CONCLUSION

In summary, the sensing platform we demonstrated here provides a novel approach of colorimetric detection of miR-106a to use for the early diagnosis of gastric cancer with a potential for clinical application. To make on-chip detection platform, we modified the glass substrate with mixed layer composed of APTES and OTMS to achieve a proper density of core AuNPs. On the modified substrate, we confirm the colorimetric change with the spectral shift of 28.33 nm wavelength for 10 μM concentration of miR-106a. This study proposes the sensing platform for a point of care diagnostics for miR-106a, a potential biomarker for gastric cancer.

[4]School of Life Sciences, University of Birmingham, UK

Abstract- *Synthetic biology is a new and emerging field. Utilizing mechanisms found in nature we can reach solutions to problems such as; ‘cloaking’ devices, not currently found within the reaches of traditional science.* [1] *Exploiting the intrinsic nature of M13, a filamentous bacteriophage, to self-assemble we have achieved tuneable 3D nanoarchitectures. Such structures have demonstrated interesting optical characteristics, where a strong non-linear dependence of light induces a resonance shift in the reflected light, and therefore the colour witnessed by you and I.*

Learning from biological processes such as self-assembly can subsequently allow us to contribute to them, from which we can produce endless possibilities in a multitude of applications; from super-lenses to cloaking devices. Taking the principal of the invisibility cloak from ‘Harry Potter’ and translating the idea into real world optical devices *i.e.* through the production of optical metamaterials, is not totally out of reach. Optically interesting materials can be achieved *via* the interaction of nanoparticles with a biomolecule surface. Harvesting the inherent self-assembly nature of biological molecules allows us to develop novel 3D structures capable of displaying metamaterial and/or photonic characteristics. [2]

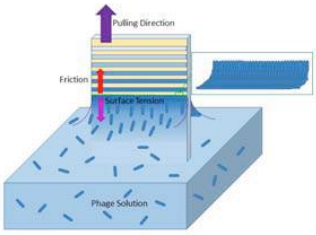

Figure 1. Templating procedure employed to achieve a tuneable 3D scaffold at the air/liquid/solid interface. The scaffold is produced as a result of opposing surface tension and friction forces to create a meniscus at the interface. Templating of M13 (phage) within the solution to the substrate is produced perpendicular to the director axis.

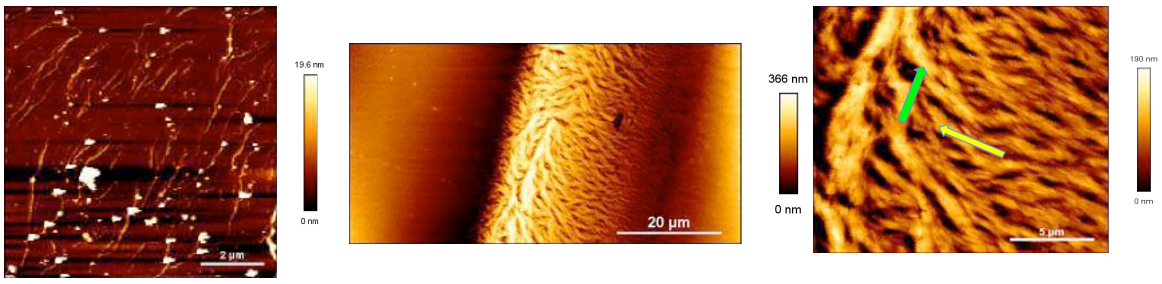
We have utilized the filamentous nature and high aspect ratio of M13 as a scaffold. It’s propensity to self-assemble at the air/liquid/solid interface has been initially set out by Chung et.al. [2] Producing a modified system, we have achieved a tuneable scaffold (Figure 2 and 3).



A **B** **C**

Figure 2. Atomic Force Microscopy imaging of M13 phage at 0.01 mg/mL drop casted onto an Au coated silicon (Si) wafer and dried under air (A). 3 mg/mL M13 phage templated at 100 µm/min of vertical shear (B) and a further image at a smaller section of B (C). C demonstrates the ability of M13 to hierarchically self-assemble under suitable conditions.

The tunability of the structure has strong dependence on both the concentration of M13 within the templating solution and speed at which vertical shear onto a substrate is employed (Figure 2). The produced surfaces are able to interfere with visible light to demonstrate non-linear angle dependence, with linearly polarized light when sputter coated with gold (Figure 3) and circularly polarized light when gold (Au) is electrolessly deposited thr

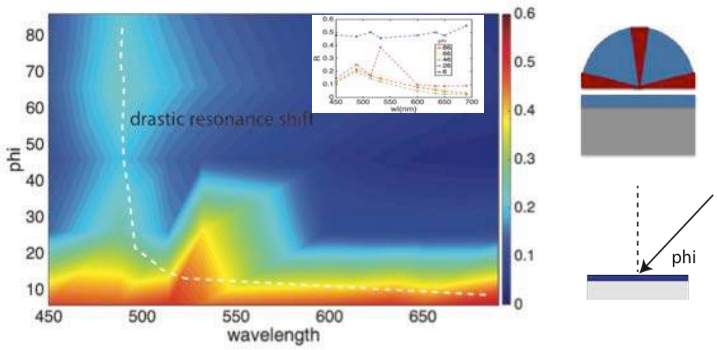


Figure 3. Left, x-polarized light transmitted through a sample of M13 (sputter coated with Au) templated at high speed to yield a densely packed array of ridges and grooves. Inset, the corresponding reflectance data plot. Right, colour respective naked-eye view of the sample.

Abstract- Control of near-field waves is the key to going beyond the diffraction limit in imaging and manipulating target objects. We present the focusing of plasmonic waves, a type of near-field waves, by the wavefront shaping of far-field waves. We coupled far-field waves to a random array of nanoholes on a thin gold film to generate speckled plasmonic waves. By measuring the far-field to near-field transmission matrix and shaping of the far-field wave, we demonstrated the focusing of plasmonic waves at arbitrary position of gold film surface.

Abstract-We present a nanoscopic investigation of optical modes near plasma frequency of a highly doped semiconductor structure. With a phase sensitive mid-IR s-SNOM [1], we have imaged the complex field distribution of localized surface plasmonic resonators and we have obtained near-field optical amplitude and phase spectrum containing precise information on the dieletric function of the sample, in agreement with simulations. Moreover, our finding corroborates a formal link between Local Density of Optical States and the phase information scattered by a local emitter.

Highly doped InAsSb is an exciting material exhibiting metallic behavior with a plasma frequency ranging from THz to midIR (up 5.5µm) depending on the doping level. Therefore it offers quite unique perspectives for infrared plasmonic devices, notably to create intense Localized Surface Plasmon Resonance (LSPR) for sensing application in the Infrared range, where specificity can be provided by spectroscopic measurement [2].

In our work, a homemade mid-IR scanning near-field microscopy is used to investigate the localized plasmonic modes of submicronic InAsSb ribbon that is 700nm wide and 100nm high. The phase sensitive images reveal the presence of an ultra confined mode on the edge of the ribbon that is confirmed by electromagnetic simulations, shown in figure 1(b). Using the same tool we investigate the peculiar nature of the signal scattered by the probe (a nano-antenna) in the vicinity of the plasma frequency where the permittivity approaches zero, shown in figure 1(d). Finally, we make a link between the obtained phase near-field spectrum and the expected LDOS spectrum.

Abstract-In this paper the dependence of the full-width at half-maximun (FWHM) of the terajet from the polarization of the incident light (TE-TM), from the orientation of the structure (two different cross-sections of the composite) is performed. S-parameters and Ey, Hz intensity distributions for TE- and TM-polarized wave was obtained in the COMSOL Multiphysics Software.

In some cases radiation propagating through a microparticle can focus into a narrow, high-intensity electromagnetic beam that continue it's way into the background medium from the shadow-side surface of a plane-wave illuminated lossless dielectric microparticle of a size greater than the illuminating wavelength, λ. This beam can maintain a subwavelength full-width at half-maximun (FWHM) transverse beam width smaller than the classical diffraction limit. It was called «photonic nanojet (PNj)», or simply «nanojet» [1.2]. Due to it's peculiarities nanojet has very promosing applications. Microparticles combined in linear chains close to each other can work as an optical waveguide [3] and assembled in a planar array put on top of a photoresist in a single layer suggests us a maskless subwavelength-resolution direct-write nanopatterning technique [4]. Giant backscattering perturbation phenomenon of PNj allows us to detect and size nanoparticles as small as a few nanometers, that is essential in various biophotonics applications [5-6].

Jet generated in THz frequency range is called «terajet» [7]. In this paper incident wave propagating through the dielectric periodical artificial structure in the shape of the parallelepiped formed a terajet [8]. The structure is perforated. The waist of the terajet (FWHM) was evaluated in COMSOL Multiphysics software using the Finite Element Method (FEM). The value of this parameter defined whether the classical diffraction limit (λ/2) was overcome or not. This parameter depends on: the polarization of the incident wave (TE, TM), the orientation of the structure (in one cross-section the incident light illuminates a rectangle with circle holes and in another one - an alternating layered structure), the permittivity of the photopolymer (ABS $\varepsilon = 2.47$, PLA $\varepsilon = 3.57$, Visijet $\varepsilon = 2.76$) and the permittivity of the 2nd component of the composite (it was air in this case), the period of the holes. The last three items could be united in one parameter – effective permittivity in terms of the effective medium theory. The ratio between this parameter and the range of frequency was obtained – dispersion relations. Devices based on the effect of the terajet could find applications in biological visualization or terahertz microscopy.

Abstract-We introduce a far field label-free SR methodology that is based on the nonlinear reflectance changes induced by photo-modulation. Following an ultra-short pump pulse, an overlapping delayed probe pulse monitors the nonlinear reflectance changes. Spatial resolution within the diffraction limited spot is enhanced as the square root of the nonlinearity order. The method is compatible with semiconductors and metals, in vacuum and air, ultrathin and thick samples alike. Examples of resolution enhancement in several materials (<90nm) are demonstrated.

Far-field super-resolution (SR) microscopy has developed to be an important tool in life sciences. However, it relies on, and therefore is limited by the ability to control the fluorescence of label molecules or nanoparticles. While in many cases, label-free far-field microscopy is required, an equivalent SR technique is not available.

We introduce a new far field label-free SR methodology that is based on the nonlinear response of the reflectance to photo-modulation [1-3]. It relies on the ability to photo-excite a temperature and/or charge-carriers spatial distribution inside the diffraction limited spot by an ultra-short pump pulse. In Nonlinear photo-modulated Reflectivity (NPMR) an overlapping delayed probe pulse monitors the nonlinear reflectance changes. By scanning over the sample and measuring the NPMR, spatial resolution is enhanced. NPMR is measured by recording the high harmonics in the probe laser reflectance. The improvement in resolution scales like $\sqrt{n}$, where n is the nonlinearity order.

In order to achieve a reliable response in high harmonics, pure sine modulation is required. By using an acouto-optic modulator coupled to an arbitrary wave-form generator, we have succeeded in modulating our pump source with harmonic impurity down to 10^{-4}.

Examples of resolution enhancement due to nonlinearities are presented: The change of thermo-reflectance of VO_2 upon its characteristic insulator-to-metal transition, the heating process of a nanostructured silicon or gold surfaces, and the nonlinear response of photo-modulated Raman spectra. Super-resolution down to 85nm is demonstrated with a probe laser of 800nm wavelength. NPMR is suitable to characterize semiconductors and metals in vacuum, ambient, and liquid, semi-transparent and opaque systems, ultrathin and thick samples alike.

Abstract-Realizing an invisibility cloak has drawn great research interests since the theory of transformation optics was proposed. However, previous demonstrations of invisibility cloaks suffered from various problems due to the complex parameters required, though significant achievements have been achieved both in microwave and optical frequencies recently. Here, we propose and demonstrate a cloak based on a two-step linear transformation that works for omnidirection at microwave frequencies. This work could push the research of cloak realizations one step forward.

Rendering an object invisible has long been a fantasy of people for decades. Recently, invisibility cloak has captured wide scientific interests since the theory of transformation optics[1, 2] was proposed in 2006. Significant achievements in invisibility cloak realizations have been achieved both in microwave[3-6] and optical frequencies[7-13]. However, due to the complex parameters required, previous demonstrations still suffer from various problems such as impedance mismatch[3, 10, 11], unidirection[6, 13], single polarization[3, 10, 11], lateral shift[4, 5, 7-9, 14] and narrow bandwidth[3, 6] etc. Here we propose and demonstrate an invisibility cloak based on a two-step linear transformation that works for omnidirection at microwave frequencies. The cloak requires extremely anisotropic media with both zero and infinity which are realized by periodic metallic structures. The work could inspire the study of extremely anisotropic metamaterials and push the research of cloak realization one step forward.

Construction methods of auxetic structures with hourglass shaped units and its application to smart transformation optics

Junhyun Kim[1] and Kyoungsik Kim[2]
[1]School of Mechanical Engineering, Yonsei University, Seoul 120-749, Republic of Korea

Abstract- In this paper, we illustrate the methods of constructing structures with negative Poisson's ratio with rigid sliding units. By numerical evaluation we describe its mechanical properties and show structures exhibit auxetic behavior indeed. We discuss its future productivity and its application to smart transformation optics.

Engineers can control electromagnetic waves through coordinate transform based on invariance of Maxwell's equation [1]. While conventional transformation optics require anisotropic permittivity and permeability, in quasi-conformal mapping, electromagnetic devices require isotropic dielectric materials only [2]. Smart transformation optics regards mechanical deformation of medium as coordinate transformation [3, 4]. Using metamaterials with negative Poisson's ratio (so called auxetic behavior), smart transformation optics satisfy quasi-conformal transformation [3, 4]. Unlike normal object, structures with auxetic behavior exhibit negative Poisson's ratio [5]. In this paper, we show how we can construct auxetic structures with 'hourglass shaped units' [6]. Changing its geometrical condition, we show that the proposed structures always exhibit auxetic behavior indeed. We also derive its mechanical properties such as on axis Young's modulus to quantify its stiffness of the structure. Last we show its possibility to application to smart transformation optics as a basic material of optical medium.

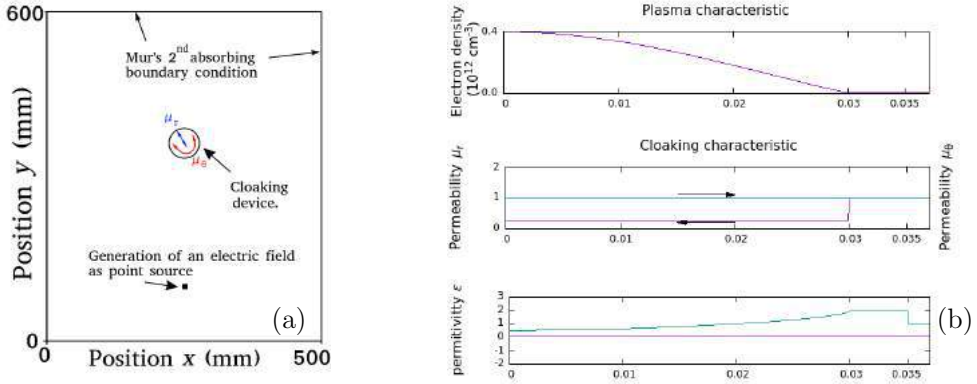
Abstract— Clocking for microwaves is investigated numerically in a model integrating plasma with anisotropic metamaterial. Realization of cloaking requires media with designed permittivity and permeability parameters. Invisibility observed in this study is based on spacial gradient of permittivity in plasma and anisotropic permeability in metamaterial. This report demonstrates our numerical results based on the finite-difference time-domain (FDTD) method. These results indicate potentials and possible advantages coming from spacial gradient of plasma permittivity with anisotropic permeability.

1. INTRODUCTION

Metamaterial has independent control of permeability μ and permittivity ϵ_p; they support all real values in arbitrary directions [1]. Characteristics of independence work as anisotropic properties and, in addition, their values can vary in space to make a gradient [8]. Anisotropie property and gradient existence are key factors for cloaking [4, 7, 8]. Alternatively, plasma can be used in a cylindrical device to change the permittivity ϵ_p, which will be shown in Figure 2(b) [8, 3]. Here we report numerical results to show an advantage about its smooth gradient for a cylindrical cloak. To find the perfect cloaking characteristic, transformation optics was used [8]; in our case the gradient has a slight mismatch between theoretical prediction from transformation optics and possible parameters of plasma. In the interest of the numerical code, we use electric and (hypothetical) magnetic currents in the Maxwell equations to include plasma and metamaterial effects on ϵ_p and permeability μ respectively. In this study, we test the size of our cloak by a numerical code integrating the requirements for cloaking. Our analysis is focused on scattering wave created by different size of cloaking.



Figures 1: (a) Schema of the numerical code, (b) characteristic use for our cloaking device.

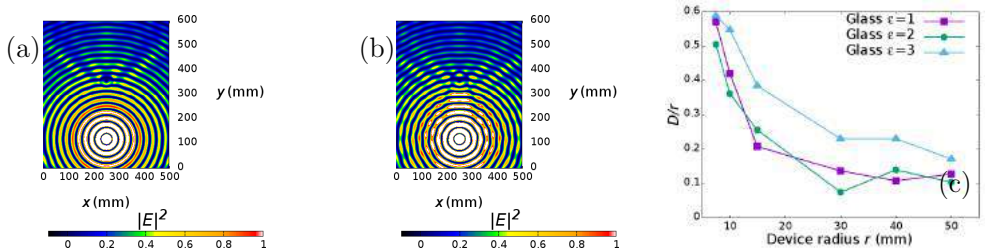
2. NUMERICAL CODE

We developed a code in the finite-difference time-domain (FDTD) method in two-dimension space (500 mm $\times$ 600 mm on the x-y plane), as show in Figure 1. A point microwave source at 6 GHz is placed at $x = 250$ mm and $y = 100$ mm. Our cloaking [4] is made around a metallic monopole placed at $x = 250$ mm and $y = 360$ mm. Integration effect of plasma with ϵ_p and metamaterial

with anisotropic μ is due to electric and magnetic current densities in the Maxwell equations [5, 6]. The time resolution for the Maxwell equations is every 0.5 ps, and the boundary of the delimited space is made of the 2nd Mur's boundary condition to have the perfect absorption boundary. We assume the plasma in a vacuum chamber composed of a dielectric container of 30-mm inner radius, and the smooth gradient of ϵ_{p} is supported by a natural profile of electron density [4], shown in a smooth gradient of permittivity in radial coordinate [2, 3]. We did not fix the permittivity of the container wall to see its impacts, like $\epsilon = 1.0$, 2.0 and 3.0.

3. LIMIT EFFECT OF THE SIZE FOR CLOAKING

Figure 2 (a) and (b) show results of power as square of electric fields at a fixed time for 60-mm- and -80-mm-diameter devices. In Figure 2 (c) we compare the cloaking size with amplitude of the scattering wave; each amplitude is devided by the radius to have calibrated values because of the mismatch between possibility from plasma and perfect cloaking. From Figure 2 (c), we note that the scattering wave is significant when the size is comparable with about quarter of the wavelength in all values of dielectric permittivity $\epsilon_{\mathrm{p}} = 1.0$, 2.0 and 3.0.



Figures 2: Scattering wave in space with cloaking of (a) 60-mm-radius, (b) 80-mm radius, and (c) fluctuation level of $|E^2|$ (D) normalized by radius r.

4. CONCLUSION

Plasma as metamaterial can be used in cloaking; the cloaking with plasma can be a configuration compressed to a lower limit. The size limit is close to quarter of the wavelength of the electromagnetic wave. The underlying physics on this limit may be based on Rayleigh diffraction, the slope of the plasma and the FDTD grid which is limited by our calculation precision.

Curvature and Transformations

Paul Kinsler[1,2,3], **Jonathan Gratus**[1,2], **and Martin McCall**[3]

Abstract— We discuss the presence and role of curvature in transformation optics and other transformation fields. Further, we show where and why it is not induced by cloaking transformations, but where and why it can be in other cases.

The original spatial cloak proposals [1] showed how light could be steered around an object in a way intended to make it invisible from all angles. The way the initially straight wavefronts – or ray paths – are transformed into curved ones begs the question: can transformation optics induce curvature? For example, a cloaking device might attempt to mimic an empty space, or a curved waveguide attempt to mimic a straight one. In such cases, despite ray paths becoming curved in the colloquial sense, the mimicry would not work if the true (mathematical) curvature differed between the device and its intended appearance (i.e. its design).

However, we can also consider other constructions, such as the Maxwell's Fisheye Lens [2] stereographic projection which makes a plane look like a sphere; or indeed any transformations between different and obviously curved surfaces. One notable case of such a "topographic transformation" [3] is the pioneering surface wave cloak of Mitchell-Thomas et al. [4]. Since we cannot escape the role of curvature in these cases, we here develop a description of the machinery and concepts needed to handle – and perhaps more importantly, *clarify* – this.

In what follows we will discuss everything in terms of transformation optics; although same arguments can be applied to other transformation fields.

Figure 1: We use device properties to hide the host space metric ($\bar{g}$) and make the space look as if it has some desired design space metric ($\hat{g}$). This means the device does not have a notion of a metric in and of itself – its constitutive properties act as a *transformation* between one metric and another. (Figure reused with permission [5]).

Any given situation, whether it be intended as a design or reference case, or as the device itself, can be codified here in terms of of three things: **First,** the geometry of the background space which will have some metric $g_{\alpha'\beta'}$; **Second,** the effect of the device we have constructed, i.e. the optical medium placed in the background space, which we denote $\mathfrak{M}^{\alpha'\beta'}_{\alpha\beta}$; **Third,** the metric seen by the light travelling within the device is a combination of the background space metric and the optical medium, the net effect giving rise to an effective or optical metric $\mathfrak{C}_{\alpha\beta}$.

We denote (a) the optical/effective metric to be $\mathfrak{C}$, (b) the lab/spacetime/background metric to be g, where the two are linked by (c) material properies $\mathfrak{M}$; so that

$$\mathfrak{C}_{\alpha\beta} = \mathfrak{M}^{\alpha'\beta'}_{\alpha\beta}\ g_{\alpha'\beta'}. \tag{1}$$

This treatment in terms of optical metrics addresses only part of the full electromagnetic system, which is a wave theory based on a full set of constitutive parameters, and contains polarization-dependent properties. However, as we will show, it performs extremely well and covers the most important features with regards to the presence or absence of curvature.

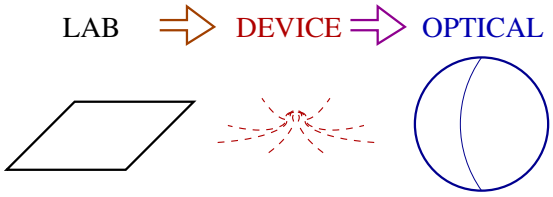

Figure 2: A flat lab space can be transformed into a curved optical space using a device with an inhomogeneous optical properties. The most famous example is the Maxwell's fisheye lens, whose index profile can be calculated by means of a standard stereographic projection from the sphere to the plane. (Figure reused with permission [5]).

From the simple representation of the transformation optics scenario shown in fig . 2, we can see that there are two places where curvature might exist, i.e. in the reference/laboratory space, and in the design space. Because any transformation must be a diffeomorphism, these two curvatures must be identical as far as the relevant optical (wave, ray) properties are concerned. For devices such as illusion generators or cloaks this is indeed the very *point* of the device design; and is independent of whether or not the laboratory space has an underlying curvature or not – e.g. because the spacetime is curved, or because the waves under consideration are confined to a curved sheet.

Despite the clear "no induced curvature" conclusion from earlier, what about Maxwell's fisheye lens? Since this is based on a stereographic projection of a sphere onto a plane, it is clearly possible to point to an initially curved laboratory space (i.e. the sphere), and a final lab space which is flat (i.e. the plane). Although the optical behaviour remains identical – propagation as if on a sphere – some aspects of curvature have altered.

We will show how a more sophisticated re-imagining of the situation shown in fig. 2 can resolve this, with allowances made for alterations in both the lab space and the device, whilst keeping the design criteria fixed.

We demonstrate that all transformation designs never induce curvature – the final in-device wave properties act to all intents and purposes as if travelling on the same space as the reference case: typically these spaces are both flat as far as the propagating wave is concerned. Nevertheless, the "location" of curvature in the system can be shifted from the lab space to the device properties, or vice versa, and we will show how to systematize this process.

Abstract-A 3D flat cuboid shaped lens calculated by spatial light transformation method for electromagnetic field shaping is proposed. The lens is capable of generating multi beams by reshaping the omnidirectional emission of a monopole antenna into four or more beams. Such manipulation is simulated and analyzed by solving the Laplace's equation. The design implies a potential 3D realization with all-dielectric gradient refractive index metamaterials.

Transformation optics (TO) is one of the most powerful conceptual techniques for the design of devices which leverage complex materials. TO enables to alter the field distribution by choosing material parameters which cause light to 'behave' as if it was in a transformed set of coordinates [1,2] and novel applications have been explored rapidly and quantitively. Hu et al. [3] found the equivalence between coordinate transformation and spatial deformation and propose to use Laplace's equation to determine the deformation of coordinate grids. Thus, it has been widely applied to design arbitrary broadband devices such as the carpet cloak [4] and functional lenses [5,6] with all-dielectric materials. In this study, we propose the design of a 3D lens with a flat cuboid shape that can significantly reshape the directivity of a monopole antenna into four directive beams [7]. Such a 3D lens can be obtained by the 2D design extension along *z* direction.

The designed model is based on quasi-conformal transformation optics (QCTO) and achieved by solving Laplace's equation. For fields' equivalence at the outer boundaries with the virtual space, Neumann and Dirichlet sliding boundary conditions are set at the edges of the cap lens:

$$\begin{aligned} x'\big|_{\overset{\frown}{A'B'}} = x, \quad x'\big|_{C'D'} = \sqrt{R^2 - y^2}, \quad \hat{n}\cdot\nabla x'\big|_{B'C',D'A'} = 0 \\ y'\big|_{\overset{\frown}{A'B'}} = y, \quad y'\big|_{C'D'} = \sqrt{R^2 - x^2}, \quad \hat{n}\cdot\nabla y'\big|_{B'C',D'A'} = 0 \end{aligned} \tag{1}$$

The range of ε_{zz} is related to the deformation between the physical space and the virtual space. We consider the initial parameters as $R = 4\sqrt{2}$ cm, r = 1 cm. In this case, the permittivity distribution ranges from 0 to 2.8. To refrain from using resonant metamaterials and to support a potential all-dielectric realization process, we have to consider ε_{zz} values below 1 as unity. The electric near field distribution of the lens for broadband performances is presented as illustrated in Fig. 2.

Abstract- A low-cost paper based frequency selective surface (FSS) for X-band frequency shielding is presented in this paper. The proposed FSS contains the unit cell made of single ring loop element with paper as its novel substrate. The overall thickness of the proposed FSS measured only 0.15mm. The designed FSS provide a band-stop response at 10 GHz with minimum 35 dB shielding effectiveness. Additionally, due to the ring loop FSS is symmetrical in nature, the designed FSS providing the advantage of polarization independency. It also exhibits angular stability up to 45° for both transverse electric (TE mode) and transverse magnetic (TM mode) fields. A prototype with overall dimension of 17.5cm x 26.3 cm of the proposed paper-based FSS is fabricated using inkjet printing method which is a low-cost manufacturing technique. The proposed FSS can be easily applied on the walls and windows of a room to block the unwanted frequency band in order to protect sensitive instruments from possible electromagnetic interference (EMI).

1. Introduction

Frequency Selective Surface (FSS) is commonly used to shield the unwanted signals which will lead to the EMI. FSS defined as either radiating or non-radiating elements that arranged in periodic array manner [1]. The FSS can be designed as either band-pass or band-stop filter respectively to electromagnetic waves [1]. Recently, rapid evolution of the wireless communication industry promote the needs of low-cost, flexible and environmentally-friendly wireless communication devices such as antennas and microwave devices [2]. Choosing the appropriate substrate is one of the most significant method to realize the flexible wireless communication devices. Flexible substrate such as PDMS, polyethylene terephthalate (PET), fabric and paper substrate had been proposed [3]. From all these substrates, paper is considered the best alternative as it is easily available, environmentally-friendly, flexible and most importantly is very low cost. However, the development of the FSS on paper is a big challenge. In the previous research, the development of the FSS on paper substrate was done by shaped the copper tape manually and glued on the paper later [4]. Another approach is to draw the design of the FSS manually using the silver conductive pen [5]. However, both of this approaches will cause high fabrication errors especially when the size of the unit cell become smaller and the design become complicated. In order to overcome the mentioned limitations, in this paper we proposed to develop the FSS on the paper substrate using inkjet printing method. We present a ring slot FSS on low-cost, flexible and environmental friendly paper substrate (permittivity = 3.1, thickness = 0.15mm and lost tangent = 0.05) to shield the X-band signal at 10 GHz.

2. FSS Unit Cell Design and Simulation Results

The proposed FSS is as shown in Figure 1. The designed FSS is made of silver-nanoparticle ink single ring slot with slot thickness of 0.003 mm. The unit cell is deposited on the paper substrate with measured thickness of 0.15 mm and tangent loss of 0.05. The performance of the FSS is evaluated through the simulation by utilizing CST Microwave Studio (CST MWS). Since the FSS is a highly resonant structure and it is important to investigate the angular stability performance, thus the frequency domain solver is utilized for the simulation. In order to reduce the simulation load, the FSS is modelled as infinite array in the software by utilized the full floquet mode to simulate single unit cell. The simulation results are as shown in Figure 2. From the results, we can observe the designed FSS provided attenuation of signal at 10 GHz up to 35dB for both TE and TM polarization. The designed FSS also managed to perform satisfactory for both TE and TM polarization up to 45 degree.

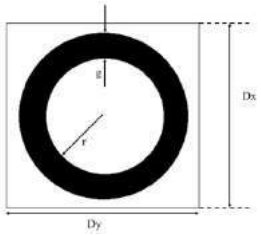

Fig1. Single Loop FSS; Dx=Dy=8.6mm, r=4mm g=0.9mm

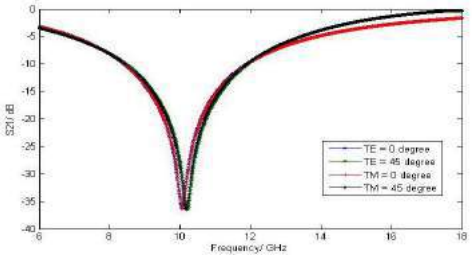

Fig2. Comparison for simulated S21 for both TE and TM polarization up to 45 degree.

3. Conclusion

In this paper, a low cost, environmentally friendly paper-based FSS is proposed. The prototype of the proposed FSS is realized using inkjet printing techniques. The proposed FSS can replaced the conventional FSS that developed on FR-4 and rogers while maintaining the performance of FSS. The fabrication technique proposed in this paper allow the accurate fabrication of the design. The detail explanation will be discussed after the acceptance of abstract.

Abstract-A contemporary, flexible and economical frequency selective surface designed for X-band shielding establish from simple inkjet printer using highly conductive silver nanoparticles ink. The resonating element of the FSS is designed using a modified square loop element and printed on top a paper substrate with a measured thickness of 0.15 mm. The performance of the FSS is examined using Computer Simulation Technology (CST) software. From the simulation outcome, the proposed structure offered band stop response at 10 GHz with attenuation up to 30 dB at normal incidence. Moreover, the modified square loop FSS is symmetrical and therefore it managed to offer a stable frequency response at oblique angle up to 45° for both TE and TM polarization. The model of the designed FSS is then developed using inkjet printing technique. The proposed FSS can be cascaded to building easily as wallpaper to block the unwanted X-band signals.

1. Introduction

Frequency Selective Surface (FSS) is commonly used as a spatial filters either as a band-pass or band-stop filter [1]. FSSs are useful as antenna radome, absorbers, antenna reflectors and in many other areas [2]. The performance of the FSSs are mainly reliable on the geometry of the element, size of the unit cell, periodicity and characteristics of dielectric substrate used [1]. In order to achieve a stable frequency response performance, the element geometry playing the most notable role. The compact FSS design will allow the FSS to operate satisfactory under different angle of incident and polarization [3]. Therefore, it is crucial to design a compact FSS element. Recently, with the rapid development of the communication devices, the demand of the flexible wireless devices is become significant [4]. Most of the study reported the development of the wireless devices on PDMS, polyethylene terephthalate (PET) and paper substrate as the dielectric body for the devices [4], [5]. From all these substrate, paper substrate is the most ordinary option as it is easily available in the market and allow the roll-to-roll production which will reduced the cost significantly [6]. To ensure the FSSs manage to perform competently, the metal depositing technique is relatively crucial. Inkjet printing is become a commendatory choice today due to it is low cost and simple to fabricate [6]. In this paper, we offered to develop the modified square loop FSS on the low-cost, flexible and environmentally friendly paper substrate (permittivity = 3.1, thickness = 0.15mm and loss tangent = 0.05) using simple inkjet printing technique to support the screening of the X-band frequency signals.

2. FSS Unit Cell Design and Simulation Results

The objective of this paper is to present a low profile FSS element that can operate satisfactory at

different angle of incident and polarizations. The proposed FSS is as explicated in Figure 1. The designed FSS comprised an unit cell of modified square loop (MSL) with conductor thickness of 0.003 mm deposited on top of a paper substrate with thickness of 0.15 mm, permittivity 3.1 and loss tangent of 0.05. The proposed MSL is transformed from square loop by introduced an inward bending U-shaped stubs to all sites of the square loop. The package density of the FSS has exacerbated when the square loop is evolved to MSL [3]. From the simulation result, we can examine that the frequency response of proposed FSS operate stability at both TE and TM polarization. Although when the angle of incident increase to 45°, the center frequency alter slightly but at 10GHz, the FSS still manage to provide attenuation more than 25 dB for both TE and TM polarizations. In a nutshell, the FSS provide a stable frequency response.

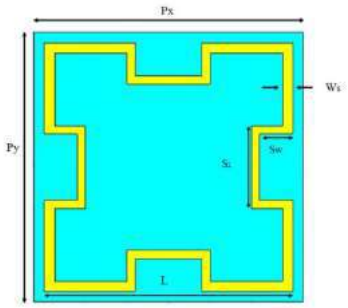

Fig1. Modified Square Loop. Px=Py=6.5mm, L=6mm Ws= 0.5mm, S_L=2mm, S_w=0.8mm

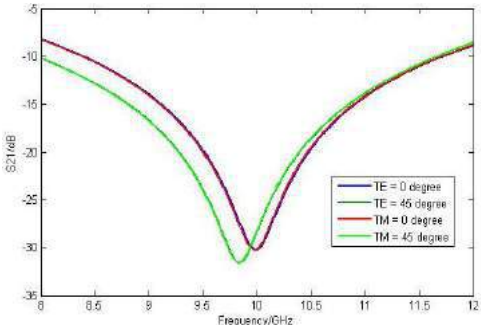

Fig2. Simulated Frequency transmission response of the proposed MSL.

3. Conclusion

In this paper, a MSL FSS deposited on a paper substrate is presented. The proposed FSS is realized using simple inkjet printing technique to deposit the silver nanoparticle ink on the paper substrate. From the simulation result, the proposed FSS provide a stable performance at both TE and TM polarization up to 45°. The detail explanation on fabrication technique, experimental setup for validation will be discussed after the acceptance of abstract.

Flexible Microstrip Polymer-Conductive Fabric Grid Array Antenna for Wearable Applications

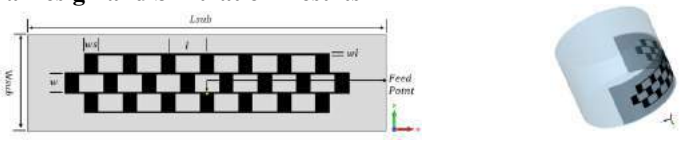
M. R. Ramli, S. K. A. Rahim, W.Y.Yong and M. I. Sabran
Wireless Communication Centre (WCC), Universiti Teknologi Malaysia
* mridduan2@live.utm.my

Abstract- A flexible microstrip grid array antenna that established using copper conductive fabric as the conducting element deposited on the Polydimethysiloxane (PDMS) as it substrate is presented. The proposed design is made up from a rectangular geometry which consists of 19 cells that build up by 22 radiating elements on the PDMS to provide a resonant frequency at 15 GHz. The proposed design managed to provide a 40% bandwidth at -10 dB bandwidth performance with maximum gain up to 14.6 dBi at normal condition. The study on the bending effect of the proposed antenna is examined using Computer Simulation Technology (CST) software. The bending effect of the proposed antenna is observed by bending the antenna into different bending radius. From the results obtained, it can be examined that the proposed antenna is insensitive toward the bending and thus it is a suitable candidate for wearable applications.

1. Introduction

The introduction of smart devices and Internet of Things (IoT) has leads to the increase demand on the communication data. The 5G communication is envision to support around 1,000 time data than the existing data[1]. As a result, the antenna that going to utilize for 5G must consist the features of large bandwidth, high gain and manage to operate at high frequency. Grid Array antenna which is designed using several number of meshes to form the grid cells with radiating elements and transmission line and a full ground plane [2]. Grid array antenna provide the credit of simple feeding technique, high gain, wide-bandwidth and most importantly it manage to provide a stable performance over high frequency [3]. Besides that, the introduction of the IoT increases the need of the wearable and flexible electronics which include the flexible antennas. One of the propose approach to realize the flexible antenna is to utilize the flexible substrate such as PDMS [4]. In this paper, we present a durable microstrip grid array antenna by using the PDMS substrate and conductive fabric which provide the flexibility characteristics. The proposed antenna manages to provide stable performance when it is bent up to certain level.

2. Flexible Antenna Design and Simulation Results



(a) (b)

Fig1. (a) The proposed antenna configuration. (b) Simulation for bending process experiment in CST

Figure 1(a) shows the configuration of the proposed flexible microstrip grid array antenna. The presented

antenna is designed on 1.6 mm thick PDMS substrate (relative permittivity εr = 2.9 and loss tangent tanδ = 0.0019) and 0.035 mm copper conductive fabric with electrical conductivity of 5.8 x 10^7 S/m as the patch and ground plane. The cell element is designed using guided wavelength equation at 15 GHz and simulated using CST Microwave Studio software. The proposed antenna consist of 19 number of cells with 22 radiating elements arranged in rectangular geometry. The optimized antenna parameters is *l*=14 mm, *w*=7 mm, *ws*=5.1 mm, and *wl*= 0.55 mm with total dimension of 130 x 35 mm. Figure 1(b) shows the simulation bending experiment in CST. The proposed antenna was bend correspond to the attached cylinder curved surface where the radius of the cylinder, R will be consider as the parameter of bending. The reflection coefficient of the antenna without bending is compared with the bending antenna in order to examine the bending effect on the antenna performance. Figure 2 shows the simulated reflection coefficient and gain for the proposed antenna with bending and without bending. The antenna provide 40% wideband characteristics at -10 dB with maximum gain of 14.6 dBi at 15 GHz at normal condition. The bending level of the antenna is depend on the radius of the cylinder where smaller radius allow higher level of bending on antenna. From the result, we can examined the proposed antenna manage to provide a stable performance over 15GHz when it is being bent.

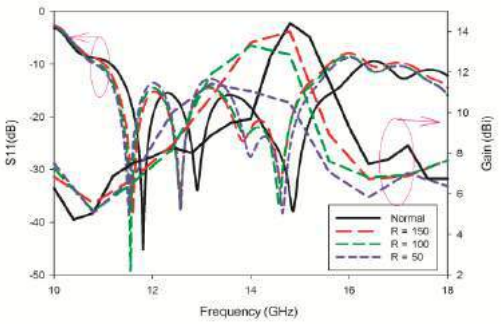


Fig2. Return loss and gain of the proposed antenna with and without bending

3. Conclusion

A flexible microstrip grid array antenna on PDMS and conductive fabric is presented in this paper. Proposed antenna manage to operate satisfactory at 15 GHz when it is bent or without bending. Such feature allow the proposed antenna to be use for wearable applications. The detail explanation about antenna performance and fabrication method will be discussed after the acceptance of abstract.

Abstract-This paper presents the design of a branch-line coupler (BLC) using a copper fabric sheet as conductive element, mounted on Polydimethylsiloxane (PDMS) substrate and superstrate (cover) dielectric layers. The BLC operates at the 2.45 GHz operating frequency and has a phase difference of 90 degree. The use of PDMS material as a dielectric layer for BLC is to add the special characteristics of PDMS on this passive microwave circuit. The PDMS has very unique properties such as durability, light weight and electromagnetic shielding. By incorporating the copper fabric as a conductive element for BLC it will enhance the durability and the electromagnetic shielding of the BLC.

Realization of electronic and photonic components on flexible, durable and stretchable substrates as opposed to conventional rigid substrates can open doors for the next generation of electronic and microwave circuits with new functionalities [1]. Typically a microwave circuit, such as a Branch Line Coupler (BLC) is commonly fabricated on a solid substrate like FR-4 or RT/duroid board. Although these substrates can give us more advantages in term of high performance, ease of fabrication and low cost, they however, are not reliable when exposed to harsh weather conditions or a mechanically stressed environment [2].

Utilizing the copper fabric sheet as a conductive element, increases the EMI capability of the proposed BLC. It has been proved by previous research [3], that the mesh structure of the copper fabric sheet can reflect the electromagnetic waves by using the principle of the Faraday cage. This material can also strengthen the polymer based substrate for the proposed BLC [3].

The conducting element for the branch-line coupler is designed on a copper fabric sheet with thickness and sheet resistance of 0.08 mm and 0.05 Ω/square, respectively whilst the thickness for PDMS is specified at 1.9 mm. The length and width of the shunt/series transmission lines for the BLC are computed using the transmission line calculator from AWR software, by taking into consideration the thickness of the copper fabric, and dielectric constant εr of the PDMS substrate. The simulated and measured S-parameter results for the planar PDMS-based BLC are shown in Fig. 1. The reflection coefficient (S11) and isolation (S41) in simulation are -31.6 dB and -37.1 dB, respectively. Meanwhile, the measured reflection coefficient and isolation for the PDMS-based BLC are -29.1 dB and -26.6 dB, respectively.

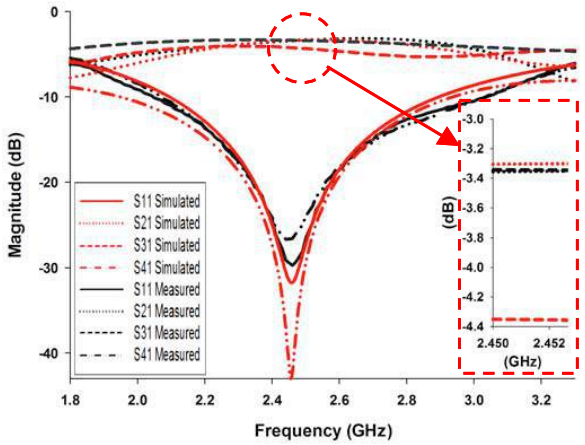

Fig. 1. Simulated and measured S-parameter results for the PDMS-based BLC

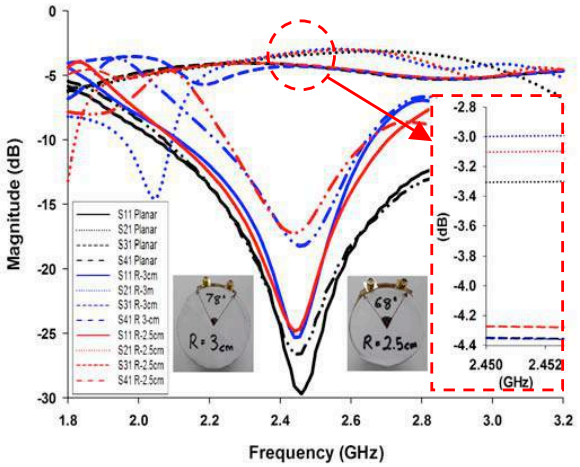

Fig. 2. Measured S-parameter results for the PDMS-based BLC at three different radii and angles.

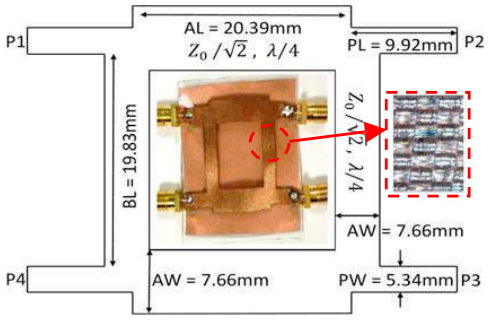

Fig. 3. (a) Design layout of the proposed and fabricated PDMS-based BLC
(b) mesh structure of the copper fabric sheet (x200 magnification)

This may be attributed to fabrication accuracy. The simulation value for coupling (S31) is -3.3 dB whilst for insertion loss (S21) it is -3.4 dB. In measurement, the values for the same are -4.2 dB and -3.5 dB, respectively. Basing on the results, the measured insertion loss of the PDMS based BLC is close to the simulated result. The fabricated prototype figure is embedded in the design layout in Fig. 3. Fig. 2 shows measured S-parameter results for the PDMS-based BLC at different radii of curvature. Although the S11 resonant peak for the 3 cm and 2.5 cm radii of curvature reduces to -25.3 dB and -24.7 dB, respectively it still hovers around 2.45 GHz.

Abstract- This paper presents the design of a novel ultrathin, light-weight and flexible X-band band-stop frequency selective surface (FSS) using instant, simple and fast inkjet printing technology. The proposed FSS design is deposited on the 0.125 mm-thick light-weight, ultrathin and flexible PET substrate with dielectric constant of 2.7 and designed to attenuate 10 GHz. The ring slot FSS is proposed as it is easy to design and symmetrical in nature which is insensitive toward the change in polarization and angle. The flexible and ultrathin FSS provide attenuation up to 30 dB for both TE and TM polarization. In addition, the proposed design provided a stable performance up to 45° at both polarization. The proposed FSS has a measured -10 dB bandwidth of 38% and 0.125 mm profile. These advantages greatly enhance the potential applications of the FSS also as a EMI shield that can be mounted onto the glass surface of buildings to shield the unwanted signals caused by the increase of wireless devices.

1. Introduction

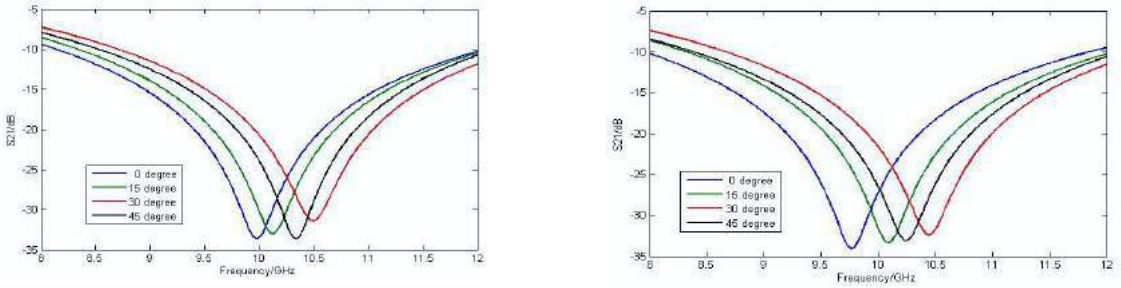
Fifth Generation (5G) communication technology envisage to support huge mobile traffic [1]. In other words, more base station will be built to support the demand from the users. However, this will lead to the electromagnetic pollution which will degrade the performance of the electronic devices [2]. The common solution using the metallic shielding to block the electromagnetic waves is impractical in this case as it is costly and labor intensive[2]. Thus, FSS is introduced as spatial filter to block the unwanted frequency. Recently, there has been a growing interest in developing flexible electronics. This trend is also happening in the wireless communication industry where the industries are looking for bendable antennas or microwave devices [3], [4]. To make the flexible communication devices into reality, the substrate used is relatively crucial. One of the common approaches is to design the antennas and microwave devices on top of Polydimethylsiloxane (PDMS) [3]. Although PDMS is the best candidate to realise the flexible wireless devices, but it is challenging to deposit the conductive element on top of it especially for the array types microwave devices such as FSS and reflect-array antenna as the conductive layers are deposited on PDMS manually. To overcome this hindrance, development of the microwave devices on top of a paper substrate and Polyethylene Terephthalate (PET) using inkjet printing technique is then introduced [4]. In this paper, we present a single ring loop FSS on the 0.125 mm-thick light-weight, ultrathin and flexible PET substrate with dielectric constant of 2.7 to provide an attenuation at 10 GHz.

2. FSS Unit Cell Design and Simulation Results

Single ring slot as shown in Figure 1 is used for the FSS element design. Ring slot FSS is chosen as it is easy to design and symmetrical in nature which able to provide a stable performance for both TE and TM polarization and insensitive toward the change of angle of incident [5]. The proposed design is realised using silver nanoparticle ink and supported by a polyethylene terephthalate (PET) substrate with thickness, h of 0.125 mm and dielectric constant ε_r of 2.7 with the tangent loss of 0.004. The unit cell of the proposed ring slot FSS is

simulated using Computer Simulation Technology (CST) Microwave Studio software. The simulated transmission response of the proposed FSS is demonstrated in Figure 2. From the results, it can be examined that the presented FSS provide attenuation at 10 GHz up to 33 dB with -10 dB bandwidth of 39% at normal incidence for TE polarization.

Fig 1. (a) Unit cell of the designed single ring loop FSS; Dx = Dy = 10.75 mm, R1 = 4.2 mm; R2 = 4.9 mm; (b) Fabricated FSS on PET substrate.



(a) (b)

Fig 2. Transmission Response of the proposed ring shape FSS for (a) TE polarization and (b) TM polarization at various angle of incident.

3. Conclusion

A flexible and low-profile PET-based FSS for X-band signals screening is presented in this paper. The element of the proposed FSS is designed using single ring loop element. The proposed design offers attenuation up to 32 dB at the centre frequency of 10 GHz. The fabrication technique of the proposed FSS and the measurement results will be discussed after the acceptance of abstract.

[*]herwansyahlago@gmail.com

Abstract-A textile artificial magnetic conductor (AMC) plane with hexagonal and triangular microstrip patch antenna was proposed. The AMC is designed to function as a perfect magnetic conductor (PMC) at 2.45 GHz to improve the antenna performance. The performances of both antennas with and without the AMC plane were investigated. The results show gain enhancement at the operating frequency while maintaining the antennas' size. Furthermore, the AMC plane has been integrated with three different MIMO orientation and its performance investigated. In addition, the presented AMC plane and both antennas are made of fabric for the entire substrate and conducting parts. For that reason, the AMC plane antennas have big potential to be implemented in wearable applications.

Introduction: Recently, research in wearable communication system has received remarkable attention due to the community needs especially in find and rescue purpose. However, the wearable antenna is suffering performance degradation caused by several factors [1]. One of the factor is human body effect when the antenna is placed near to the body. Textile artificial magnetic conductor (AMC) has been introduced in [2] to overcome the drawback faced by wearable antennas. This research intends to improve and analyze the performance of the wearable antennas on the AMC plane.

Figure 1: Proposed (a) AMC octa-rift unit cell, (b) AMC plane, (c) triangular patch and (d) hexagonal patch antenna.

A textile AMC unit cell has been designed which exhibit PMC's characteristics at 2.45 GHz as illustrated in Figure 1(a). Then the AMC unit cell is arranged into 5x3 matrix formation to form the AMC plane (see Figure 1(b)). The triangular and hexagonal patch antennas (see Figure 1(c)) are designed with an operating frequency of 2.45 GHz and placed on the AMC plane. As the result, the antenna gain is enhanced up to 23% with present of the AMC. In addition, the electric density also improved for both patch antennas. To investigate the MIMO

characteristics, the antennas are placed side by side and form three different orientations named as antenna orientation A, B and C (see Figure 2). The reflection coefficient for all antenna orientations remained unchanged. Furthermore, all of these MIMO antenna have shown good performance in term of isolation (S_{21}), diversity gain and envelope correlation coefficient as tabulated in Table 1.

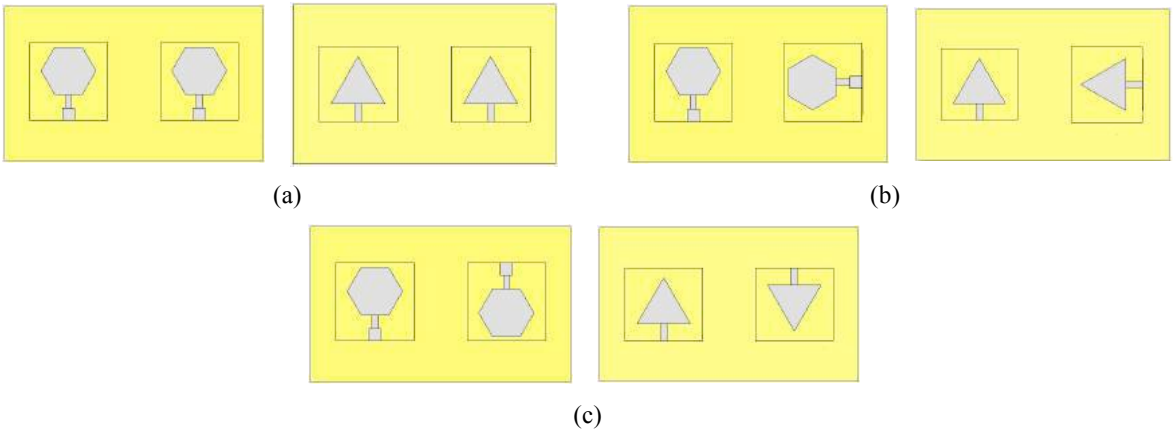

Figure 2: Antenna orientation (a) A, (b) B and (c) C for hexagonal and triangular MIMO antenna.

Table 1. Comparison performance of the crescent shaped array antenna with and without AMC.

Orientation	Antenna	Isolation (dB)	Diversity Gain	Envelope Correlation Coefficient
A	Hexagonal	-45.22	10	0.28m
	Triangular	-53.31	10	0.15m
B	Hexagonal	-55.06	10	65 μ
	Triangular	-56.48	10	68μ
C	Hexagonal	-46.71	10	0.66m
	Triangular	-56.32	10	0.6m

Conclusion: A textile AMC with hexagonal and triangular microstrip patch antenna which operate at 2.45 GHz was proposed. Through the simulation process, the AMC potentially to be placed near to the radiating element without any frequency shifting. The performances of the single and MIMO antenna are potentially to be improved with aid of the proposed AMC plane.

Abstract-A coplanar waveguide (CPW) loaded complementary split-ring resonator (CSRR) harmonic rejection filtenna designed on low-cost flexible PET substrate operates at 5.8 GHz is presented. The proposed antenna comprised of square slots built-in the rectangular patch structure, developed using inkjet printer with highly conductive nanoparticle silver ink. CSRR is implemented at the transmission line to suppress unwanted harmonics. The antenna performance is simulated and optimized using Computer Simulation Technology (CST) software. The proposed antenna achieved acceptable 2nd and 3rd harmonic rejection with minimum reflection coefficient of -4.56 dB and -3.3 dB respectively, offers efficiency up to 88.66%.

1. Introduction

Filtenna (filter-antenna) is the term used for integration of antenna and the filter into one structure [1]. Filtenna is developed to improve RF front end communication system performance in terms of size, losses, complexity and cost by eliminating the use of band pass filter module [2]. To filter out the unwanted harmonics, it can be achieved by using various shapes of stubs, slits and slots on the antenna structure [2]–[4]. The performance of harmonic rejection and good return loss can be achieved by optimizing the dimensions of the stubs, slits and slots [3]. Complementary split-ring resonator (CSRR) is an alternative solution to achieve frequency notching by implementing the metamaterial in antenna design. It has distinct electromagnetic (EM) characteristic of negative refraction thus make it suitable to be applied as filters in miniaturized design [5]. With the increasing demand on the flexible device, number of researchers starts to develop the antenna on flexible substrate such as SU-8/polydimethylsiloxane (PDMS), paper and Polyethylene (PET) substrates. From that, PET substrate is the best candidate as it is more flexible, thin, foldable, bendable and transparent as compared to others [6]. Recently, inkjet printing has become a promising solution for fast, low-cost and precise way of antenna fabrication especially for flexible materials. In this paper, an attempt of designing a CPW filtenna on low-cost flexible PET substrate is developed using inkjet printing technique and it is realized by introducing CSRR on the transmission line, thereby suppressing the harmonics of the resonance frequency.

2. Filtenna Design and Simulation Results

The design on the proposed CPW antenna is shown in Figure 1. The designed antenna is composed of rectangular radiating shape with square slots, coplanar waveguide (CPW) feeding with CSRR loaded on the transmission line and ground plane (g = 0.17 mm). The structure is printed on 35mmx40mm PET substrate which has thickness of 0.125 mm (ε_r = 2.7, tan δ=0.004). The antenna has parameters of Wp=9 mm, Lp=33.5 mm, Wf=2.5 mm, Lf=16 mm, G_{LP} =0.5 mm, G_{WP}=1.6 mm, L_1=5.5 mm, L_2=12.5 mm, D_1=0.5 mm, D_2=1.7 mm, S_1=2.3 mm, S_2=3 mm, G_1=0.1 mm, G_2=0.2 mm and D_S=0.2 mm. Silver nanoparticles conducting ink has been

used for printing of the radiating elements. Figure 2 illustrates the reflection coefficient performance of the antenna from the conventional basic design until the proposed harmonic suppression technique applied. It can be observed that the initial reflection coefficient, S11 result is improved by integrating the square slots at the radiating element. The antenna structure is further modified by integrating CSRR to the transmission line for harmonic rejection at 10.73 GHz and 19.46 GHz. Although the centered frequency alters slightly, the filtenna manage to achieve suppression of the second and third harmonics with reflection coefficient -4.56 dB and -3.3 dB respectively.

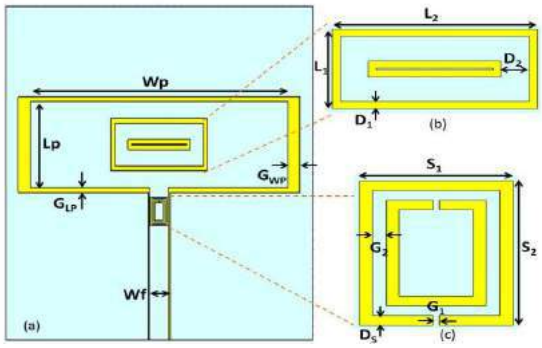

Figure 1: Filter arrangement (a) Proposed antenna structure, (b) Square slots, (c) CSRR loaded on transmission line

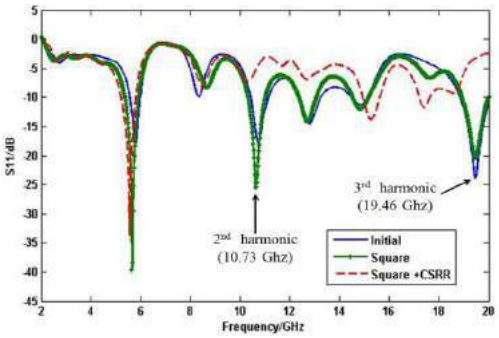

Figure 2: Reflection coefficients performances of the proposed antenna with filter

.

3. Conclusion

A CPW filtenna with CSRR on flexible substrate is presented in this paper. The proposed antenna design is sufficient for the 5.8 GHz with blocked 2nd and 3rd harmonics. The CSRR unit on the transmission line acts as a filter to suppress harmonics, with reflection coefficient -4.56 dB and -3.3 dB respectively. The details of fabrication technique and the measurement result will be discussed after the acceptance of abstract.

Abstract- This paper present the design of metamaterial frequency-selective surface for chipless Radio-frequency Identification. Three circular ring with different radius are as resonating elements as main identification element for coding of chipless RFID. The gap of metamaterial-split ring resonators are adjusted using frequency shifting technique to maximize amount of number or bits, From simulated result, the proposed structure archive high transmittance, which is range between 95% and 90% at 3.50, 4.88 and 6.73 GHz The proposed chipless RFID tag offer high amount bit number without any size and capability of operating when mounted on metamaterial.

Introduction- Chipless radio frequency identification (RFID) offer several attractive feature such as compact and high capacity and does not including any silicon chip. [1]. Effort to investigate the potential chipless RFID design and technique has been blooming ever since the discovery of minimizing structure and improving RFID performance[2-3]. Metamaterial structure is one solution for solving the challenge of designing high capacity and compact chipless RFID. One of the popular metamaterial structure is split ring resonator (SRR) was invented by Hardy [4] as shown in Fig 1a. The gaps between two rings determine capacitance and the outer ring store the magnetic field. Pedry [5] was improved the SRR design with combination of two concentric ring with split on opposite side as shown in Fig 1 b) for non-magnetic array effect. The model equivalent circuit has approximated same with the SRR model as shown by Falcon [6] as shown in Fig 2. The complementary SRR are introduced at the back side substrate achieve high magnetic coupling between line and ring resonance by Martin [7].

Multi-frequency Metamaterial Frequency-Selective Surface- This paper proposed a split ring resonator (SRR) structure for operating at three frequencie bands (3.56, 4.87 and 6.7 GHz) with narrow bandwidth from previous research [8-9]. The structure can absorb the incident of EM wave coming from a direction (+z). The substrate is used Rogers RT 5880 which has dielectric constant of 2.2, loss tangent of 0.0009 and thickness of 0.17mm. The

resonating elements are made by 0.017 mm thick copper. The corresponding dimensions are listed in Table 1. The dimension of the unit cell (W x L x H) is 18 mm x 18 mm x 0.127mm. The frequency shifting approach for chipless RFID as shown in Fig 3 is introduced to improve the amount of bit generated by a single resonator. From the analysis, the length of split ring resonator has inverse relationship with resonant frequency. The addition of gap size reduces the length of resonator and increases the resonant frequency. The simulated reflectance and transmittance of multi-resonant SRR metamaterial are shown in Fig 4. The transmittance of all resonant frequency above 90% show the proposed metamaterial structure enable to produce high transmittance.

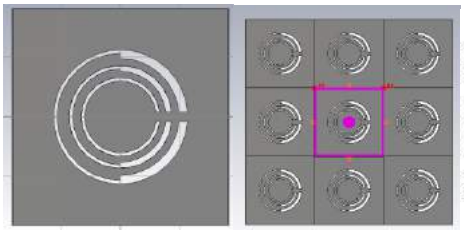

Fig 3. The proposed structure

Conclusion : A novel chip-less RFID tag base metamaterial structure using split ring resonator on the flexible substrate, Rodger 5880 operates between 2.5 to 6.5 GHz with multiple bits of data have been designed and analysed. The concept of modified complimentary split ring resonator metamaterial based frequency-selective surface is proposed to miniaturize the size and reduces the space consumption for chipless RFID application

Abstract- Metamaterial-HIS of Electromagnetic Band Gap (EBG) incorporated onto dual band array antenna operate at 2.45 GHz (lower band) and 5.8 GHz (upper band) is proposed. The four configurations of EBG unit cells successfully realizes a dual band antenna with dedicated pattern reconfigurability. The antenna is suitable for steering the main lobe direction to intended directions.

Introduction

EBG is a High Impedance Surface (HIS) of metamaterial which exhibits unique properties in suppressing the propagating wave within the microwave structure [1] at its resonance frequency. This properties can be used to block away the desired wave of particular frequency in reaching the antenna radiating patch [2]. In this paper, a multiband array antenna which operates at 2.45 GHz and 5.8 GHz with EBG for pattern reconfigurability is presented and discussed.

Result and Discussion

Figure 1(a)-(b) shows the back and front view of the EBG cells with region "S0" and "S1" which can be "ON" and "OFF" with connection or removal of copper strips respectively. The "ON" and "OFF" are represented by "1" and "0" respectively. Suspended Transmission Line (STL) method in Figure 1(c) is used to analyzed the band gap, S21 of EBG and the result is shown in Figure 1(d). It can be observed that EBG produces band gap at lower band (2.45 GH) and upper band (5.8GH) with different EBG configurations. EBG is then incorporated to array antenna as shown in Figure 1(e) and 1(f). Various configuration of EBG1, EBG2, EBG3 and EBG4 have achieved pattern reconfigurability as shown in Figure 1(g). It is observed from Figure 1(h) and 1(i), that the multiband array antenna successfully resonates at 2.45 GHz and 5.8 GHz despite difference in configuration of the EBG unit cells. Figure 1(j) and 1(k) shows the polar plot of the H-field of the array antenna. The proposed antenna is very useful in wireless communication service (WCS) where the antennas are required to direct its pattern at desired coverage or intended receiver in the dynamic environment.

Abstract

This paper is introduced a passive sensor to detect the performance of the structure using three-dimensional (3D) Frequency Selective Surfaces (FSS). The proposed 3D Circular FSS results are proved behave as passive sensor with changing of sensitivity incident angles to be apply in Structural Health Monitoring (SHM) system. Moreover, this 3D Circular FSS capable to operate without stand to any (DC/AC) power and very low cost in term of installation and maintenance.

1. Introduction

Nowadays, SHM system has been offered a huge beneficial for building structure safety and performance. By developing SHM system, it is proved that the percentage of safety increased. SHM is commonly applied to tracking and detect any poor structure performance such as tilting, crack and movement of structure with using various sensors [1].

There are many type of sensors have been proposed and applied in SHM system which are wired and wireless sensors. Besides that, mostly researchers are more concentrating to wireless sensor compared to wired sensor due to their higher active element needed and difficulties in installation [2], [3].Characteristic of passive sensor has been overcome the active sensor problem in term of easier installation and maintenance, less power consumption and long term of endurance element [4].

The 3D Frequency Selective Surfaces with circular shaped was introduced here to act as a passive sensor. A good performance in term of sensitivity angular response for this circular shaped was chosen [5], [6]. A new technique of 3D FSS was proposed in this paper to tracking abnormalities structure performance for SHM system. The electromagnetic wave characteristic will varies by changing the angle of FSS due to the building tilting as shown in Figure 1 (b). The changing (frequency shifting) of different electromagnetic wave characteristics were presenting in two polarizations which is TE- and TM- incident angle. For this case, the TE- and TM- incident angle required to obtain in two different characteristic frequency responses TE and TM angle such sensitive and insensitive angular response respectively. See Figure 1 (b), sensitivity of angular response indicating that the frequency response (band stop) shifting from 3.8GHz to 3.86 GHz with the angle 0° to 20° respectively. Meanwhile, insensitive frequency response (band stop) is maintained in one location of frequency response with various angles up to 60 degrees. Therefore, the building tilting is monitored by a different of sensitivity angular response changing. The 3D Circular FSS design is shown in Figure 1(c), where behaves as a passive sensor and attached on the building structure.

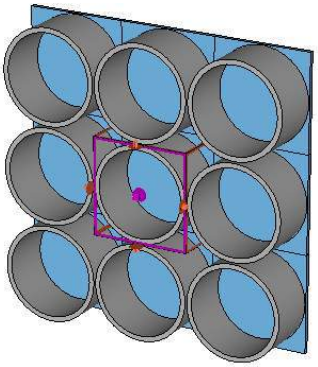
(b)



(c)

Figure 1: (a) Incident angle effect as building tilting (b) Frequency response shifting as incident angle changed (from 0° to 20°) (c) 3D Circular FSS design with unit cells.

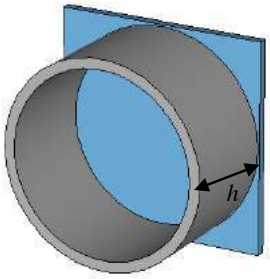


Figure 2: Elevating the height of conducting element.

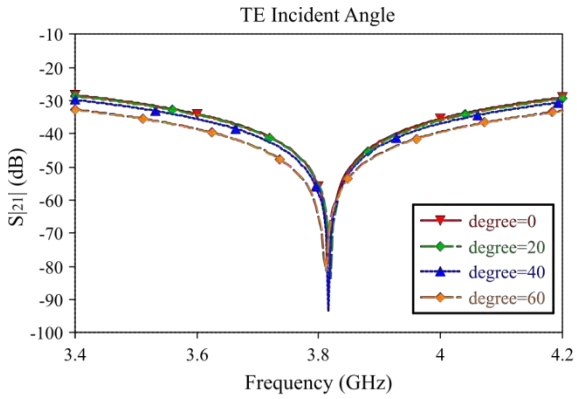
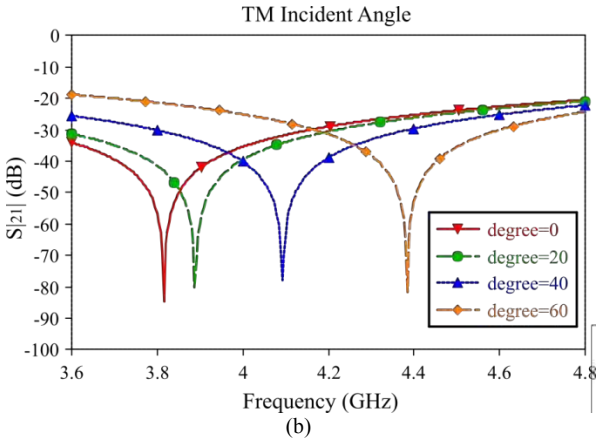
See Figure 2, by increasing the conducting element will render the frequency characteristic. The geometry FSS play an important role towards the frequency behavior [7]. Therefore the frequency response of FSS can be control in two different polarizations by alter the geometry size.



(a)



(b)

Figure 3: Frequency response results up to 60° (a) TE incident angle, insensitive (b) TM incident angle, sensitive.

In Figure 3 indicate that two different polarization TE- and TM- incident angle have been simulated. Result in Figure 2 (b) looks sensitive in various angles and will be used for monitoring in SHM system. Table 1 indicated the percentage different center frequencies in each angle as the FSS (building) changed.

Table 1: Values center frequencies of the 3D Circular FSS with different angle.

TE incident angle		
Degree (°)	Frequency (GHz)	Deviation (%)
0	3.81	0
20	3.816	0.15
40	3.816	0.15
60	3.815	0.13
TM incident angle		
0	3.81	0
20	3.893	2.17
40	4.12	8.13
60	4.38	14.9

2. Discussion

The FSS shape was designed in circular geometry. FSS structure was modified by elevating the height of conducting element. Besides that, 3D Circular FSS has shown the different S_{21} band stop results in two polarization TE and TM incident angle. Controllable FSS performance and characteristic made the two polarization results become sensitive and insensitive in various angle. Simulation on 3D FSS has been done from 0° up to 60°.

3. Conclusions

The proposed of 3D Circular FSS was introduced to perform as a passive sensor in SHM system. 3D Circular

FSS able to utilize without depends on the power supply on it. Moreover, various angles S_{21} results shown a sensitivity incident angle (TM-polarized), meanwhile insensitivity (stable) incident angle at TE-polarized. 3D Circular FSS proved that can controlled the sensitivity incident angle in both polarizations instead of 2D FSS structure. A result in Figure 2 (b) has shown a terrific sensitivities frequency shifting as the incident angle of building changed. Therefore, a result will be used as monitoring building performance due to sensitive on different building condition.

Multiband Salisbury Screen Absorber Using Double Layer Cross Dipole FSS

F. C. Seman[1*], S. Omar[1], W. Y. Yong[2] and S. K. A. Rahim[2]

[1]Research Centre for Applied Electromagnetic, Universiti Tun Hussein Onn, Malaysia

Abstract

In this paper the microwave absorbing properties of multiband Salisbury screen absorber design which is constructed using multi-layer FSS is investigated. The structure exhibits triple operating band where the -10 dB reflectivity bandwidth of a Salisbury screen operating at normal incidence is 36.3%, 11.9% and 14.5% at the resonant frequencies of 6.56 GHz, 9.1 GHz and GHz respectively. Reflectivity predictions for normal incidence are shown to be in close agreement with bistatic measured results over the frequency range 8 - 12 GHz.

1. Introduction

The Salisbury screen is a resonant absorber created by placing a 377 Ω/square resistive sheet on a dielectric substrate backed by a metal plate as illustrated in Figure 1(a). The loss mechanism in this dielectric-based and conductor-backed thick (d) absorber exploits the terminating impedance property of an open circuit which is transformed from a short circuit that is presented when the signal is reflected from the ground plane with a phase of 180° [1]. This reduces the amount of energy reflected back to the transmitter, and so effectively reduces the RCS of the structure. Equation (1) defines the phase criteria necessary to generate the reflection null [2];

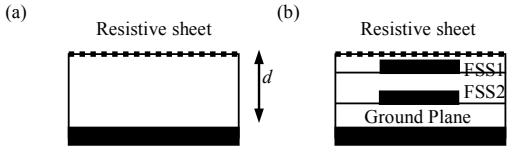

Figure 1 : (a) Conventional Salisbury screen absorber d= λ/4 (b) Salisbury screen with double layer FSS.

$$\emptyset_{GP}(f) + \emptyset_{PL}(f) = 2n\pi \quad [1]$$

Where n = 1,2,3 …

$$\emptyset_{PL}(f) = \frac{2\times 2\pi \times d\sqrt{\varepsilon_r - \sin^2\theta}}{\square} \quad [2]$$

where ϕ_{GP} is the reflection phase (180º) attributed to the ground plane, ϕ_{PL} is the path length phase in the cavity, d is the physical spacing between the resistive sheet and metal backing plate, θ is the angle of incidence and ε_r is the permittivity of the spacer material. In conventional Salisbury screen absorber, additional phase length of 180° is contributed by the λ/4 to provide total phase of 360° at reflection null. The same phase characteristic can be realised by integrating multilayer FSS between the resistive sheet and metal back as illustrated in Fig.1 (b). Here, manipulation of total phase of 360° is obtained multiple times therefore multiband Salisbury screen may be realised.

In this paper, design concept of multiband Salisbury screen is explored by integrating multilayer cross dipole FSS. The phase characteristic in Salisbury screen absorber is discussed in details in relation the reflection phase provided by the conductor layer (solid metal backed or FSS) and the path length phase contributed by the substrate layer. This is designed to generate additional reflection nulls at predetermined frequencies by optimising the size, periodicity and shape of the periodic elements in each FSS unit cell. Later, verification of design concept of multiband Salisbury screen is realised by fabricating a prototype of Salisbury Screen with two layers of cross dipole FSS so that each layer generate the reflection phase of 180° thus generating additional absorbing bands above the inherent absorption band of the structure [3].

2. Cross Dipole and Fundamental

Fig. 2 shows the geometry of cross dipole FSS printed on vacuum spacer (ε_r =1.0) where the geometry can be represented as a series of capacitance and inductance. Note that the vacuum spacer is used to ease explanation of phase changing in Salisbury screen. The resonant frequency of the FSS occurs when the electrical length of the dipole is about λ/4. The cross dipole patch perform as a bandstop filter at its resonant frequency. Fig. 3 shows that a microwave signal is completely reflected by the cross dipole FSS, l =15 mm at 9.41 GHz with reflected phase of 180°. This demonstrates that the FSS behaves as ground plane as in conventional Salisbury screen at the resonant frequency. This phase can be manipulated to compensate the required total phase in the Salisbury screen as given in equation [1] and [2]. Fig. 4 shows the transmission characteristic of a cross dipole FSS. As the dipole length, l increases from 15 mm, 17 mm to 19 mm, the resonant frequency reduces from 9.41 GHz, 8.43 GHz to 7.32 GHz. To obtain FSS reflection phase of 180°, the physical dimension of cross dipole FSS can be varied therefore the absorbing band provided by Salisbury screen

can occur at the specified frequency. Consider for case with FSS l = 15 mm, as the reflection phase from the FSS is 180° at 9.41 GHz, the path length of 180° is required which is a 7.97 mm thick vacuum spacer. Note that absolute value of FSS reflection phase is included as the negative sign indicates out-phase. Therefore total phase of 360° is accomplished and a reflection null is occurred. If a thicker vacuum spacer is employed which bring more than 180° path length phase, the reflection null is expected to occur below 9.41 GHz. Note that the same vacuum spacer will provide different path length phase at other frequencies range then it may compensate the reflection phase from another FSS layer to create another reflection null. On the other side the total phase of 180° in the Salisbury screen absorber will produce a reflection peak.

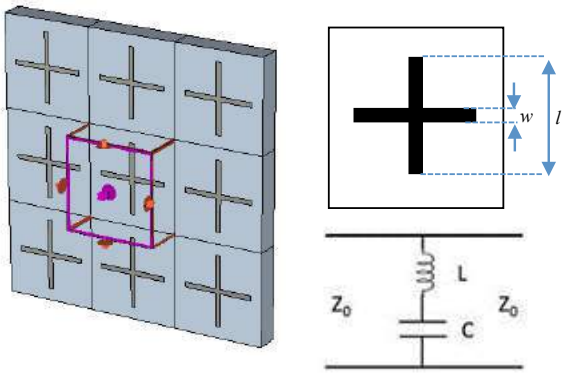

Figure 2 : Unit cell of cross dipole FSS

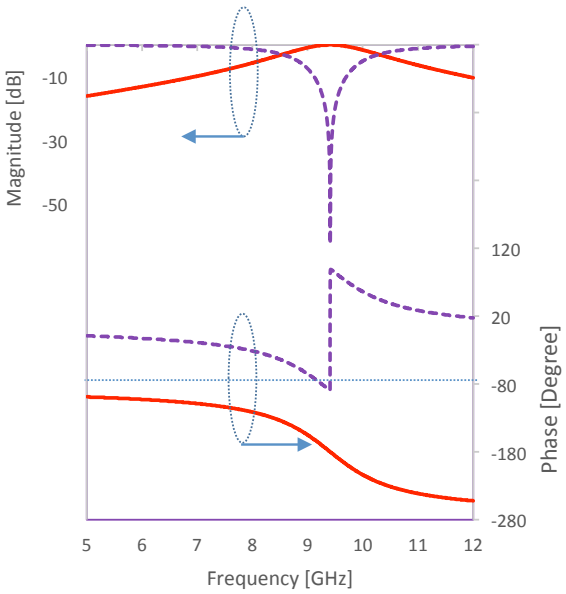

Figure 3 : Scattering parameters for Cross dipole FSS l = 15 mm where —— for reflection, S_{11} and - - - for transmission, S_{21}

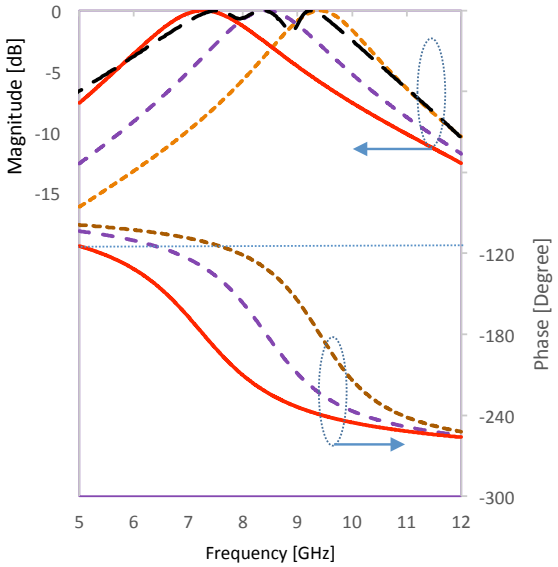

Figure 4 : Scattering parameters for Cross dipole FSS l = 15 mm (- - - - -) , l = 17 mm (- - -), l = 19 mm (——) and cascaded 3 FSSs (— —) mm for transmission, S_{21}

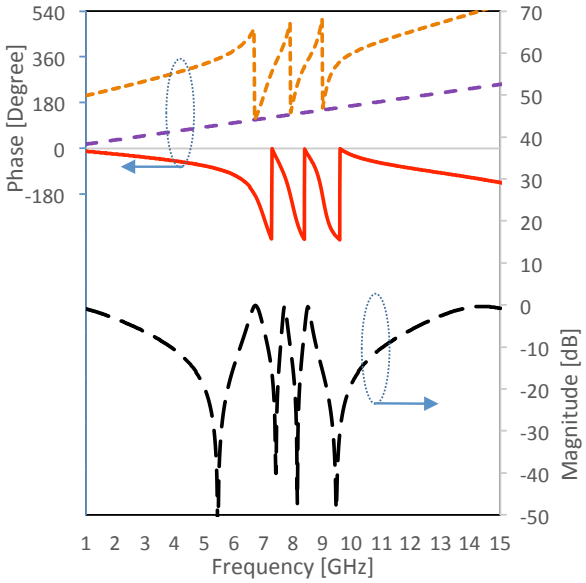

Figure 5 : Phase characteristic in a Salisbury screen, reflection phase, S_{11} for a cascaded FSS1 l = 15 mm, FSS2 = 17 mm, FSS3 l = 19 mm (——), path length phase in 7 mm thick vacuum spacer, (- - -) and total phase (- - - - -), and absorbing band of Salisbury screen absorber, S_{11} (— —) at normal incidence.

Consider for multilayer FSS in the construction of Salisbury Screen, the three layer of cross dipole FSS are cascaded with 1.5 mm separation. Fig. 4 shows that the

transmission characteristics of the cascaded FSS are slightly shifted due to the coupling between each FSS layer. If the FSS are separated to be more than a 1.5/λ, the coupling is not significant then the scattering characteristics of each FSS layer can be maintained. Fig. 5 shows that with 7 mm thick of vacuum spacer, additional path length phase is demonstrated to contribute 17° to 249° phase in frequency range of 1 to 12 GHz. Total phase given by the path length and the cascaded FSS determine the characteristic in the scattering parameters of in Salisbury Screen. The total phase of 360° is achieved to generate four reflection nulls at 5.5, 7.4. 8.1, 9.5 GHz. Here, the reflection phase from each FSS layer is not necessary to be 180°.

3. Fabrication and Measured Results

Multiband Salisbury screens was fabricated and measured to validate the design methodology presented in the previous section. Two layers of cross dipole FSS were fabricated on 1.6 mm thick FR4 substrate, $\varepsilon_r = 4.3$. The first FSS layer with $l = 0.5$ mm and the second FSS layer with $l = 7.5$ mm, and $w = 0.5$ backed by a solid metal plate. Both FSS layers were bonded directly. The manufacture of the Salisbury screen absorbers was completed by glueing the surfaces of a 5 mm thick foam spacer, to the patterned side of the FSS and a 400 Ω/square resistive textile sheet. The Salisbury screen with two cascaded cross dipole FSS layer was fabricated in 30 x 30 cm size. The reflection and transmission measurement were made in a semi anechoic chamber relative which was placed 50 cm distance from the aperture of a pair of standard gain horns which cover the frequency range 8 – 12 GHz. For transmission measurement, the FSS was placed between two antenna horns in a far field region. The reflection measurement was carried out by positioning Salisbury screen absorber in front of two horns placed side by side as shown in Fig. 6.

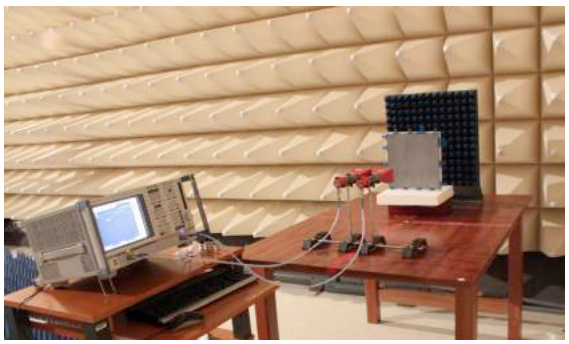

Figure 6 : Measurement setup for scattering parameters for Salisbury screen.

Fig. 7 illustrates the transmission magnitude of the fabricated cross dipole FSS. The FSS with $l = 7.5$ mm resonates at 11.14 GHz while FSS with $l = 6.5$ resonates at frequency 13.26 GHz. However it was observed that when the two FSS layers are attached together, the transmission magnitude produces dual resonances at 9.16 GHz and 12.5 GHz. This demonstrates a significant downward shifts in resonance frequencies because of strong coupling between two electrical closely separation. Both simulation and measurement are in a very good agreement.

Fig. 8 shows the absorbing parameters of constructed Salisbury screen at normal incident. Within 1 – 20 GHz frequency range the multilayer FSS generates three absorption bands of -10 dB bandwidth at 4.96 – 7.3 GHz (38.1%), 8.5 – 9.6 GHz (12.1 %) and 11.7 – 13.9 GHz and (17.2%). The reflection null occurred at 6.56 GHz, 9.1 GHz and 13 GHz due to the total phase of 360° was satisfied at these three conditions. Note that each reflection null was obtained due to reflection at particular virtual ground plane, the lowest reflection null was on the metal backed side, the middle reflection null was on the FSS layer, $l = 6.5$ mm and the highest reflection null on the FSS layer, $l = 7.5$ mm respectively. On the other side the reflection peaks were produced at 6.85 GHz, 7.76 GHz and 8.58 GHz when the total phase in the structure was 180°.

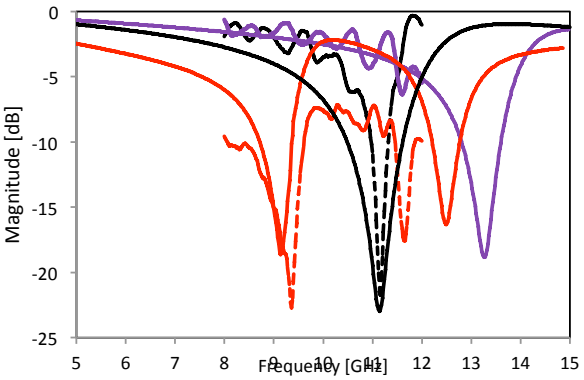

Figure 7 : Transmission magnitude for standalone cross dipole FSS $l = 6.5$ mm, simulated (——), measured (– – –) ; standalone cross dipole FSS $l = 7.5$ mm, simulated (——), measured (– – –) ; cascading both FSSs simulated (——), measured (– – –).

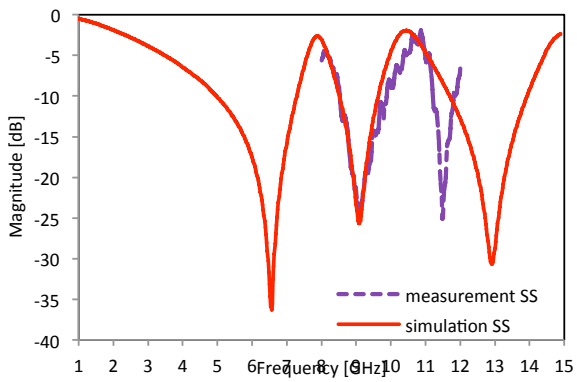

Figure 8 : Scattering parameters for Salisbury screen, simulation (——), measurement (– – –)

4. Conclusions

This paper has presented about phase interaction between path length phase and reflection phase by either a metal backed or an FSS. The concept has been explained in detail by integrating three FSS layers in the Salisbury screen. To validate the concept a prototype of Salisbury screen absorber with two layer FSS has been realised. In this paper the microwave absorbing properties of multiband Salisbury screen absorber design which is constructed using double layer FSS is investigated. The structure exhibits triple operating band where the -10 dB reflectivity bandwidth of a Salisbury screen operating at normal incidence. Reflectivity predictions for normal incidence are shown to be in close agreement with bistatic measured results over the frequency range 8 - 12 GHz.

Modeling, Computational Techniques and Verification of Theory

Application of the Mathieu's equation for an analysis of photonic crystal – supported surface electromagnetic waves: *s*- and *p*-polarization cases

E. Rostova, S. K. Sekatskii*, and G. Dietler
Laboratoire de Physique de la Matière Vivante, IPHYS, BSP, Ecole Polytechnique Fédérale de Lausanne, CH1015 Lausanne, Switzerland

*corresponding author: Serguei.Sekatski@epfl.ch

Abstract- Recently, we showed that an analogy between a 1D Photonic Crystal and a structure with a sine-modulated refraction index enables to apply the Mathieu's differential equation for an analysis of Photonic Crystal - supported surface electromagnetic waves [1]. Here we present the detailed analysis for *p*- and *s*-polarizations and show that the *s*- polarization case is described exactly by the Mathieu's equation while that corresponding to the *p*-polarization gives rise to a slightly modified equation.

In a recent paper [1] we discussed the general principles of use of the famous Mathieu's differential equation [2] to analyze the 1D photon crystal (PC) – supported electromagnetic waves and to design appropriate structures. Now we give a detailed analysis for both *s*- (TE) and *p*-polarization (TM) cases: it is well known, that metal-free PC-based systems can support electromagnetic waves of both polarizations, and their co-existence is indeed very important for sensor applications to unambiguously separate surface and volume effects [3].

Geometry of the problem is shown in Fig. 1. Let us start with the *p*-polarization. We are interested in the surface modes (electromagnetic waves) strongly confined at the photonic crystal surface and decaying exponentially away from the surface. This property of the surface modes immediately prescribes the choice of the function *f(z)* in the most external medium with the dielectric constant ε_1 as an exponentially decaying function $f_1(z) = \exp(S_1 z)$ for *z<0* and $S_1 > 0$. Here $\vec{H} = \vec{H}_0 f(z)\exp(i\omega t - i\beta x)$ is a magnetic field propagating along the *Ox* axis and for all media $S_i^2 = \beta^2 - \varepsilon_i k^2$ (Fig. 1A), k is a wave number in vacuum, and β is a complex propagation constant. We suppose that our PC with a period *L* is a medium having the sine-modulated dielectric permeability $\varepsilon_3(z) = \varepsilon_{av} + \Delta\varepsilon\cos(2\pi z / L)$ while its magnetic permeability, as it usually takes place in optical frequency range, does not depend on the coordinate. The full forms of the wave equation in a medium are (see, for example, [4]): $\nabla^2\vec{E} - \mu\varepsilon\dfrac{\partial^2\vec{E}}{\partial t^2} + (\nabla\ln\mu)\times(\nabla\times\vec{E}) + \nabla(\vec{E}\cdot\nabla\ln\varepsilon) = 0$,

$\nabla^2\vec{H} - \mu\varepsilon\dfrac{\partial^2\vec{H}}{\partial t^2} + (\nabla\ln\varepsilon)\times(\nabla\times\vec{H}) + \nabla(\vec{H}\cdot\nabla\ln\mu) = 0$, and for our particular case, the equations describing the appropriate magnetic field inside the PC is reduced to the following equation, which is *not* that of Mathieu (but can be written as Hill's equation):

$$\frac{d^2H_y}{du^2} + \frac{2\Delta\varepsilon\sin(2u)}{\varepsilon_{av} + \Delta\varepsilon\cos(2u)}\frac{dH_y}{du} + (a - 2q\cos(2u))H_y = 0 \qquad (1).$$

Considering for the *s*-polarization case an electric field propagating along the *Ox* axis $\vec{E} = \vec{E}_0 f(z)\exp(i\omega t - i\beta x)$, we in a similar fashion obtain the Mathieu's equation

$$\frac{d^2 E_y}{du^2} + (a - 2q\cos(2u))E_y = 0 \qquad (2).$$

For both cases here $u = \pi z / L$, $a = -\beta^2 L^2 \pi^{-2} + \varepsilon_{av} k^2 L^2 \pi^{-2}$, $q = -\frac{1}{2}\Delta\varepsilon k^2 L^2 \pi^{-2}$.

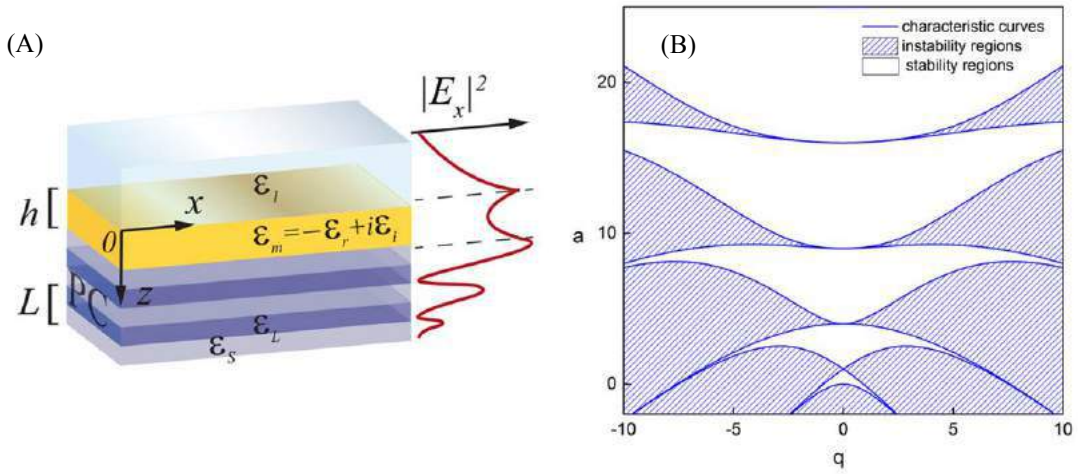

Figure 1. (A) A schematic of the investigated structure: a metal layer surrounded by a dielectric and a photonic crystal. The red line corresponds to the surface wave in the photonic crystal and the surface plasmon at the metal interface. Metal intermediated layer is not necessary present and can be absent (e.g. for the *s*-polarization case) (B) A stability diagram for the Mathieu's equation: the lines display the periodic Mathieu functions, the regions marked "U" belong to the instability regions (*a* and *q* here are the parameters in the Mathieu's equation), adapted from [2].

The procedure how to find the appropriate solution describing the photon crystal – supported electromagnetic waves (that is to fulfill the necessary conditions of continuity of tangential magnetic and electric fields), has been described in [1]. It rests the same, but now for *p*-polarization exponentially decaying to the infinity solution of eq. (1) rather than that of the Mathieu's equation (2) should be taken. Certainly, this modifies the concrete parameters to be applied for specific structures design, as well as the stability and instability regions shown in Fig. 1B. All these questions are analyzed in the present submission. In particular, we show that for real experimental situation neither the difference between two aforementioned differential equations nor that between their solutions and conditions necessary to ensure the existence of PC-supported surface electromagnetic waves are large.

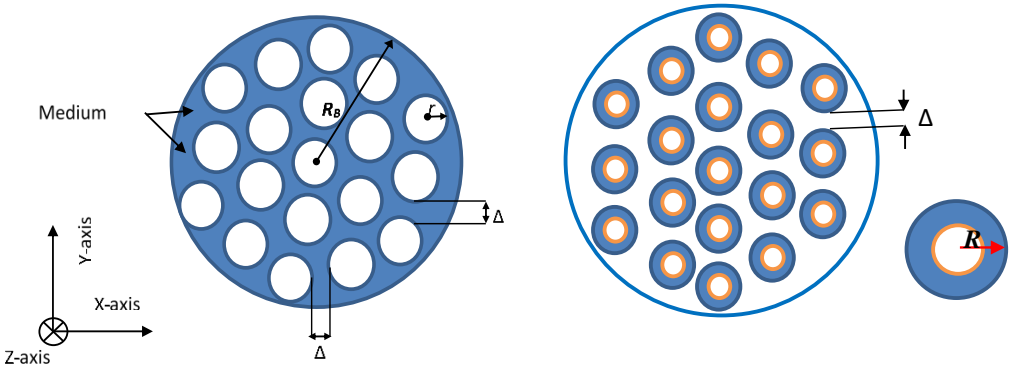
Abstract-The performances of bundle carbon nanotubes (BCNTs) and bundle carbon nanotubes composite (BCNTs-composite) materials for the antenna applications in the terahertz and gigahertz frequency ranges are evaluated. The performances of these bundles are compared based on the electromagnetic properties of their dipole antennas, where the cross sections of bundles are circular geometry. Furthermore, comparative studies are performed to show the size and frequency dependent of these bundles.

In this work, the BCNTs contains (N) a number of metallic single-walled carbon nanotubes SWCNTs which are identical have the same dimensions, radius (r) and length (L_S). While, the BCNTs-composite contains (N) a number of SWCNTs coated by a thin layer of another materials (t) such as, graphite or copper materials, radius ($R = r + t$). Both bundles BCNTs and BCNTs-composite have configuration characterized by closely packed structure with a circular geometrical structure. Also, all tubes are aligned parallel along the axis of bundle and the lattice constant of the bundles is (Δ) to personify the distance between each two contiguous walls of SWCNTs and SWCNTs-composite. The minimum required radius of the cylinder that contains all SWCNTs or SWCNTs-composite is the radius of bundle (R_B). Figure (1) explains the sketch of BCNTs and BCNTs-composite with a circular geometrical structure.

The mathematical model of SWCNTs-composite structure derived based on the mixture rule [1], the simple parallel model of the radial interface of coating material and SWCNT for a simple parallel model of the radial interface of coating material and SWCNT. The general formula of the electrical conductivity of

SWCNTs-composite material was presented in Equation (1).

$$A_{Compisite}\sigma_{Structure} = C_{SWCNT}\sigma_{SWCNT} + A_{Coat}\sigma_{Coat} \quad (1)$$



(a) (b)

Figure 1: (a) Schematic configuration of BCNTs and (b) Schematic configuration of a BCNTs-composite

The simulation results for both bundles are compared between each other and with the BCNTs which are presented in previous research [2]. These comparisons carried out based on their electromagnetic behaviors such as, S11 parameters response with various numbers of tubes included in bundles, efficiency, gain and directivity. The simulation results of BCNTs with different numbers of SWCNTs are illustrated in Figure (2).

Abstract- This paper presents a dual band circularly polarized wearable textile patch antenna slotted with split-ring for WBAN application. The antenna consists of a patch, fed through coaxial probe and is designed to radiate in two bands, 1.8 and 2.6 GHz. A split-ring slot is integrated onto the top radiator. The antenna achieved a 10-dB impedance bandwidth of 3.9 % at 1.8 GHz and 15 % at 2.6 GHz, respectively. The 3-dB axial-ratio bandwidths are 3 % and 13 % at 1.8 GHz and 2.6 GHz, respectively, with a maximum gain of 4.1 dB.

With the fast growth of wireless systems, the demands for reliable and efficient integrated wearable system are increasing. In biomedical applications, for example, researchers have employed wearable health monitoring systems, such as VTAM (Clothes for Teleassistance in Medicine Project), the European Wearable Healthcare System (WEALTHY) and LifeShirt [1]. In addition, these wearable health monitoring systems incorporate enablers which are capable of transmitting collected health information to the healthcare personnel for further diagnosis. This long range transmission at high data rates can be achieved through the established communication networks, e.g., the Global System for Mobile Communication (GSM) and fourth Generation Long Term Evolution (4G-LTE).

To achieve circular polarization in textile patch antennas, several techniques have been introduced, e.g. by annular ring slots [2], single-feed aperture coupled slots [3] and coplanar waveguide feeds (CPW) [4], [5]. The CPW feed technique is especially effective due to its better tolerance on difference body's conditions and it consists of single layer of metal usage. However, the main disadvantage of CPW-fed based technique is the absence of a full ground plane on its reverse side, thus causing higher frequency detuning effect due to the body coupling when the antenna is placed in its vicinity. To solve this, a novel wearable circularly polarized textile antenna slotted with a Split Ring (SR) for Internet-of-Thing (IoT) and home-based wireless wearable healthcare sensing system is presented. The antenna is capable of providing dual band coverage for the entire 1.8 GHz (f_1) and 2.6 GHz (f_2) Long Term Evaluation (LTE).

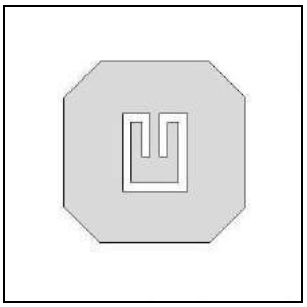

Figure 1: Structure of SSR textile antenna

The simulated 10-dB impedance bandwidths are 3.9 % (from 1.78 to 1.85 GHz) and 15 % (from 2.47 to 2.84 GHz), as shown in Figure 2a. The axial ratio is an indicator of the quality of circular polarization. The 3-dB axial-ratio bandwidth, which is an indicator of the quality of the circular polarization are 3 % (from 1.78 to 1.85 GHz) and 13 % (from 2.47 to 2.84 GHz), respectively. Figure 2b shows the effects of changing the width of split-ring, *w*, from 1 to 5 mm on the antenna resonance. When the *w* increases, the impedance bandwidth is enhanced and the frequency band is shifted down. This change also results in a variation in f_1, where the resonant frequency is shifted to the right when the *w* value increases. Thus, the best 10-dB impedance bandwidth is achieved when *w* is 2 mm. The maximum realized gain for the proposed antenna is 4.1 dB.

Abstract- Paper present a reduced size of patch loop antenna is proposed on glass-reinforced epoxy laminate sheets substrate with copper conductive as a microstrip line for wireless power transfer purpose. Single square loop antenna is designed on each of front and back FR4 layers at 13.56MHz to optimize the used of near-field communication that already embedded in almost middle and high end smartphone. An optimized antenna is able to achieve 13.9% wireless transfer efficiency improvement with 47% size reduction.

1. Introduction

Mobile devices become highly demanding in the evolution of high-end technology. Researchers gain an interest on recharging the batteries wirelessly to enable mobility and inductive coupling is preferred due to its simplicity and safety. This technology already implemented on some contactless transactions applications using RFID and NFC. NFC frequency, 13.56MHz is selected to maximize the benefit of near-field communication (NFC) that available in most smartphones. Therefore, NFC can be used not limited only to wireless data transfer but also for wireless energy transfer (WTE) purpose [1]. Various studies have been done insensitivity using low-cost glass reinforced epoxy laminated boards (FR 4) [2-4]. In WET, wireless transfer efficiency (WTE) is the most important factor to be focused. In short, large size of antenna will offer higher WTE rather than small antenna. However, increasing size of antenna will limit the mobility of the device itself. This paper presents the reduced size of single square loop antenna compared to the initial design. The performance of the antenna will be analyzed and discussed. The reduced size of antenna that offers performance at least equal to initial design is expected at the end of the research.

2. PLA Design and Simulation Results

This WET system use identical antennae as transmitter and receiver as shown in Figure 1(a). Figure 1(b) shows the initial design of antenna configuration. The antenna designed on 80mm x 80mm FR4 with antenna side length, ws_1 = 60mm. Microstripe line wide, wl_1 = 0.5mm, port gap, pg_1 = 10mm and port length, lp_1 are being used. WTE of 44.5% is recorded at 13.56MHz with 50mm distance between transmitter and receiver. Figure 1(c) shows the proposed reduced size of antenna that can operate without any performance degradation. Designed on 50mm x 50mm FR4, side length, ws_2 = 30mm, microstripe line wide, wl_2 = 2mm, port gap, pg_2 = 10mm and port length, lp_2 are used as parameters. Figure 2(a) shows the size of wl_2 that will yield WTE larger than the initial antenna design. Referring to Figure 2(b), the proposed antenna offers WTE = 50.7% with 47% size reduction, which is 13.9%

performance improvement. The results show that the reduced antenna at almost half size can works even better than the original size of antenna version.

ilmanjais86@gmail.com

Abstract-This paper presents a scanning and tracking system based on received signal strength indication (RSSI). Deployed raspberry-pi (Rpi) is used as a mechanism to control reconfigurable receiver ability and as a tracking decision maker based on captured incoming RSSI. The proposed prototype is verify by the obtained real-time experimental and found as ±4° and angel error for mode II and III of reconfigurable receiver. Hence, this work validates Rpi as a mechanism to control reconfigurable receiver ability of RSSI scanning and tracking system modeling with minimum angle error.

1. INTRODUCTION

We proposed a scanning and tracking system modeling based on received signal strength indication (RSSI) deployed by raspberry-pi as a switching control mechanism in this paper, based on the related research works [1]–[4]. The scanning and tracking system model is developed by own solitary reconfigurable receiver cooperate with SZ05 ZigBee Module. The core of the proposed system modeling is configured with a single board computer (SBC) raspberry-pi (Rpi) is set as a controller and RSSI processing module. Rpi has limitation in terms of CPU and memory required to develop the algorithm to scan incoming RSSI, process captured RSSI and decision making to control solitary reconfigurable receiver. The main contribution of this work is to introduce an algorithm for scanning RSSI and decision making which will control the switching reconfigurable receiver simultaneously to track the strongest RSSI. The proposed prototype for scanning and tracking system is presented in Fig. 1(a). The scope is limited to the study of the receiver end only. Section 2 and 3 presents the system structure and performance verification respectively.

2. SYSTEM STRUCTURE & MODELING

The proposed prototype is configured by three (3) major components: a single board computer (SBC), SZ05 ZigBee RF Module and a developed reconfigurable receiver as shown in Fig. 1(a). A Python program developed an algorithm was sniff and process the incoming RSSI from various transmitters. Verification of this proposed prototype based on angle error tracking estimation is compared with initial experiment setup. Effect of distance coverage between transmitter and receiver toward angle error tracking estimation is also obtained by applying equation 1.

$$P_R = P_T + G_T + G_R - FSPL \quad (1)$$

Where P_R and P_T are the received power and transmitted power; G_T and G_R are the gains of both receiver

and transmitter antennas; FSPL represents free space path loss. The findings and verification of the proposed scanning and tracking system modeling are presented in section 3.

3. PERFORMANCE VERIFICATIONS & ANALYSIS

The experimental angle error estimation is presented in Fig. 1(b). Five (5) angular positions are considered with 30° angular separation. At each position, angle error tests were performed. The result shown in ±4° angle error between region -30° and 30° because proposed reconfigurable receiver can achieve maximum tilt angle of ±30°. Effect of distance between receiver and transmitter toward angle error tracking estimation are demonstrated in Fig. 1(c). Referred equation (1), the received power inversely proportional to the distance. Thus, the angle error increases with the gap increment between receiver and transmitter.

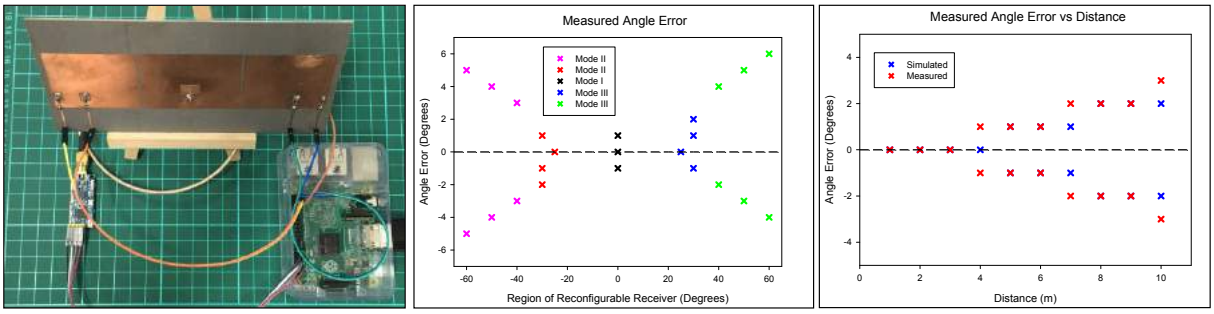

Figure 1:(a) The proposed prototype RSSI scanning and tracking system modeling. (b) Measured angle error by region. (c) Measured Angle Error Result vs Distances.

4. CONCLUSION

A scanning and tracking system modeling are presented in this paper. From the findings, it is obvious that, the proposed prototype can perform the scanning and tracking system with low angle error tracking estimation. Hence, the proposal can meet the requirement Rpi as a mechanism to control reconfigurable receiver in order to reduce angle error tracking and enhanced scanning and tracking coverage. However, this prototype possesses significant indoor experimental result operated at ISM band and can be beneficial in near-field indoor scanning and tracking system.

Abstract— Dynamic analysis of hexagonal cellular lattice structures with geometric and material irregularities is considered. Effective in-plane elastic properties for steady-sate harmonic response of the system is discussed. A dynamic stiffness based approach in the frequency domain is developed for this purpose.

Two-dimensional lattice metamaterials have gained considerable attention in the recent years as an advanced material due to its capability of meeting high-performance requirements. The applications range across different length scales such as honeycomb core in sandwich structures to nanomaterials like graphene and boron nitride nanosheets. This paper concerns elastic and dynamic behaviour of such metamaterials.

Equivalent static elastic properties of regular cellular solids [1] using an unit cell approach is the most common approach. However, the underlying analytical methods cannot be directly extended to dynamic analysis or when there are spatial irregularities in the cell geometry or material properties. For predicting equivalent elastic properties of irregular lattices or dynamic analysis, direct finite element simulation has been the predominant method of choice [2]. This is computationally expensive, but perhaps most importantly, does not provide intuitive understanding provided by analytical formulations available for static analysis of regular lattices [1]. We propose a dynamic stiffness based approach in the frequency domain. Individual elements of the lattice have been considered as damped Euler-Bernoulli beams with the equation of motion

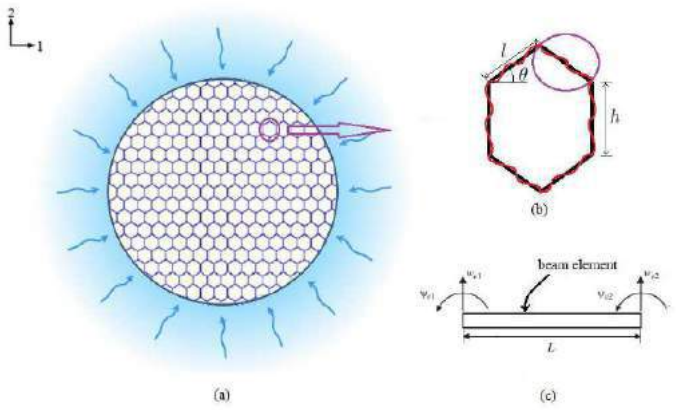

Figure 1: (a) Typical representation of a hexagonal lattice structure in a dynamic environment (e.g., the honeycomb as part of a host structure experiencing wave propagation). (b) One hexagonal unit cell under dynamic environment (c) A dynamic element for the bending vibration of a damped beam with length L. It has two nodes and four degrees of freedom. The displacement field within the element is expressed by complex frequency dependent shape functions.

$$EI\frac{\partial^4 V(x,t)}{\partial x^4} + c_1\frac{\partial^5 V(x,t)}{\partial x^4 \partial t} + m\frac{\partial^2 V(x,t)}{\partial t^2} + c_2\frac{\partial V(x,t)}{\partial t} = 0 \tag{1}$$

Here EI is the bending rigidity, m is mass per unit length, k is the elastic filler modulus, c_1 is the strain-rate-dependent viscous damping coefficient, c_2 is the velocity-dependent viscous damping coefficient and $V(x,t)$ is the transverse displacement. The length of the beam is assumed to be L.

Exact closed-from expressions for effective in-plane elastic moduli of the entire irregular lattice have been derived in the frequency domain. By conducting a limiting analysis, it was shown that the derived values reduced to the classical expressions [1] when the frequency becomes zero (static case). Asymptotic values and convergence of the frequency dependent homogenized properties are discussed for the case when a very large number of cells are present. The closed-form expressions are validated against detailed finite element simulations.

High Efficient Plasmonic Spectral Imaging using Algorithmic Data Compression and Recovery Techniques

W. Y. Jang[1, 2*], Z. Ku[2], J. Park[2], A. Urbas[2], and M. Noyola[2]

Abstract-We report the progress on developing the next generation IR imaging strategy based on plasmonic sensor incorporated by the data-efficient sensing algorithm with compression and recovery techniques. The geometry of the plasmonic coupler was modified to shape the sensor's spectral sensitivity in order to bring the multispectral imaging capability. The technique termed the band-compressive algorithmic spectrometer was incorporated in the plasmonic sensor to compress required number of bands (by minimum band selection) and successfully reconstructed high resolution spectral contents.

Summary –*n*The surface plasmonic structure [1] has been reported as a spectral tuning element for IR imaging application because of its ability to shape the sensor's spectral sensitivity or responsivity by controlling the interaction of light when coupled to the sensor structure. The data processing technique termed the band-compressive algorithmic spectrometry (BAS) [2] was incorporated in the design of plasmonic IR sensor to find sensor's minimum spectral requirements associated with signatures of interest. Key concept behind the BAS is the compressive spectral sensing [3], which effectively compresses the number of required plasmonic spectral sensitivities thereby finding a minimum and essential bandset to be used for recovering signatures of interest. Another key step is the reconstruction or recovery of spectral signatures using a minimum set of plasmonic bands. The reconstruction is done by linearly synthesizing a collection of raw plasmonic output images with a set of weights prescribed by the BAS. This synthetic image reconstructs radiations from targets at a specific wavelength. The reconstruction step is simply repeated for multiple signatures of interest by applying different sets of weights, producing a series of synthetic images. Recently a plasmonic structure was modeled by using a square coaxial aperture (SCA) array and was coupled on a state of the art HgCdTe (MCT) sensor platform operating in the longwave IR (LWIR). By the parameter study, twenty six spectral sensitivities of a plasmonic MCT (P-MCT) sensor were produced as a pitch size of SCA structure was varied from 2.3 to 3.5 μm shown in Fig.1a. The spectral tunability was observed with a peak shift in an 8-12 μm range despite having some overlaps among engineered sensitivities. To realize the P-MCT sensor in actual fabrication, the BAS algorithm was performed to select the subset from original 26 spectral sensitivities based on three following requirements: (1) select 9 bands or less, (2) reconstruct spectral signatures for at least 40 different wavelengths and (3) produce the reconstruction error with 20% or less. As shown in Fig. 1a, the BAS selected a minimal subset with 9 P-MCT bands with a good compression ratio of 9/26 from 26 original bands. The BAS designed narrowband synthetic spectral filters centered at 40 distinct wavelength locations by the weighted synthesis with 9 selected bands. Each synthetic filter represents a signature of interest. This demonstrates an excellent spectral recovery with a 40/9 (i.e., over ×4) reconstruction ratio. Also the designed synthetic filters showed a fine resolution of 250 nm

full-width half maximum and a reconstruction error of 14% in average. Designed synthetic filters were applied to the test scene for extracting high resolution LWIR spectral signatures. Series of synthetic images in Fig. 1b show successful reconstructions of distinct spectral signatures at multiple wavelengths.

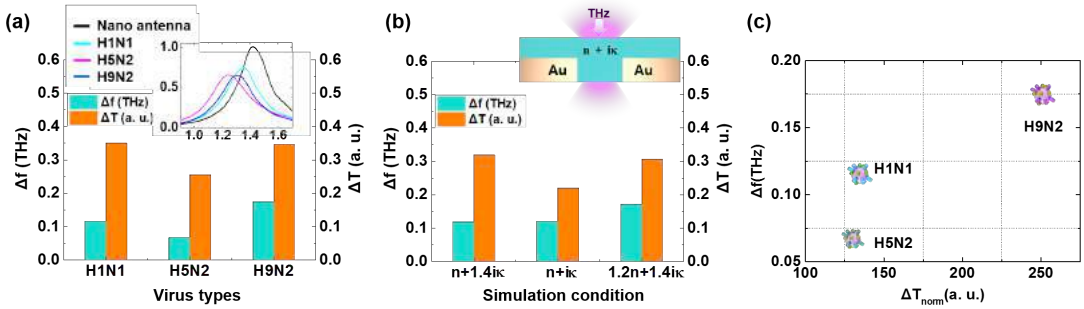
Abstract-Optical characteristics of three different subtyped Avian influenza viruses were measured using nano scaled metamaterial sensing chip based terahertz (THz) time-domain spectroscopy (TDS) system. The enhanced THz field via metamaterial structures can lead to increase absorption cross section of the targeted viruses, in turn, increase the detection sensitivity. The three virus samples can be discriminated by measured optical parameters including normalized transmittance change and shifted frequency at maximum transmittance, assigning subtype of viruses.

Recently, metamaterial sensing chip based terahertz (THz) detection technique has been developed for highly sensitive and selective detection of various bio- and chemical-molecules overcoming the limit of sensitivity of general THz time-domain spectroscopic (TDS) systems. Especially THz spectroscopy with various bio-materials have been attracted great attention, because many intra- and inter-molecular vibration modes of bio-materials such as protein and DNA etc. are located within THz range. One of important viruses as a highly pathogenic Avian Influenza (HPAI), which should be intensively studied for quick and accurate field diagnosis, was investigated in terms of the optical characteristics assisted by the THz metamaterials.

In this research, we analyzed THz optical characteristics of AI viruses using nano-slot-antenna sensing chip and applied them for distinguishing subtype of AI viruses and quantification. In previous studies [1, 2], the sensing chip was designed for increasing of absorption cross section of the targeted sample molecules that is related to the transmitted THz near field enhancement [3]. In contrast to earlier studies, it was noted that there is no specific absorption feature at the reliable frequency for the AI viruses, since they are composed of complex combination of surface proteins as hemagglutinin and neuraminidase. The optical characteristics measurement, therefore, were performed via multi resonances nano antenna sensing chip with a log-periodic alignment [4]. Most sensitive frequency, 1.31 THz was selected by the transmittance measurements with the multi resonance nano antenna sensing chip, then applied for further experiments.

The transmittance spectra for the three subtypes of virus samples such as A/NWS/33 (H1N1), A/wild bird/Korea/K09-652/2009 (H5N2), and A/Korean native chicken/Korea/K040110/2010 (H9N2), are shown in Fig. 1(a) with differences in transmitted intensity (ΔT) and shifted resonance frequency from each fundamental resonance peak of bare nano-slot-antenna (Δf). Each virus sample shows a distinct transmission change and a change in resonance frequency associated with different surface protein and unique strain of it. Further analysis of THz optical characteristics for these viruses was performed through finite-difference time-domain method (FDTD) simulation and the results are shown in Fig 1(b). In addition, the experimental results of the concentration dependent measurement of a virus are well consistent with the simulation results. Depending on

the assigned optical properties, including complex refractive indices, the examined viruses can be classified according to their subtypes (Fig. 1(c)).



Figures 1. (a) The difference in transmitted intensity (ΔT) and shifted resonance frequency from each fundamental resonance peak of bare nano-slot-antenna (Δf) for three subtype (H1N1, H5N2, H9N2) of virus samples are represented. Inset is transmittance spectrums of three samples and bare nano-slot-antenna. **(b)** FDTD simulation results of the differences in transmitted intensity (ΔT) and shifted resonance frequency (Δf) with various composition of dielectric constants (n and κ) are shown. Inset shows a used geometry for simulation. (c) Mapping of classified viruses in terms of ΔT and Δf.

The THz spectra measured for various virus samples are analyzed as effective optical properties, and FDTD simulations show that the spectral changes can be represented with the optical properties of the sample through the nano-slot-antenna. According to these results, nano-metamaterial based THz spectroscopy can provide a possibility of rapid yet highly accurate solution for discrimination and quantification of AI viruses in non-contact and label-free manner.

Abstract- We measure the image Mueller matrix (MM) of human cancerous cells. We apply three different decomposition and transforming methods (Polar decomposition, Mueller matrix transformation and differential decomposition) over these matrices in order to look for an adequate polarimetric parameter that allow us to characterize and differentiate these tumor cells. Due to the intrinsic difficulty of applying polarimetry to these kind of samples we set out two proposals in order to enhance the sensitivity of the polarimetric parameters.

In recent years, imaging polarimetry has become a field of increasing interest in diagnosis [1] because of its non-invasive nature and its potential to identify abnormal properties in propagating media. Specifically, polarized light has been used to perform studies over tumor tissues [2] such as colon, cervix, thyroid or skin. When light interacts with matter its polarimetric properties are affected by the nature of the material. Consequently, the analysis of polarimetric parameters should give information about the tissue and processes that take place therein.

MM contains all the information relative to polarization for any given working conditions. In order to reveal useful information of the system, there are two important lines of work: one consists in selecting the most adequate conditions (geometry of sample and setup, wavelength, etc). The other one is the adequate manipulation of the MM. Some methods have been widely used to extract the information given by the Mueller matrix (MM), transforming it into useful parameters that may contribute to providing a physical interpretation.

The experimental device used for the measurement of the MM in this work consists basically of a Dynamic Rotating Compensator Polarimeter with a tunable laser source and a microscope objective (Figure 1).

We are focused on the analysis of human cells corresponding either to normal or tumor tissues. We have performed imaging polarimetry and measured the transmission MM of such samples. Over these matrices we have applied three different transforming methods for its analysis. Namely: polar decomposition (MMPD) [3], Mueller matrix transformation (MMT) [4] and differential decomposition

(MMDD) [5], looking for useful parameters that allows us to better characterize the cells and, eventually, to identify them.

Tumor and normal cells present very small differences in their refraction index [6]. This fact, together with its main transparent nature, translates into a low polarimetric activity of the samples, making a challenge to apply polarimetry to the recognition and study of tumor cells. Because of this, we consider two lines of actin: 1) Use of some statistical analysis over the most significant parameters taking advantage of the high number of measurement contained in an image and 2) Try other configurations like dark field in order to make the parameters more sensitive to the small changes in the cells.

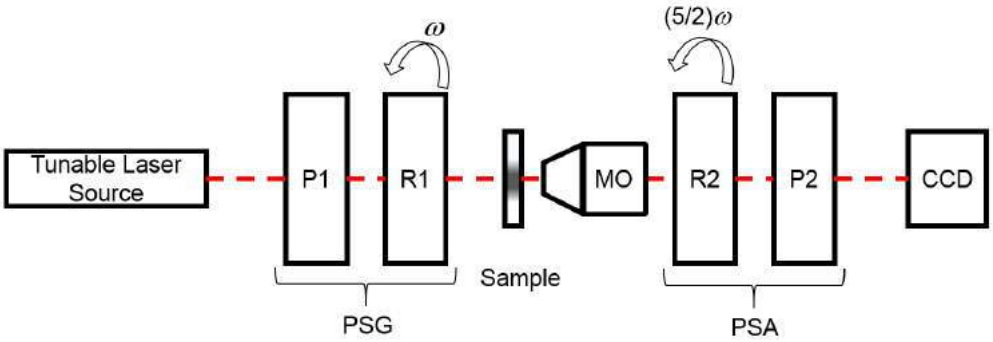

Figure 1. Schematics of the imaging polarimeter. The light source is a supercontinuum laser, P1 and P2 are polarizers, R1 and R2 are retarders (quarter waveplate), MO is the microscope objective, PSG and PSA stand for Polarization State Generator and Analyzer respectively.

Abstract-Nanofabrication techniques is essential for exploring nanoscience including nanophotonics, plasmonics and optical metamaterials. Recently, 3D nanofabrications have been actively investigated to make sophisticated nanoscale 3D metamaterials and metadevices, but it is still challenging to fabricate elaborate 3D nanostructures. In this work, ultra-high accurate and precise electron beam lithography overlay process is developed for fabricating elaborate nanometers-sized 3D metamaterials and metadevices. Sub-20nm alignment accuracy and over-75% repeatability are achieved through well-defined alignmarks and specific calibrators.

Metamaterials, artificially fabricated materials composed of sub-wavelength unit cells, have enabled unprecedented and extraordinary phenomena such as invisibility cloaking, negative refraction and super-resolution imaging. Especially working frequencies of metamaterials are demonstrated by the size of unit cells called meta-atoms. By shrinking the size of the meta-atoms, the operating frequency of metamaterials have moved to higher frequencies. Now, thanks to nanometer scale fabrication technologies, we can fabricate "optical metamaterials" working at near-infrared, visible, or ultra-violet regions. So far, most of the optical metamaterials have been fabricated on 2D substrates in a forms of planar nanostructures called metasurfaces [1]. Various interesting physics and applications of metasrufaces have been reported, but there are several drawbacks arising from their own 2D structures, such as anisotropic and inhomogeneous properties, polarization and incident angle dependency. In order to tackle these issues, many researchers are investigating 3D nanofabrication technique for 3D metamaterials including, but not limited to, direct laser writing [2], transfer printing [3] and bottom-up based fabrications [4, 5]. In this abstract, I will discuss our efforts in realizing 3D metamaterials and metadevices based on specially-developed ultra-accurate and precise electron beam lithography (EBL) overlay process showing sub-20nm alignment error and over-75% reproducibility. First, I will present the method of highly accurate EBL overlay process including the strategy for designing alignmarks and calibrator and accuracy verifications experiment [6]. Second, I will present the design and fabrication methods for two kinds of 3D metamaterials. One is stacked 3D metamaterials for asymmetric transmission of linearly polarized light like optical isolator. The other one is 3D chiral induced negative index metamaterials working at optical frequencies. Finally, I will present the design and fabrication method of 3D metadevices, which are mode-multiplexed nanophotonic modulators and waveguides system [7]. The mode-multiplexed modulators can suggest new strategy for enhancing functionality per area in the integrated photonic and optoelectronic devices. I believe our efforts for

making a truly 3D metamaterials and metadevices will lead to novel and practical applications of metamaterials in optics, nanoscale science and engineering.

Abstract A self-assembly of gold (Au) nanostructures was employed over a dielectric spacer and an underlying bottom Au layer for a plasmonic refractive index (RI) sensor. Its exposures to distinct surrounding media with different refractive indices result in visible color changes due to plasmonic resonance shifts in the reflectance that are attributed to the changes of the surrounding RI. The resonance absorption occurred at λ = 550.3 nm, 634.7 nm, and 725.3 nm for the RI's of n = 1.000, 1.343, and 1.516, respectively.

Surface plasmon resonance (SPR), collective oscillation of electrons at the interface between metal and dielectric material, has attracted great attention both in scientific and commercial fields for sensing purpose.[1] A conventional SPR sensing system not only requires a huge and expensive Kretschmann configuration but also experiences the difficulty of tracking the changes of the RI in local areas.[2] Instead, localized surface plasmon resonance (LSPR) is advantageous in tracking the RI changes around metallic nanostructures that act as hot-spots of highly localized electromagnetic wave. [3] However, LSPR sensors by serial fabrication processes such as electron beam lithography, and focused ion beam is highly limited on a large-area application.[4, 5] Besides they still require particular sensing equipment to monitor the SPR phenomena.

Here, we report visible RI sensor platform which enable to monitor changes of the RI around the Au-nanostructures with simple and easy fabrication processes for a large-area application. The proposed RI sensor composed of underlying Au layer and self-assembled Au nanostructures, separated by CYTOP (n = 1.4) insulating film (inset; Fig. 1a). The Au nanostructures over the hydrophobic CYTOP layer is achieved by control of deposition conditions, followed by vertically etching process leaving inert Au-nanostructures atop the nano-pillar CYTOP structure. The surrounding medium such as gas (Fig. 1b) or solvents with distinct RI values (Figs. 1c and 1d) infiltrates into etched empty spaces of the insulating layer. This allows changes of effective RI around the Au-nanostructures, resulting in visible color changes. During the measurement process, air (n = 1.000), anisole (n = 1.343) and acetonitrile (n = 1.516) were selected for different refractive indices. The resonance absorption appears at 550.3 nm for the surrounding medium of n = 1.000, 634.7 nm for n = 1.343, and 725.3 nm for n = 1.516 (Fig. 1e).

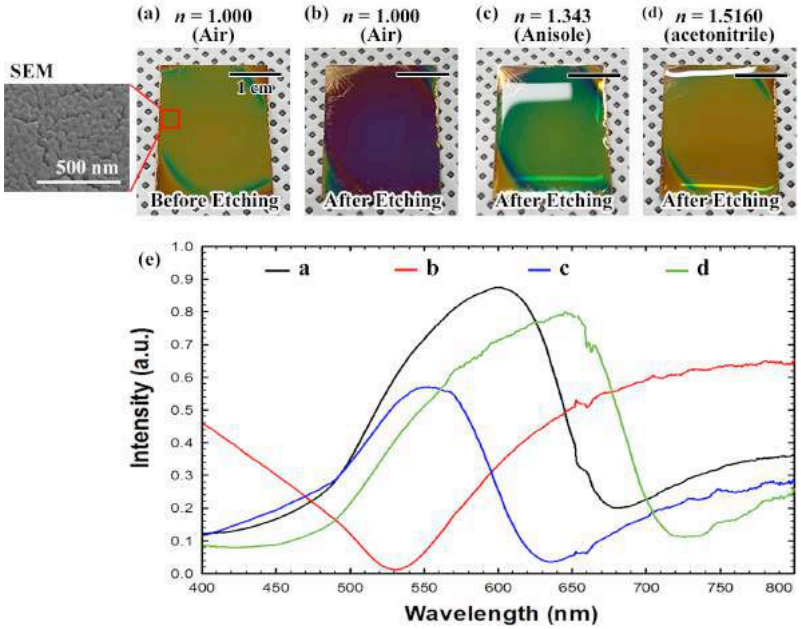

Figure 1: Sample images before (a; inset: SEM image of red square zone) and after O_2 plasma etching process (b - d) in different surrounding media: (b) n = 1.000; air, (c) n = 1.343; anisole, and (d) n = 1.516; acetonitrile. [*] corresponding author: dybyun@skku.edu

Abstract - We demonstrated the capability of terahertz metamaterial sensor fabricated using electrohydrodynamic jet printing for the accurate and on-site detection of microorganism (yeast). The ESRR unit structures could be printed on a large area. It was shown that the metamaterial sensor fabricated on a flexible polyimide film had higher sensitivity by more than six times, due to the low refractive index of the PI substrate and the extremely thin substrate thickness which lowers the effective index further.

THz metamaterials with the gap structures characterized by strongly localized and enhanced fields are able to provide sensitive detection of extremely small amounts of chemical or biological substances to overcome the low scattering cross-section of THz spectroscopy to detect small size of substances [1]. THz metamaterials becomes compatible as an ideal platform for the sensitive detection of small size microorganisms such as molds, yeast cells, and bacteria [2]. The resonance frequency shift is considered as a function of the dielectric constant and the density of the microorganism. The sensitivity can be improved by decreasing the effective dielectric constant of metamaterial, such as using a substrate with a low refractive index.

Electrohydrodynamic (EHD) jet printing technology using the drop on demand (DoD) technique of patterning has become an alternative choice for fabricating metamaterial structures on both rigid and thin flexible substrates with low refractive index [3]. Compared to conventional fabrication techniques such as photolithography, e-beam lithography, and focused ion beam, EHD jet printing technology has several advantages, such as being an inexpensive, non-contact, and simple procedure and being environmentally friendly.

In this communication, we present the fabrication of THz metamaterials for the high-speed-on-site detection of microorganism using the DoD technique of EHD jet printing, as shown in Figure 1(a). Yeast was used as the microorganism to be detected due to its high dielectric constant that makes it ideal to test and optimize the microbial sensing system in THz frequency range. The resonance frequency shift of the metamaterial was investigated as a function of the weight of yeast deposited on the metamaterial for two types of substrate: silicon and PI. Due to its lower dielectric constant, the thin PI film has been chosen to decrease the effective dielectric constant of the metamaterial structure in order to improve the sensitivity of the sensor.

Figure 1(b) shows the schematic of THz time-domain spectroscopy used to measure the transmission amplitudes of the metamaterial samples with and without the yeast deposition. The response of THz transmission obtained by Fast Fourier Transform gave the resonance frequency due to the electric field enhancement in the capacitive gap. When the yeasts were deposited on the metamaterial structures, the resonance frequency will be

shifted due to the change of capacitance in the gap by the presence of yeasts. This frequency shift can be used to detect the quantity of the yeast. Figures 1(c) and 1(d) show comparisons of the terahertz transmission response of the metamaterials on the silicon wafer and the PI film, respectively, before and after yeast deposition with the weight of 74 $\boldsymbol{\mu}$g. The frequency shifts of the metamaterials ($\Delta \boldsymbol{f}$) on the silicon wafer and the metamaterial on the PI film were 7 GHz and 47 GHz, respectively. Moreover, the sensor is also possible to be cleaned by a fungicide and to be reused again. After the cleaning of the sensor, the resonance frequency would shift to the initial resonance frequency. The thin flexible PI film also gave higher sensitivity due to its small thickness that made its effective dielectric constant close to the dielectric constant of air. The sensitivity enhancement by about 3 times has been reported when we use the substrate with the lower dielectric constant (i.e., quartz substrate instead of Si substrate) in the case of the slot antenna array sensors [4].This is because the relative change in the effective dielectric constant with the presence of the yeasts is higher for substrates with lower permittivity. The enhancement effects were much better in the case of thin PI films of this work as compared to the quartz substrate, although the dielectric constant values are not far from each other. This unexpected sensitivity enhancement is due to the thin film effects of PI flexible substrates, which lowers the effective dielectric constant as mentioned already. Using substrate with small thickness can offer a useful guideline how to improve the sensitivity significantly in metamaterials sensing. Our work demonstrates a simple, inexpensive, and environmentally friendly fabrication technique without chemical waste that we expect will contribute to the rapid, accurate, and on-site detection of small size microorganisms.

Abstract
Here we establish the fabrication method for self-collapsed aluminum oxide nanowires from anodization process. A lattice and length of nanowire bundle can be controlled readily by anodization time, wet etching, and drying conditions. With the metal or metal-oxide deposition, the optical characteristic dramatically changes to ultra-broadband absorption or selective emission. The nanowires can be transferred onto adhesive tape or polymer films for practical applications as well.

Recently, we developed a dielectric nanowire structure using an anodization process for nanoporous aluminum oxide. The aluminum oxide nanowires are produced by conventional anodization and additional wet etching and drying processes, and the nanowires arrays are formed as by aggregation at the tip of each nanowire. The nanowires are developed as microscale funnel structures composed of thin nanowires of tens of nanometers. We sputtered metal and metal oxide on the structure as well. The nanoscale aluminum nanowires with metal show strong plasmonic absorption of visible and near-infrared light by adiabatic nanofocusing of surface plasmons. For the mid-infrared light, we can change the wavelength range and peak of absorption by controlling the microscale funnel structures and deposited materials. The dielectric and metal-dielectric nanowire array can be applied to control the light behavior in optoelectronic, and thermoplasmonic applications.

Abstract: Polarization extinction ratio of a stacked double-layer subwavelength metal grating structure was investigated. Top and bottom grating layers were fabricated with nanoimprint lithography on silicon wafer, separated by a dielectric spacer. We characterized the linear polarization extinction ratio of the stacked gold gratings (100-nm thickness) in the mid-infrared regime with various pitches of 0.4, 0.7, and 1.0 μm, whose width-to-pitch ratio and spacer thickness were 0.7 and 0.45 μm, respectively. Numerical simulations were performed to design the geometrical parameters.

Infrared (IR) imager has been used in a variety of applications from non-invasive medical diagnostics to industrial and military applications such as night vision, overhead intelligence system, and thermal track and search [1,2]. In particular, polarized IR contains richer surface information, such as shading, roughness, and shape, which can enhance image quality and detection capability [3-6]. The ultimate goal of this research is to develop a lightweight, compact IR focal plane array (FPA) monolithically-integrated with a linear polarizer [2,3]. Here, we designed and characterized a stacked double-layer 1-dimensional subwavelength gratings (1dSGs), separated by a dielectric layer, benzocyclobutene (BCB), as illustrated in Figure 1(a), to improve the performance of linear polarization detection, i.e., polarimetry extinction ratio (*ER*) given by

$$ER(\lambda) = \frac{T_{TM}(\lambda)}{T_{TE}(\lambda)} \quad (1)$$

where T_{TM} and T_{TE} are the transmission of transverse magnetic and electric polarization (of note, transmission for the polarized IR incidence perpendicular and parallel to the gratings), respectively. Computational simulation (CST Microwave Studio) was carried out to find the optimized geometrical parameters, pitch (p), width (w), gold (Au) grating thickness (t_{Au}), and BCB thickness (t_{BCB}) as shown in Figure 1(b). Figure 1(b) shows that calculated *ER* of stacked-1dSGs is 10^4 times higher as compared to single-1dSGs, in which the designed p, r (w/p), t_{Au} and t_{BCB} were 0.4 μm, 0.7, 0.1 μm, and 0.45 μm, respectively. In our preliminary results, the single-1dSGs and stacked-1dSGs fabricated by nanoimprint lithography (NIL) show similar trends in T_{TM} and T_{TE} characterization (Figure 1(c)) while measured *ER* in the stacked-1dSGs is only four times greater than the single-1dSGs. We are currently testing various sets of geometry parameters (p = 0.4, 0.7 and 1.0 μm, r (w/p) = 0.7, t_{BCB} = 0.45 μm, and t_{Au} = 0.1 μm).

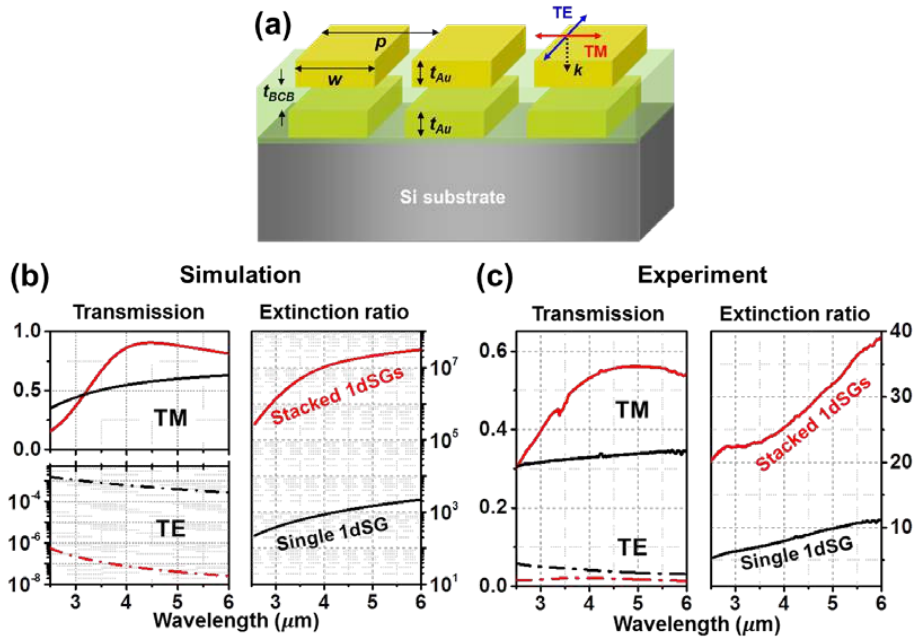

Figure 1. (a) Schematic view of unit cell of stacked-1dSGs on Si substrate. (b) CST-simulated and (c) FTIR-measured transmission / *ER* (λ) of a single- and stacked-1dSGs for TM and TE polarization (*p* and *r* is fixed at 0.4 μm and 0.7, respectively). The figure of merit, as the measure of linear polarization detection performance can be given by $\max\{T_{TM}(\lambda)/T_{TE}(\lambda)\}$.

Abstract -Here we describe a self-assembled, template-assisted approach for the fabrication of anisotropic metamaterials which exhibit dipolar plasmonic resonances in the deep ultraviolet spectral range. This technique is based on the electrochemical deposition of UV plasmonic nanorods in anodic aluminium oxide templates. Such materials exhibit dipolar plasmon resonances, related to the nanorod geometry, with the quality factor determined by the intrinsic loss of the constituent metals. This research advances many applications, including fluorescent enhancement, surface enhanced resonant Raman scattering and bio-sensing.

Ultraviolet (UV) plasmonics has received considerable attention recently due to its many potential applications, such as fluorescent enhancement[1] and UV-surface enhanced resonant Raman scattering[2]. Moreover, it may further enhance the sensitivity of biological detection by taking advantage of many natural resonances displayed by biological molecules in the UV-range[3], as well as enabling control over photochemical reactions[4]. The materials commonly employed for plasmonics, namely gold and silver, do not exhibit plasmonic responses in the deep-UV region which, when combined with practical considerations, has meant that the majority of research has been limited to the visible to infrared (IR) regions.

Self-assembled metamaterials comprised of gold nanorods have been shown to exhibit strong anisotropy, which leads to hyperbolic dispersion at frequencies below the epsilon near zero (ENZ) condition and have been employed as highly sensitive sensors for the detection of biological molecules, ultrasound[5] and hydrogen[6] due to their extraordinary refractive index sensitivity. However, transferring this approach to the ultraviolet has been challenging, due to either poor optical properties of the constituent metals (Pd, Pt) or challenging chemistry (Al).

In this work we discuss the fabrication and optical characterization of a UV-plasmonic metamaterial comprised of arrays of aluminium nanorods and compare the optical properties with the well-known noble metals, palladium and platinum. Investigations in UV-plasmonics[7] have revealed aluminium to be the most suitable choice, due to its low losses in the UV range and is particularly advantageous for scalable techniques and future applications as it also benefits from low cost and high natural abundance.

Self-assembled metallo-dielectric metamaterials based on gold nanorod arrays have been widely studied due to the ability to precisely tailor the optical properties by varying the template geometry (pore separation and diameter) and nanorod length during the electrochemical deposition[8]. This flexibility

allows the epsilon near zero (ENZ) frequency to be varied throughout the visible spectral range and therefore also the onset of hyperbolic dispersion. Until recently, it was not possible to extend this approach to the fabrication of aluminium nanorod based metamaterials due to a paucity of chemical procedures for aluminium, an issue that was solved recently by the development of ionic liquid based electrochemical baths[9]. In order to produce aluminium based metamaterials, templates were first fabricated as described elsewhere[10] followed by the electrodeposition of aluminium from an ionic liquid comprised of a 60:40 molar concentration of $AlCl_3$(99.999%, Alfa Aesar) and organic salt [EMIm]Cl (98+%, Alfa Aesar). This procedure was necessarily carried out in an oxygen and water free (< 1 ppm) glovebox environment to prevent degradation of the electrodeposition solution.

Following fabrication, the aluminum nanorod samples were optically characterized by acquiring the zero order transmission spectra. Collimated light was provided by a deuterium-halogen lamp and the metamaterials illuminated with an incident beam at varying angles and polarizations (TE and TM). The transmitted light was collected by a long working distance, deep-UV objective lens before being passed through a solarisation resistant optical fibre to a spectrometer equipped with a UV enhanced EMCCD. Experimental extinction spectra obtained from a metamaterial comprised of aluminium nanorods with radii of 20 nm, an inter-rod separation of 100 nm and length of approximately 200 nm, are shown below Figure 1.

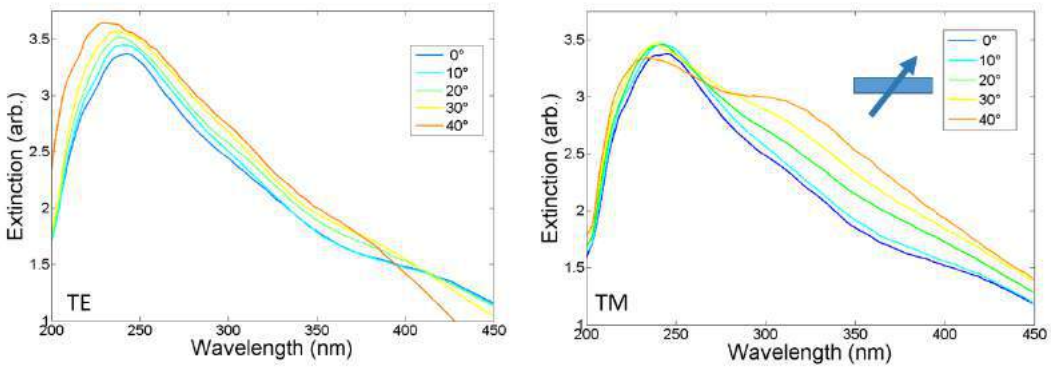

Figure 1 – Extinction spectra for an array comprised of aluminum nanorods having a separation of 100 nm, diameter 20 nm and length of approximately 200 nm measured in (a) TE (b) TM incident polarization. Spectra were taken at various angles of incidence of the illuminating light for both polarizations.

The experimental data in Figure 1, exhibits a transverse mode at 230nm for TE polarized light (left) which is angle independent. In the case of TM polarization however, two dipolar plasmonic resonances are observed; the transverse mode at 230 nm and the angle dependent longitudinal mode at 320 nm, related to the short and long axes of the nanorods respectively.

In summary, we experimentally demonstrate the hyperbolic, and tunable plasmonic response, of self-assembled aluminum nanorod arrays in the deep to near-UV region. The strong plasmonic response in the UV range, tunable by varying the dimensions of the template and length of the rods, can aid in enhancing many plasmonic studies into the deep-UV range; such as the study of non-linear properties, fluorescent enhancement or UV-SERRS as well as research involving quantum dots that operate in the UV-region.

Abstract-We demonstrate a fabrication technique of gold nanocrystals with periodic anodic aluminum oxide groove template by evaporation and high-temperature heat treatment processes. Employing diverse groove templates with different lattice constants and proper evaporation condition, we fabricated gold nanocrystal arrays with few tens of nanometer-diameter. Compare with chemically synthesized gold nanocrystals, our gold nanocrystals are not aggregated nor piled but periodically distributed as a monolayer in accordance with the periodicity of the groove template. With enhanced dipolar plasmon mode supported by faceted nanocrystal shape, the gold nanocrystal array can be used for plasmonic sensing applications.

A-two steps method, first preparing periodic groove template, and then forming nanocrystals via evaporation on the template and high-temperature heat treatment processes, is used. We utilize an anodic aluminum oxide template as the periodic groove with diverse lattice constants of 75, 100, and 140 nm, depend on the template's first anodization voltage; 30, 40, and 52 V, respectively. Thickness optimization of gold evaporation process, leads us to highly regular-sized nanocrystal creation via high-temperature heat treatment. Thanks to well-established manufacturing process of the anodic aluminum oxide template, 40, 65, and 80 nm-diameter gold nanocrystals are fabricated with lattice constants of 75, 100, and 140 nm, respectively.

Plasmon-induced local heating for optically controlled nano-architectures

This poster discusses new results in optically controlled nano-architectures of gold nanoparticles, prepared using the temperature responsive polymer poly(N-isopropylacrylamide) (pNIPAM). We show how assemblies can be selected according to size using local plasmonic heating. We also discuss how these assemblies relate to a type of self-limiting assemblies called actuating nanotransducers (ANTs) prepared in our lab[1].

Abstract - This work reports optical patternable metamaterial (OPM) for ultraviolet nanolithography below the diffraction limit. The OPM features mono-dispersed silver nanoislands (AgNs) embedded within photosensitive polymer by using solid-state embedment of AgNs into ultrathin polymer. This unique configuration simultaneously exhibits both negative effective permittivity and high lithographic contrast in the ultraviolet range, which enables the superlens effect for the clear photolithographic definition of 70 nm in minimum feature size beyond the Fraunhofer distance.

Metamaterials become of considerable interest thanks to the miscellaneous and compelling capabilities such as negative index[1,2], which overcomes the optical diffraction limit by compensating the information loss at the sub-diffraction limit scale[3]. Recently, metamaterials have demonstrated the sub-diffraction limit imaging in the ultraviolet (UV) range based on the superlens effect[4-6]. However, most previous works still have intrinsic limitations in defining the nanopatterns on a photoresist thinner than the Fraunhofer distance, because the pattern information passing through the superlens exponentially decays in a dielectric medium of photoresist. Furthermore, the direct patterning of photoresist film on the substrate of a photomask with superlens or hyperlens intrinsically impedes the practical use for nanolithography as well as the subsequent nanofabrication process.

Here we report optical patternable metamaterial (OPM) of mono-dispersed silver nanoislands (AgNs) embedded within photoresist polymer for ultraviolet nanolithography. The OPM exhibits the superlens effect under UV exposure and defines clear sub-diffraction limited photoresist pattern thicker than the Fraunhofer distance (**Fig. 1**). The superlens effect is clearly visualized by using the finite difference time domain (FDTD) method (**Fig. 2**). The electric field intensity of UV at 365 nm clearly maintains the sub-diffraction limited image within the OPM whereas conventional photoresist shows significantly blurred and highly diffracted images. Optical properties of OPM were numerically calculated by using the FDTD method for different width, gap, and thickness of AgNs. The calculated results of permittivity and lithographic contrast show the OPM efficiently exhibits the superlens effect (ε_M' ~ -2.7) and acceptable contrast of $C > 0.5$ for the nanoisland widths relatively larger than the gap spacing.

Ultraviolet nanolithography on a wafer level has been experimentally demonstrated by combining the OPM with a conventional contact mask aligner (**Fig. 3**). The OPM was simply prepared on a 4 inch silicon wafer by using spin-coating of ultrathin photosensitive polymer (SU-8), oblique angle deposition (OAD) of thin silver film, and solid-state embedment of AgNs. The chrome photomask with sub-diffraction limited patterns was fabricated by using an e-beam lithography and metal lift-off process. Nanopatterns were defined in the OPM by using a conventional UV mask aligner. The experimental results clearly demonstrate that the OPM defines the sub-diffraction limited under one-shot UV exposure whereas

conventional photoresist (SU-8) significantly diffracts and broadens the identical images (**Fig. 4**). Based on the topographic measurements with atomic force microscope (AFM), "N" textured patterns of 70 nm (<~λ/5) line width are clearly defined in the OPM but significantly broaden up to 240nm in the SU-8 resist.

Abstract-We developed two-step organothiol-assisted nanoparticle growth system, which is capable to direct morphology of plasmonic nanoparticle in solution. Rationally designed organothiols incorporated in growth process of nanoparticle and induce a distinctive interfacial interaction at the gold nanoparticle surface. We achieved novel nano-morphology control ranging from simple polyhedron to concave rhombic dodecahdron and chiral 432-symmetry structures, which show characteristic extinction, SERS enhancement, and chiroptical property.

Design and fabrication of nanostructure have been essential parts of plasmonics and metamaterial researches. Although lithographic techniques are widely used for making complex and asymmetric nanostructure, simple and large-scale fabrication of geometry-controlled 3D nanostructure is still challenging. In this respect, nature is highly skilled at nano-structuring inorganic materials using organic-inorganic interaction. Here, inspired from organic modifier in nature, we developed organothiol assisted growth system which is capable to direct morphological development through distinctive interaction between organothiol and gold surface. We constructed the morphology diagram describing the morphology development modes of low-index-faceted nanoparticle for the foundational understanding of the colloidal nanoparticle growth in the system we utilized[1]. Based on the morphology diagram, we designed 2nd growth of nanoparticle and produced the unique nanoparticles with high-index-faceted morphology. Addition of organothiol during the growth mediated the formation of substructures in the nanometer resolution which enable the synthesis of concave rhombic dodecahedral nanoparticle[2]. Furthermore, using asymmetric interaction of organothiols and high index surfaces, we successfully synthesized unprecedented chiral morphology with 432 point group symmetry. We expect that this research will open a venue of the solution-based fabrication of plasmonic metamaterials.

Abstract

***Abstract*—In this paper, a design a 3-dB coupler with 45^0 phase difference is implemented using a low-cost instant inkjet silver-nano printing technology. The responses of the coupler show that the return loss and isolation are both below -20dB at the designed frequency. However, for the output phase difference it can be observe that there is 45^0 phase difference and the amplitude imbalance in dB is less than 0.05 at the center frequency.**

***Index Terms*—3dB hybrid coupler, nonstandard phase differences, silver-nano technology.**

1. Introduction

Branch Line Coupler (BLC) is a four port 3dB power divider, with only one input, two equal outputs having 90^0 phase difference, and an isolated port. It is a crucial component in the rapidly growing applications of microwaves in communication systems, electronic warfare and radar systems. It is often used in frequency discriminators, balanced mixers, automatic level controls, and in many wireless applications due to its planar and relatively simple structure[1].

Couplers with quadrature outputs have been reported widely in different techniques such as microstrip [2], substrate integrated waveguide [3], multilayer microstrip [4], coplanar waveguide [5] and inkjet printing technology [6]. Despite their importance, little has been done on arbitrary output phase-difference characteristics.

In this research, new sets of equations for the 3dB coupler utilizing non-standard phase-difference and arbitrary power division ratio is proposed and validated by prototyping the coupler using Inkjet Printed silver-nano technology.

2. Instant Inkjet Printing Process

The printing technique presented in this paper uses inkjet printer manufactured by Brother Industries, Ltd. (DCP–J140w) because it is of low cost, availability, and their nozzles specially eject large amount of ink volume. This translates to deposition of excessive amounts of conductive ink making undistorted conductive [7]. Unlike the inkjet printing technique presented in [6], where it requires curing to achieve high conductivity. Once printed, this desktop inkjet printing technology gives good conductive pattern with resistance less than 0.3 Ω per square in fraction of seconds. This is achieved using Polyethylene terephthalate (PET) as a substrate which is chemically coated by means of photolithography for fast absorption of the ink and effectively prevent coating. This thin, absorbent coating plays a vital role in the chemical sintering process of the silver nanoparticle ink thereby supporting the ink to dry up instantly. The printing technique does not use any special software to drive the printer. But, some customized settings are necessary for achieving optimum performance. With this setting, the ink deposition is done in such a way to ensure that, each 'dot' of ink merging with its neighbors to form a continuous conducting pattern [7].

3. Coupler with 45^0 phase-difference

The transmission line model of the proposed coupler is shown in Fig. 1a. where Z_1, Z_2 and Z_3 are the impedance of the main line and the branch of the coupler. Also, θ_1,θ_2 and θ_3 represent the electrical length of the main line and the branches as shown in Fig. 3. Z_2 is choosing to be equal to Z_3 for simplicity and Port 1 is taken as the input, port 4 and port 3 are the through and the coupled ports respectively while port 2 is completely isolated. Taking the advantage of the symmetrical nature of the coupler, Even-Odd mode nalysis was used to analyzed the circuit. Fig. 1b shows Even and Odd mode equivalent circuit representation of the coupler in

Fig. 1(a). The design criteria are aim at achieving a variable phase difference, variable power division, good return loss and isolation. The power division ratio P(f) and the phase difference ψ between the output ports 2 and 3 are defined as follows:

$$\psi(f) = \angle S_{21} - \angle S_{31} \quad (1)$$

$$P(f)^2 = \left|\frac{S_{21}}{S_{31}}\right|^2 \quad (2)$$

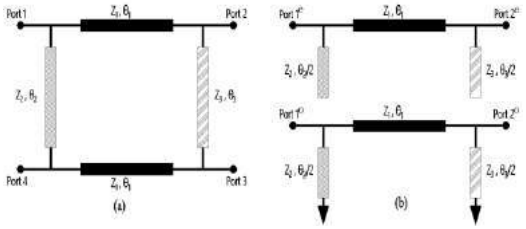

Fig. 1: (a) Schematic representation of the proposed coupler; (b) Even-Odd mode representation

Referring to Fig. 1b, the transmission characteristics of the even or odd mode is obtained using the transmission (ABCD) matrix, The ABCD matrix used in obtaining the overall transmission and reflection characteristics of the network are used to obtained the following designed equation:

$$Z_2 = Z_0 P|\sin\psi| \quad (3)$$

$$Z_1 = Z_3 = \frac{Z_0 P \sin\psi}{\sqrt{1+P^2\sin^2\psi}} \quad (4)$$

$$\theta_1 = \pi - \tan^{-1}\left(\frac{(Z_0\tan\psi)}{Z_1}\right) \quad (5)$$

$$\theta_2 = \frac{\pi}{2} \quad (6)$$

$$\theta_3 = \tan^{-1}\left(\frac{(Z_0\tan\psi)}{Z_1}\right) \quad (7)$$

From the design equations formulated (1) – (7), a 3-dB coupler was designed and implemented using instant inkjet printing technique. The coupler is meant to operate at a frequency of 6.0GHz. By setting the phase difference between the outputs to be 45^0 and the reference impedance $Z_0 = 50\Omega$, for 3dB power division ratio, the impedances of the coupler arms are: $Z_1 = 35.36\Omega$, $Z_2 = Z_3 = 28.87\Omega$, $\theta_1 = 90^0$, $\theta_2 = 120^0$, and $\theta_3 = 60^0$. Fig. 2 shows the layout of the proposed coupler. Other power division ratios is possible using the design equations.

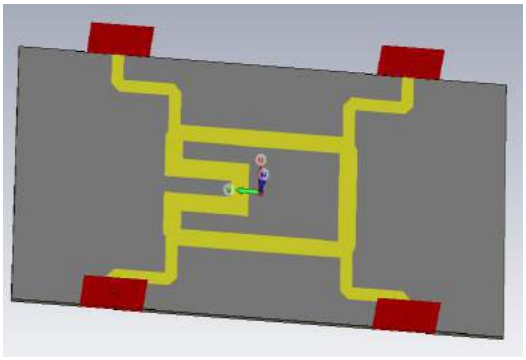

Fig. 2: Layout of the proposed 45^0 Coupler.

The Simulation was carried out in CST Microwave Studio 2005® and fabricated on a transparent Polyethylene terephthalate (PET) substrate specially coated with resin. The measured dielectric constant, thickness, and a loss tangent of the substrate are 0.125mm, εr = 2.72 and 0.043 respectively. Silver-nano printing technology was used to produce the prototype. This technology is accessible and of low cost that support fast prototyping of electronic circuitries [7].

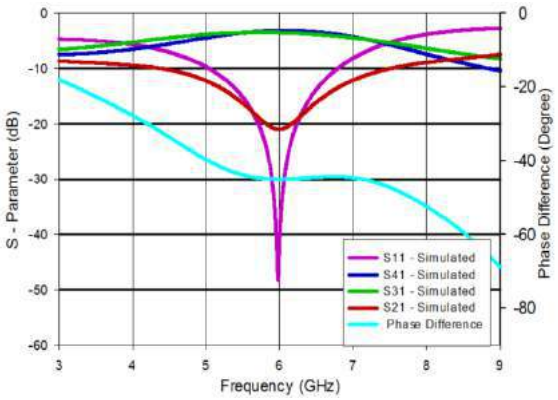

Fig. 3: Simulated S- Parameter Response for the Proposed Coupler. Magnitude in dB and output Phases difference in degrees.

4. Conclusions

In this paper, 3dB hybrid coupler with non-standard phase difference was designed and implemented using low-cost, silver nano inkjet printing technology on a transparent PET substrate. This coupler could be useful in number of applications like in antenna beam steering and in feeding networks for phased antenna array without the use of additional phase shifter. Explicit design equations with variable phase differences ψ was derived and validated by fabricating a prototype of the coupler operating at 6.0 GHz. At the designed frequency, both the measured (not shown

for now) and the full wave simulated results agreed with little discrepancy, this is because of fabrication tolerances.

***Abstract*—Butler Matrix (BM) utilizing only 3dB hybrid couplers and a crossover is presented. It is implemented on a specially coated PET substrate using a low -cost silver-nano inkjet printing technology. The results show a return loss better than -19 dB at 6.0GHz. When port 1 is exited, the transmission coefficients are $S_{51} = 6.89$dB, $S_{61} = 6.68$dB, $S_{71} = 6.04$dB, and $S_{81} = 6.54$dB at the operating frequency. Similarly, when port 2 is exited, the transmission coefficients are $S_{52} = 6.11$dB, $S_{62} = 6.98$dB, $S_{72} = 6.80$dB, and $S_{82} = 7.11$dB at the center frequency. The proposed design has a good performance in terms of amplitude and progressive phase difference at the output ports.**

***Index Terms*—**Butler Matrix, couplers, crossover, return loss, and amplitude imbalance.

I. INTRODUCTION

A Butler Matrix (BM) is one of the popular beamforming network due to its simplicity, easy fabrication and low power loss. One of the many options for constructing the beamforming network is by the application of BM [1]. 4X4 Conventional BM has four input and four output ports. It comprises of four quadrature hybrid couplers, two Phase Shifters, and two Zero dB Cross-over [2]. By exciting any of its input port, there will be an equal amplitude and progressive phase differences at the output ports. When an antenna array is connected to the outputs, there will be four dissimilar beams in the radiation pattern [3].

Directional couplers are the essential building block of BM, due to the quarter wavelength requirement of the couplers, the layout of the BM is usually very large [4]. Recently, several techniques have been proposed to miniaturize the coupler to reduce the size of the BM. In [5], an artificial transmission line was used in miniaturization of the couplers. Substrate integrated waveguide technology has been proposed in [6]. For the branch line couplers presented in [7], high impedance lines are meandered to achieve size reduction. Reference [8] proposed a low-temperature co-fired ceramic technique.

Most of the above techniques use either lumped elements or phase shifters for the implementation of the BM which tend to reduce the performance of the Butler matrices. To have BM with a better performance, Reference [9] proposes a BM without crossovers. But the multi-layer technique requires the use of vias which increase the fabrication difficulties.

In contrast to the BM presented in [9], this paper present a 4x4 Butler matrix utilizing only microstrip couplers and a crossover in planner structure. Employing 45^0 couplers in the design eliminate the use of phase shifters. This reduces the dimension and transmission loss of the device by shortening transmission line path.

II. INKJET PRINTING

The printing technique presented in this paper uses inkjet printer manufactured by Brother Industries, Ltd. (DCP–J140w) because it is of low cost, availability, and their nozzles specially eject large amount of ink volume. This translates to deposition of excessive amounts of conductive ink making undistorted conductive [10]. Unlike the inkjet printing technique presented in [9], where it requires curing to achieve high conductivity. Once printed, this desktop inkjet printing technology gives good conductive pattern with resistance less than 0.3 Ω per square in fraction of seconds. This is achieved using Polyethylene terephthalate (PET) as a substrate which is chemically coated by means of photolithography for fast absorption of the ink and effectively prevent coating. This thin, absorbent coating plays a vital role in the chemical sintering process of the silver nanoparticle ink thereby supporting the ink to dry up instantly. The printing technique does not use any special software to drive the printer. But, some customized settings are necessary for achieving optimum performance. With this setting, the ink deposition is done in such a way to ensure that, each 'dot' of ink merging with its neighbors to form a continuous conducting pattern [10].

III. BUTLER MATRIX DESIGN

The concept used in the design of this novel 4x4 Butler Matrix is centered around the design of 45^0 hybrid coupler. The use of this hybrid coupler 45^0 phase-difference eliminates the need for additional components in building Butler Matrix, thereby making it compact in size and retain its good performance. This is because it replaces the combination of quadrature coupler and phase shifter in the design of conventional Butler Matrix.

All the components of the BM are designed and fabricated on a transparent Polyethylene terephthalate (PET) substrate specially coated with resin. The measured dielectric constant, thickness, and a loss tangent of the substrate are 0.125mm, εr = 2.72 and 0.043 respectively. A commercial Simulation software (CST) was used throughout the

simulation and a Silver-nano printing technology was used to produce the prototype. Fig. 1 shows the layout of the proposed 4x4 Butler Matrix.

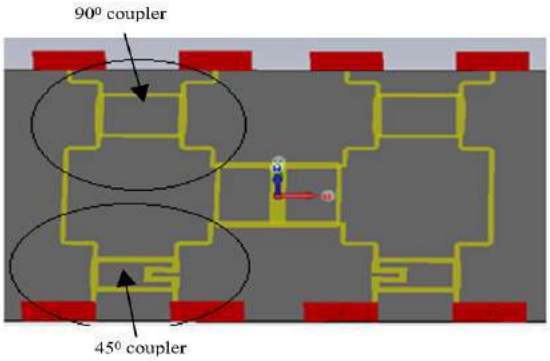

Fig. 1: Layout of the proposed 4x4 Butler Matrix

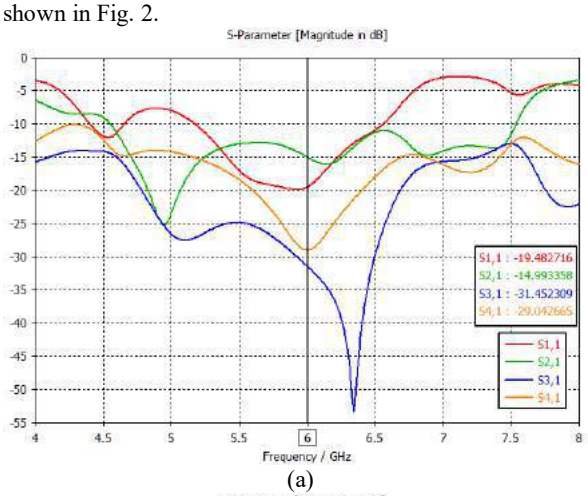
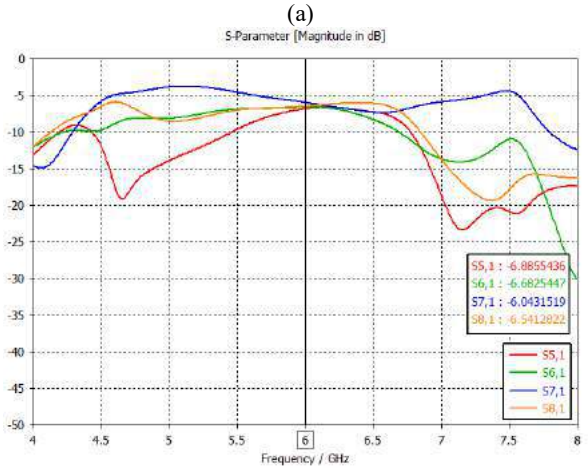
IV. PERFORMANCES OF THE BUTLER MATRIX

By exciting port 1 of the BM, the simulated return losses and the transmission coefficients at its output ports is shown in Fig. 2.



(a)



(b)

Fig. 2: Simulated S-Parameter of the 4X4 Butler Matrix when port 1 is exited. (a) Magnitude in dB; (b) Phases in degree.

The simulated return losses and the transmission coefficients at the various output ports when port 1 is fed are shown in Figure 4. The return losses are better than -19 dB and the transmission coefficients are $S_{51} = 6.89\text{dB}$, $S_{61} = 6.68\text{dB}$, $S_{71} = 6.04\text{dB}$, and $S_{81} = 6.54\text{dB}$ at the operating frequency. Similarly, when port 2 is exited, the transmission coefficients are $S_{52} = 6.11\text{dB}$, $S_{62} = 6.98\text{dB}$, $S_{72} = 6.80\text{dB}$, and $S_{82} = 7.11\text{dB}$ at the center frequency.

ACKNOWLEDGEMENTS

The authors acknowledge the Ministry of Higher Education Malaysia and Universiti Teknologi Malaysia for providing financial support under a vot 4J299. This grant is managed by Research Management Center, Universiti Teknologi Malaysia.

V. CONCLUSION

A novel 4×4 Butler matrix has been designed and simulated to operate at center frequency of 6GHz. In this BM, only couplers and cross over are used, phase shifter is not needed as in the design of conventional BM. The result results obtained shows that, the proposed design has a good performance in terms of amplitude and progressive phase difference at the output ports as they are in good agreement with the practical values. Some of the advantages of this design are: its compactness due to the absent of phase shifters and low transmission losses by shortening transmission line path. With this structure, the proposed Butler matrix can serve as a good candidate for the future 5G beam forming network.

Abstract- Application of Q-switched microchip laser for 3D printing by two-photon polymerization is reported. With optimized laser configuration and photo-resist high resolution high throughput 3D printing of polymer is achieved.

Among 3D nano- and micro-structuring techniques, only two-photon polymerization (2PP) [1-2] technology allows true 3D micro and nano-fabrication. Because of the threshold behavior and nonlinear nature of the 2PP process, resolution beyond the diffraction limit can be achieved by controlling the laser pulse energy and focal spot size. Since the absorption cross-section for two-photon process is very small, a high intensity laser radiation is required. Typically, tightly focused output beam from femtosecond laser is used to achieve high peak power avoiding optical break down of the materials.

2PP technology has been successfully applied for 2D and 3D nano-fabrication in different disciplines [3]. However, wide industrial usage of the 2PP technology is limited due to lack of low cost industrial grade femtosecond lasers. Competitiveness of 2PP in industrial applications will be improved significantly if cheaper and more reliable pico- and nano-second lasers are used. It is especially attractive to apply passively Q-switched microchip lasers for 3D printing of polymers by 2PP. Although successful 2PP structuring by pico- and nano-second lasers has been already demonstrated [4], structuring characteristics achieved with femtosecond lasers are still far superior. The most significant drawback of the standard microchip lasers is low repetition rate of the generated pulses that is not compatible with 2PP technology.

We are presenting for the first time application of the high repetition rate Nd:YVO_4 Q-switched microchip laser with SESAM for 3D micro-/nano-fabrication by 2PP. Energy of the pulses generated by this microchip laser is of about 95 nJ with pulse duration of 90 ps and repetition rate up to 500 kHz. Since the microchip laser is radiating at 1064 nm, optimization of the photosensitive material was necessary. Specifically, various photo-initiators were investigated for application in the 2PP process at this wavelengths. Optimal photo-initiator was selected allowing effective 3D fabrication by 2PP. Examples of the fabricated structures are shown in Fig. 1.
